Chapter 1 Physical and Chemical Properties 1
Allan H. Harvey

Chapter 2 Mathematics in Chemical Engineering 35
Sinh Trinh, Nandkishor Nere, and Doraiswami Ramkrishna

Chapter 3 Engineering Statistics 199
Daniel W. Siderius

Chapter 4 Thermodynamics of Fluid Phase and Chemical Equilibria 255
Kwang-Chu Chao, David S. Corti, and Richard G. Mallinson

Chapter 5 Fluid Flow 393
Ron Darby

Chapter 6 Heat Transfer 479
Kenneth J. Bell

Chapter 7 Radiation Heat Transfer 567
Z. M. Zhang and David P. DeWitt

Chapter 8 Mass Transfer 591
James R. Fair

Chapter 9 Industrial Mixing Technology 615
Douglas E. Leng, Sanjeev S. Katti, and Victor Atiemo-Obeng

Chapter 10 Liquid-Liquid Extraction 709
D. William Tedder

Chapter 11 Chemical Reaction Engineering 737

J. B. Joshi and L. K. Doraiswamy

Chapter 12 Distillation 969

James R. Fair

Chapter 13 Absorption and Stripping 1073

James R. Fair

Chapter 14 Adsorption 1119

Kent S. Knaebel

Chapter 15 Process Control 1173

James B. Riggs, William J. Korchinski, and Arkan Kayihan

Chapter 16 Conceptual Process Design, Process Improvement, and Troubleshooting 1267

Donald R. Woods, Andrew N. Hrymak, and James R. Couger

Chapter 17 Chemical Process Safety 1437

Richard W. Prugh

Chapter 18 Environmental Engineering: A Review of Issues, Regulations, and Resources ... 1485

Bradly P. Carpenter, Douglas E. Watson, and Brooks C. Carpenter

Chapter 19 Biochemical Engineering 1501

James M. Lee

Chapter 20 Measuring Physical Properties 1531

Lyle F. Albright

Chapter 21 Selecting Materials of Construction (Steels and Other Metals) 1539

David A. Hansen

Chapter 22 Solid/Liquid Separation 1597

Frank M. Tiller, Wenping Li, and Wu Chen

Chapter 23 Drying: Principles and Practice 1667

Arun S. Mujumdar

Chapter 24 Dry Screening of Granular and Powder Materials 1717
A. J. DeCenso and Nash McCauley

Chapter 25 Conveying of Bulk Solids 1729
Fred Thomson

Chapter 26 Principles and Applications of Electrochemical Engineering 1737
Peter N. Pintauro

Chapter 27 Patents and Intellectual Property...1831
M. Henry Heines

Chapter 28 Communication...1841
F. S. Oreovicz

Chapter 29 Ethical Concerns of Engineers...1859
Lyle F. Albright

Appendix: Conversion Factors 1867

Index 1881

Preface

This handbook was written to provide a thorough discussion of the most important topics of interest to engineers and scientists in chemically oriented fields. The expected readers will vary from students in the university to those employed in industry, academia, and the government. Because the engineering disciplines are broad and complex, and growing more so, a wide variety of subjects needed to be covered in the 29 chapters of this handbook. The first 27 chapters are technical in nature; the last two chapters are not. Because technical personnel need to communicate their ideas with others, one chapter focuses on communication approaches. Ethics has also become a key issue, especially in the last several years, and this is covered in the final chapter. As industry becomes increasingly internationalized, ethical concerns will likely continue to grow, because standards often vary in different countries.

Let me share some of the thoughts that I had as I planned and organized this handbook. First, a chapter in this handbook should differ from one to be expected in a textbook. In a handbook, each chapter should be succinct, providing basic information (including case examples) and indicating where additional information can be found. The topics selected for the various chapters in this handbook were chosen with the advice and counsel of individuals whose opinions I respect. Some overlap of material on specific examples is sometimes found in two or more chapters. For example, the determination and prediction of chemical and physical properties is discussed in both Chapter 1 (Physical and Chemical Properties) and Chapter 4 (Thermodynamics). As editor, I permitted and even encouraged some overlap when the authors were reaching their conclusions from different perspectives. But I tried to be certain that the different authors were each aware of this overlap so that they could handle it to the best advantage of everyone involved.

Second, there have been major advances in technical information in the last few years. It was therefore imperative that these advances be reported and discussed as needed. These include fundamentals, new approaches, and improved applications. Much better mathematical and statistical models are now available. Computers have become of ever-increasing importance, leading to much improved research, plant design, plant operations, and so forth. Several groups currently market important computer models, and these are reported here. In some cases, free information can be found on the Internet. For example, the National Institute of Standards and Technology (NIST) has made available a large statistics handbook at no charge. Chapter 3 of the current handbook emphasizes the applications of statistics to chemically oriented problems.

Third, the selection of an author for a specific chapter was often made after receiving the advice of others. For all chapters, I outlined my thoughts on the expected emphasis that I hoped to be presented throughout the handbook. In all cases, the authors were given the chance to modify my suggestions. As a result, even better manuscripts were received. Several authors later added one or more coauthors, whom I welcomed. In my opinion, this handbook is blessed with expert authors.

I hope that this handbook will promote better engineering and plant operations.

The Editor

Professor Lyle F. Albright, emeritus professor of chemical engineering at Purdue University, is proud that he was able to assemble 43 distinguished authors for the 29 chapters of this handbook. These authors have been associated with 13 universities in the United States, three universities in other countries, and industrial companies, government laboratories, and consultants. Professor Albright says his education increased greatly from reading the manuscripts of this book. This handbook emphasizes established fundamentals plus newer developments. Although no single handbook can provide all the necessary details, this one provides many important approaches for both students and the professional engineer.

In preparing this handbook, Professor Albright called on his 65 plus years in industry, academia, and consulting. He first served as a shift supervisor from 1939 to 1941 at Dow Chemical in a large semi-works plant that produced a highly purified butadiene. Several years later, he learned that this butadiene was employed to help develop a process to produce synthetic rubber, which helped to keep the Allied armies mobile during World War II. He was also employed by E.I. DuPont de Nemours, Inc., at the Hanford Engineering Works from 1944 to 1946 as part of the Manhattan Project.

After obtaining his Ph.D. in chemical engineering at the University of Michigan, he joined Colgate-Palmolive Co. in Jersey City. His academic career includes the University of Oklahoma (1951–1955) and Purdue University (1955–present). Sabbaticals were at the University of Texas (summer, 1952) and Texas A&M University (all of 1985). For the last 50 years, he has been an active consultant in the following areas: production of high-quality alkylates in refineries, ethylene and propylene production, nitration, partial hydrogenation of vegetable oils, and pulping of wood. His consulting work emphasizes the need to understand the fundamentals of the process in order to improve plant operations. That theme is carried over to this handbook.

1.1 INTRODUCTION

No single handbook could tabulate more than a small fraction of the physical and chemical property data needed by engineers. Therefore, this chapter does not contain extensive tables of data, but instead points readers to reliable sources of data and to methods for extrapolation, estimation, or measurement of data.

We cannot emphasize enough the importance of *quality* of data. Much data—whether in handbooks, on the Internet, or in scientific journals—are inaccurate or simply wrong. This can be due to problems with experiments, errors in processing measurements, misuse of extrapolation or estimation techniques, or something as simple as a copying error. For the responsible engineer, the goal is not just to "get a number," but to get a *reliable* number. Obtaining reliable physical and chemical property data requires *evaluation* of data. This involves expert evaluation of experimental techniques (including sample purity), consistency tests, comparisons among multiple data sets and multiple measurements for the same substance, and other factors such as trends within chemical families. It is preferable to use sources where the data are evaluated and where some indication of their quality is given.

A related issue is *uncertainty*. A datum has little value if one does not know whether it is uncertain by 1% or 100%. Ideally, all data would have a quantitative uncertainty given, which could be propagated into engineering design calculations. In practice, we often have to settle for approximate or qualitative estimates of uncertainties, but the more that can be said about uncertainty, the better.

Data sources listed here range from those that are free, to data available at low cost (for example in a single book or inexpensive database), to databases that may cost thousands of dollars. Of course, engineers want to save money, but often "you get what you pay for." While one can sometimes take advantage of free products from government agencies or academic groups, reliable data often cost money, because data collection and evaluation require skilled labor. The engineer who uses free data (perhaps from a Web search) of unknown quality as the basis for a multimillion-dollar design is being foolish if more trustworthy data could be obtained for a reasonable price.

As process simulation programs become routine tools, many engineers treat their thermodynamic calculations as a "black box" without giving thought to the underlying data or models. To their credit, developers of process simulators have spent much effort to validate both data and models. However, it is unwise to put blind trust in numbers merely because they are produced by

a computer; the best software can still produce nonsense if inappropriate thermodynamic methods and data are used. This chapter should provide resources to help the reader make informed judgments about which models and data to choose in process simulation, and to supplement simulation software in those cases where necessary data are missing.

Before proceeding, we mention sources for a few areas not covered in this chapter. Basic chemical thermodynamics is the subject of Chapter 4. For polymers and their solutions, the *Polymer Handbook* [1] is an indispensable source, and more on polymer thermophysical properties may be found in two books from AIChE's DIPPR project [2, 3]. The estimation of properties of mixtures described by distillation curves (typically petroleum fractions), or of the pseudocomponents derived from such curves, is covered in the *API Technical Data Book* [4]. Many molecular data, such as dipole moments and spectroscopic constants, are tabulated in the *NIST Chemistry Webbook* [5].

1.2 THERMODYNAMIC PROPERTIES OF PURE FLUIDS

1.2.1 Importance of Pure-Fluid Properties

While chemical engineers most often deal with mixtures, knowledge of pure-fluid properties is indispensable for at least three reasons. First, many processes make use of fluids that are close enough to pure that pure-fluid properties suffice. Many industrial uses of water and steam fall into this category. Second, pure-fluid behavior can often be used as a surrogate for a mixture of similar compounds; for example, sometimes it is desirable to model hydrocarbon mixtures as a small number (perhaps even one) of known components. Third, and perhaps most important, most models for thermophysical properties of mixtures employ properties of the pure components as a starting point; the underlying pure-component data must be accurate in order to describe the mixture.

1.2.2 Relative Importance of Different Properties

While the relative importance of properties depends on the context, it is often the case in chemical engineering that the vapor pressure is the most important pure-fluid property. This is because of the prevalence of separation operations that depend on vapor-liquid equilibria, and also because of the importance of volatility for safety and environmental concerns.

Because energy usage and heat transfer are important in process operations, caloric properties (enthalpy, heat capacity) can be considered the second most important area. The enthalpy of vaporization is particularly important in vapor-liquid separations.

Volumetric properties (density and, to a lesser extent, derivative properties such as isothermal compressibility) enter into many process calculations. However, it is usually relatively easy to measure and/or predict fluid densities with sufficient accuracy for most purposes.

Other properties of interest include surface tension and transport properties (viscosity, thermal conductivity, diffusivity). Transport properties will be covered in a later section.

1.2.3 Water and Steam

Water, in pure or nearly pure form, is widely used both as a process stream and (as cooling water or steam) as a heat-transfer fluid. Because of its importance, international standards exist for its thermophysical properties. These standards are set by the International Association for the Properties of Water and Steam (IAPWS; see www.iapws.org).

In the past, engineers used "steam tables" to obtain properties of water and steam. While such books still exist [6, 7], it is now usually more convenient to use software that implements IAPWS property standards [8]. Table 1.1 reports the thermodynamic properties of water for saturated liquid and vapor. Such short tables are useful for quick reference; design calculations usually require more extensive tables or software.

TABLE 1.1
Thermodynamic Properties of Saturated Water and Steam as a Function of Temperature

1.2.4 Pure Fluids with Reference-Quality Data

Some chemicals have received particular attention because of their industrial importance. These include the major components of air, common light hydrocarbons, and common refrigerants, for which accurate measurements of a variety of properties have been made over wide ranges of temperature and pressure. This has allowed the development of comprehensive, reference-quality equations of state (EOS) that can be used to calculate thermodynamic properties of the pure fluids essentially within the uncertainty of the underlying data. When a fluid has such an EOS available, that is the preferred data source.

Reference-quality EOS typically have a complicated functional form, with many parameters. However, software is available [9, 10] that implements these EOS for many fluids; for example, the database from NIST [9] incorporates formulations for approximately 80 pure fluids. A subset of this information is available in the *NIST Chemistry Webbook* [5].

1.2.5 Pure Fluids with Moderate Amounts of Data

Many other substances have insufficient data for a reference-quality EOS. There may be a few vapor-pressure data, and perhaps some other measurements such as liquid density or heat capacity. In such cases, there are two basic approaches.

The first approach is simple correlations of properties. This is most convenient when the property of interest is a function of only one variable, such as the vapor pressure (a function of temperature only). Such correlations can also be useful for properties of liquids (as long as they are not close to the critical point), since most liquid-phase properties are relatively insensitive to pressure and can be approximately represented as a function of temperature only. Several databases [11–14] contain correlations for pure-fluid properties as a function of temperature for many common substances, and vapor-pressure correlations for many substances are in some additional sources [5, 15]. It is important to be aware of the range of conditions in which a correlation has been fitted, as extrapolation can lead to significant errors.

If sufficient data exist but have not been correlated, it is of course possible to fit the data yourself. In such cases, one should choose an equation with a physical basis and/or a reliable record of correlating the property in question for other fluids. The functional forms used in the databases mentioned in the previous paragraph can provide guidance in this regard. In addition to the databases mentioned in the previous paragraph, sources with extensive pure-fluid data exist for vapor pressures

[16, 17], liquid densities [18], liquid heat capacities [19, 20], liquid heat capacities at 298.15 K [21], and enthalpies of vaporization [22].

For the vapor pressure, the Antoine equation is widely used:

$$\ln\left(\frac{p^{\text{sat}}}{p_0}\right) = A - \frac{B}{T + C} \tag{1.1}$$

where p^{sat} is the vapor pressure; p_0 is a reference pressure (typically 1 in the units of pressure being used); T is the absolute temperature in kelvins, and A, B, and C are parameters fitted to the data. Sometimes Equation (1.1) is written with a base-10 logarithm, and sometimes with the denominator written as ($T + C$– 273.15), so when using reported Antoine parameters, one must be careful to use the correct equation format. Because the Antoine equation has a physical basis (it is derived from the Clausius-Clapeyron equation), it can be extrapolated for small distances in temperature, as long as one stays well below the critical temperature. Extended versions of the Antoine equation, with more parameters, are sometimes used to cover a wider temperature range.

The Wagner equation for vapor pressure is capable of covering a wide range of temperatures:

$$\ln\left(\frac{p^{\text{sat}}}{p_{\text{c}}}\right) = \frac{1}{T_{\text{r}}}(a\tau + b\tau^{1.5} + c\tau^3 + d\tau^6) \tag{1.2a}$$

where $T_r = T/T_c$; T_c and p_c are the critical temperature and pressure of the fluid, respectively; $\tau = 1 - T_r$; and a, b, c, and d are adjustable parameters. Because the Wagner equation is constrained to give the correct critical pressure, it is better suited for extrapolation to high temperatures. Unlike the Antoine equation, it requires reliable values of T_c and p_c. Sometimes a slightly different Wagner form gives better results:

$$\ln\left(\frac{p^{\text{sat}}}{p_{\text{c}}}\right) = \frac{1}{T_{\text{r}}}(a\tau + b\tau^{1.5} + c\tau^{2.5} + d\tau^5) \tag{1.2b}$$

Use of the Wagner equations requires relatively extensive and internally consistent data; they may produce unphysical slopes of the vapor-pressure curve if fitted to inconsistent data. Neither the Wagner nor the Antoine equation should be extrapolated far below the temperature range in which it was fitted. Vapor-pressure data at low temperatures (where the vapor pressures are small) are scarce. Often, better estimates of the vapor pressure at low temperatures may be obtained from extrapolation techniques that make use of heat-capacity data, as discussed in *The Properties of Gases and Liquids* [15].

The second approach for calculating thermodynamic properties when some data are available is to use an equation of state (see Chapter 4, “Thermodynamics of Fluid Phase and Chemical Equilibria”). The most popular EOS are cubic equations, especially the Soave-Redlich-Kwong (SRK) and Peng-Robinson (PR) equations. The parameters in these equations were originally computed from the critical parameters and the acentric factor. However, it is also possible to fit the EOS parameters directly to experimental data; it has become common practice to fit parameters in advanced versions of these EOS to vapor-pressure data. Such fitting is generally necessary to get a good representation of the vapor pressure for polar fluids. Twu et al. [23] provide an overview of modern cubic EOS technology.

Because software for cubic EOS calculations is widely available, it is tempting to use these EOS for everything without considering that choice. This is unwise, because these methods have limitations. The common EOS forms like SRK and PR were optimized primarily for hydrocarbons;

without refinement, they are less reliable for polar fluids. Cubic EOS are inaccurate near the critical point. Also, their prediction of liquid densities and heat capacities tends to be inaccurate unless additional modifications are made.

The two approaches presented in this section need not be mutually exclusive; one can use a correlation for some properties and an equation of state for others. Because of the poor liquid density predictions of many cubic equations of state, it is common to use semiempirical correlations for liquid density (such as the Rackett equation [15]) while using an EOS for vapor-liquid equilibria.

1.2.6 Pure Fluids with Little or No Data

Often, engineers must estimate thermophysical properties for compounds where few, if any, measurements exist. A comprehensive source for such estimation techniques is the book *The Properties of Gases and Liquids* [15], which should be consulted by anybody who is serious about property estimation. We will restrict ourselves here to more general comments.

Many estimation techniques are *corresponding-states* methods, where the properties of the target fluid are scaled to the properties of a well-known fluid. Scaling factors are often based on the critical temperature and pressure and the acentric factor (which in many cases must be estimated). It is essential to recognize that most correlations were developed for certain classes of fluids, making it dangerous to use them for fluids that are very different from those used to develop the correlation. For example, a correlation developed for nonpolar hydrocarbons should not be applied to a polar fluid such as ammonia or methanol.

Other estimation techniques are categorized as *group-contribution* methods, where a property (or a parameter in a property model) is estimated based on the chemical structure of a compound, with each piece of the molecule contributing to the total. These methods depend on the existence of data on enough compounds to be able to regress contributions due to different groups. Group-contribution methods should also not be used for systems significantly different from those used to develop the method.

Sometimes the results from estimation techniques can be calibrated if only one or two data points are known. For example, if only a single vapor-pressure datum is known and the estimation method produces a vapor pressure that is low by 30% at that point, one can adjust the predicted vapor pressure at other temperatures by 30% to produce an improved estimate. Such estimates become more uncertain the farther one gets from the experimental datum.

One may also extrapolate from limited data if more extensive data exist for a similar compound. Most properties for similar compounds follow similar curves when plotted on appropriate coordinates (for example, $\ln(p^{sat})$ *versus* $1/T$ for vapor pressure). When all else fails, one can extrapolate a single data point on such a plot by drawing a curve through the point that is parallel to that for a similar compound where data exist. One must be able to judge what is a similar compound; for organic compounds, the addition of methyl groups or changes in branching typically do not qualitatively alter the fluid thermodynamic properties, whereas the addition or subtraction of functional groups (-OH, -Cl, -NO, etc.) is more significant. Data for similar compounds may also be used to validate purely predictive methods; a method that agrees with reliable data for 2-pentanol can be used with more confidence for 2-hexanol.

Predictions based on as little as one data point are much more reliable than those using no data at all. Sometimes, a single data point can be found in a source other than the usual property databases. For example, the normal boiling point (NBP) provides a point on the vapor-pressure curve. The NBP (along with the room-temperature liquid density, usually reported as specific gravity) is often reported in chemical supply catalogs, although the uncertainty is usually unknown. Such single points may also sometimes be found in chemistry handbooks such as *Beilstein* [24] or *Gmelin* [25] (see Sections 9.8 and 9.9), in the *CRC Handbook of Chemistry and Physics* [26], or even in the literature article where the compound is first reported.

An additional alternative is to measure the needed data. The difficulty and cost will depend on the fluid and on the property and conditions of interest. Experiments may well be needed if an important project is at stake, especially if you do not have high confidence in the available estimation methods. Measurement of fluid properties is discussed in Section 1.8 of this chapter.

1.2.7 Ideal-Gas Properties

For gases at relatively low pressures, the ideal-gas law is often sufficient to calculate the density. The ideal-gas heat capacity (and its integrated form, the ideal-gas enthalpy) are used not only for calculating the properties of gases assumed to be ideal, but also as a starting point in many calculations of the heat capacity and enthalpy of nonideal fluids.

Ideal-gas heat capacities may be estimated from gas-phase heat-capacity measurements, but more often they are calculated from statistical mechanics based on molecular information, usually obtained by spectroscopy [27–29]. The results of such calculations have been tabulated for many molecules [5, 11–15, 28–30]. Predictive methods also exist based on molecular structure; the leading methods are reviewed in *The Properties of Gases & Liquids* [15]. Calculations from one of these methods (that of Benson) are available in the *NIST Chemistry Webbook* [5].

1.2.8 Critical Constants and Acentric Factors for Pure Fluids

The values of temperature, pressure, and density at the critical point, and the acentric factor (which characterizes the shape of the vapor-pressure curve) are seldom of direct interest. However, they are used in many correlations and equations of state.

The critical temperature and pressure have been measured for a few hundred fluids; these are mostly relatively small molecules because most larger molecules with high critical temperatures begin to decompose before the critical temperature is reached. The critical density is less often measured but is seldom used in correlations. Extensive tabulations of critical parameters exist [5, 11–15, 31]; in some cases these sources supplement measured values with those obtained from estimation techniques. Some sources [11, 12, 14, 15] also contain values for the acentric factor. It is also possible to calculate the acentric factor from its definition (see Chapter 4, "Thermodynamics") from the vapor pressure and values of the critical temperature and pressure.

Techniques exist to estimate the critical parameters and acentric factor from molecular structure; these are reviewed in *The Properties of Gases and Liquids* [15]. Since these techniques depend on the regression of experimental data to assign contributions to individual groups within the molecule, they are reliable only when the functional groups in the molecule for which the prediction is made are present in similar molecules in the dataset used to develop the correlation.

1.3 THERMODYNAMIC PROPERTIES OF SINGLE-PHASE MIXTURES

1.3.1 Density

Three major approaches are used to predict the density of a multicomponent vapor or liquid. Many methods may be enhanced if some mixture data are available.

One approach is to use a mixture equation of state (EOS). This could be one of the cubic EOS mentioned in Section 1.2.5, but their poor performance for pure-fluid densities also carries over to mixtures. More sophisticated mixture EOS are available that make use of the reference-quality equations of state described in Section 1.2.4. If such an EOS exists for each component in a mixture, such an approach can produce good densities. A computer database is available [9] that implements this approach for common refrigerants and light hydrocarbons.

Mixture EOS models generally contain adjustable binary parameters that can improve the predictions if some experimental mixture data are available. Often, these models have been optimized to reproduce vapor-liquid equilibria rather than densities, although such parameters still

usually improve the density prediction compared to omitting them completely. If the components in a mixture are chemically similar, often the binary parameters can be set to zero without significant loss of accuracy. For pairs where experimental data are not available, the binary interaction parameter for a similar pair may provide a reasonable estimate.

For gases at low and moderate pressures, it is often preferable to use the virial expansion that provides successive corrections to the ideal-gas law (see Chapter 4, "Thermodynamics"). The first correction (called the second virial coefficient, B) has been derived from volumetric data for many pure fluids. Higher virial coefficients are much less well known, as are the cross-coefficients for interactions between unlike molecules. Estimation techniques for second (and to a lesser extent third) virial coefficients exist [15] and work reasonably well for many fluids, especially organic compounds of low polarity. Dymond et al. have compiled extensive experimental data for virial coefficients [32].

A second approach is the mixture corresponding-states approach. These are similar to the corresponding-states correlations for pure fluids mentioned in Section 1.2.6, but with the addition of "mixing rules" to obtain effective mixture parameters (for example, critical properties) to insert into the correlations. These methods are thoroughly discussed in *The Properties of Gases and Liquids* [15]. These models can also contain binary interaction parameters, and the comments given above for such parameters in mixture EOS models apply here as well.

The third approach, used primarily for liquid mixtures, requires reliable pure-component density values (see Section 1.2). One starts with an "ideal" mixture volume, defined by

$$v^{\mathrm{id}} = \sum_i x_i v_i \tag{1.3}$$

where v is the volume per mole, the sum is taken over all components in the mixture, x_i is the mole fraction of component i, and all volumes are evaluated at the same temperature and pressure. For chemically similar compounds, the ideal mixture volume as defined by Equation (1.3) usually produces reliable mixture volumes (and therefore densities, since the molar density is the reciprocal of the molar volume) if the pure-component values are known accurately.

Data are sometimes available for the excess volume of mixtures, particularly binary mixtures. These may be used to improve upon Equation (1.3). The excess volume is defined by

$$v^{\mathrm{E}} = v - v^{\mathrm{id}} = v - \sum_i x_i v_i \tag{1.4}$$

The simplest representation of excess volume is a quadratic composition dependence for v^{E}, where the single parameter for each binary pair may be evaluated from one mixture density. Under the assumption that the interaction between a pair of components is not affected by the presence of a third component, the mixture excess volume is

$$v^{\mathrm{E}} = \sum_i \sum_j x_i x_j A_{ij} \tag{1.5}$$

If good volumetric data are available for all the binary pairs in a mixture (except perhaps for trace components), Equation (1.5) can provide good liquid densities. For pairs of components that are chemically dissimilar, higher-order terms beyond A_{ij} may be necessary.

The most significant limitation of Equation (1.5) is that all the pure-component volumes must be at the same temperature and pressure. If the pure components are not all in the same phase at

this temperature and pressure, the definition of an "ideal" mixture volume in Equation (1.3) loses its usefulness. In practice, Equation (1.5) is useful only for liquid mixtures where all the components are liquids in their pure state at the condition of interest. Equation (1.5) also tends to be less useful in mixtures containing dissimilar components and/or many different functional groups. More parameters are usually needed in such systems, and the implicit assumption that the pair interactions are unaffected by other components in the mixture is less likely to be true.

To use Equation (1.5), reliable data are needed for v^E in binary mixtures. These data are also useful in equation-of-state or corresponding-states approaches if it is desired to fit a binary parameter to improve the performance. References to many binary excess-volume data (but not the data themselves) may be found in the series of books by Wisniak and Tamir [33], and data may be found in the Dortmund Data Bank [13] and a volume of the Landolt-Börnstein series [34].

1.3.2 Caloric Properties

The three approaches mentioned in the previous section may also be used to describe caloric properties (enthalpy, entropy, heat capacity) of mixtures. The same considerations mentioned earlier are also true for the application of mixture equations of state and corresponding-states methods for the prediction of caloric properties.

For the third approach mentioned in Section 1.3.1 (modeling a liquid solution in terms of deviation from ideality), one can use Equations (1.3) to (1.5), substituting the excess enthalpy h^E for the excess volume. As with density, such an approach is useful primarily for mixtures of liquids, and for cases where the interactions in solution are not too complex. Strong interactions in solution, such as hydrogen bonding, have a greater effect on h^E than on v^E. h^E data can be found through the bibliography by Wisniak and Tamir [33] and in some additional databases and compilations [13, 31, 35].

The excess enthalpy of a liquid mixture can be rigorously related to the excess Gibbs energy g^E of the solution; models for g^E are typically used for calculating phase equilibria with activity coefficients. The relationship is

$$h^E = -RT^2 \left[\frac{\partial (g^E/RT)}{\partial T} \right]_{p,x} \tag{1.6}$$

where R is the molar gas constant. Equation (1.6) seldom provides a successful approach in practice, probably because the temperature dependence of g^E models is often not very accurate (especially if the parameters have been fitted at only a single temperature). However, it provides a reasonable approximation if good phase-equilibrium data exist over a range of temperatures. Conversely, if measurements of h^E are available, Equation (1.6) may be used to find the temperature dependence of g^E (and therefore the temperature dependence of activity coefficients).

1.4 PHASE EQUILIBRIA FOR MIXTURES

1.4.1 Types of Phase-Equilibrium Calculations

The basic principles of phase equilibria are discussed in the chapter covering thermodynamics (Chapter 4). In general, two or more phases are in equilibrium when they have the same temperature, pressure, and fugacity (or, equivalently, chemical potential) for each species.

While an enormous variety of phase equilibria exist, if we restrict ourselves to fluids, we need consider only the possible presence of a vapor and one or more liquid phases. The case most commonly encountered in chemical engineering (for example, in distillation) is vapor-liquid equilibrium (VLE). Multiple liquid phases (such as oil and water) can be in equilibrium, so one

can have liquid-liquid equilibrium (LLE), VLLE, LLLE, etc. Chemical engineers rarely deal with more than two simultaneous liquid phases. Phase equilibria involving solids are outside the scope of this chapter; thermodynamic modeling of solid solubility in liquids is covered in some standard texts [15, 36].

The principles and algorithms for calculating fluid-phase equilibria are discussed in many textbooks [36–40]. Here, we focus on methods and data requirements for calculating the component fugacities in a phase as a function of temperature, pressure, and composition; this is the key element in all phase-equilibrium calculations.

1.4.2 Equation-of-State Methods

As discussed in the thermodynamics chapter (Chapter 4), an equation of state (EOS) can be used to calculate the fugacities of all components in a mixture. This approach finds widespread use in the chemical and petroleum refining industries; cubic equations of state are used most often, particularly the Soave–Redlich–Kwong (SRK) and Peng–Robinson (PR) equations.

A prerequisite for mixture EOS calculations is reliable EOS parameters for the pure components. As discussed in Section 1.2.5, these may be obtained in a generalized way from critical constants and the acentric factor, or they may be fitted to data for the specific fluid. For an accurate representation of mixture phase equilibria, the EOS must produce accurate vapor pressures for the pure components.

Once the pure-component EOS parameters are established, the next piece of the EOS model is the *mixing rules*. A mixing rule is an algorithm for determining a parameter for the mixture from the composition, the pure-component parameter values, and perhaps other data. The simplest mixing rule would be a linear mole-fraction average of the pure-component values; this rule is typically used for the "*b*" parameter (associated with size) in the SRK or PR equations. Phase equilibria in these EOS are much more sensitive to the mixing rule for the "*a*" parameter (associated with intermolecular energy); the simplest common mixing rule for this parameter is

$$a_{\text{mix}} = \sum_i \sum_j x_i x_j a_{ij} \tag{1.7}$$

where the sums extend over all components and values where $i = j$ are the pure-component values.

Equation (1.7) requires a_{ij} for unlike pairs. The method of calculating a_{ij} from a_{ii} and a_{jj} is called a *combining rule*. It is in the combining rule that a *binary interaction parameter* is typically introduced:

$$a_{ij} = (a_{ii}a_{jj})^{1/2}(1 - k_{ij}) \tag{1.8}$$

where the parameter k_{ij} (which should be small unless the mixture is highly nonideal) is fitted to data for the binary mixture of components *i* and *j*. Mixture phase equilibria are sensitive to the k_{ij}, which may be temperature dependent.

Simple mixing rules such as Equation (1.7) are usually adequate for mixtures of nonpolar fluids. For mixtures containing polar compounds, more complicated mixing rules have been devised, often containing more than one adjustable parameter per binary. These methods are beyond the scope of this chapter; more details may be found elsewhere [15, 22, 41, 42]. For some complex mixtures, particularly those containing polymers or associating components, better results can be obtained from a molecular-based approach such as the statistical associating fluid theory (SAFT). Advanced models like SAFT require more effort to implement, but often they can be accessed as a part of commercial process simulation software or other software packages.

A German academic group has provided a software package called PE [43] that may be used to perform phase-equilibrium and density calculations with many different equations of state and mixing rules. Parameters are built in for a limited number of components and mixtures, but the software also has the capability to fit parameters to pure-component and mixture data.

It is also possible to calculate mixture phase equilibria based on the reference-quality equations of state described in Section 1.2.4. In this approach, the Helmholtz energy is written as the sum of pure-component contributions (given by the reference-quality EOS for each pure component) plus a residual term. The residual term contains one or more adjustable parameters for each binary. Software implementing this approach is available [9].

For some important classes of compounds, methods have been developed to predict EOS parameters, including binary interaction parameters, from molecular structure. The PSRK method [44] has found significant use, and a promising new method is known as VTPR [45].

1.4.3 Activity-Coefficient Methods

The use of activity coefficients for phase equilibria is based on writing the fugacity f_i of each component in the liquid phase as the product of an ideal term and a correction (activity coefficient γ_i) for nonideality:

$$f_i^{\mathrm{L}} = \gamma_i x_i f_i^{0\mathrm{L}} \tag{1.9}$$

where the standard-state fugacity $f_i^{0\mathrm{L}}$ is the fugacity of pure component i at the temperature and pressure of interest. Fugacity $f_i^{0\mathrm{L}}$ is related to the pure-component vapor pressure p_i^{sat} by

$$f_i^{0\mathrm{L}} = p_i^{\mathrm{sat}} \phi_i^{\mathrm{sat}} \exp\left[\int_{p_i^{\mathrm{sat}}}^{p} \frac{v_i^{\mathrm{L}}}{RT} dp \right] \tag{1.10}$$

where ϕ_i^{sat} is the fugacity coefficient of component i at saturation, v_i^{L} is the liquid molar volume of pure component i, and the exponential is the Poynting factor, which accounts for the effect of pressure on liquid fugacity. Fugacity coefficient ϕ_i^{sat} can be assumed to be unity in many cases (exceptions would be if p_i^{sat} is significantly above atmospheric pressure or if component i associates strongly in the vapor phase [i.e., carboxylic acids, HF]). The Poynting factor can also be taken as unity at pressures near atmospheric; for higher pressures, it may be simplified by assuming that v_i^{L} is independent of pressure.

The activity coefficients γ_i are typically computed from a model for the excess Gibbs energy g^{E}, as described in the thermodynamics chapter (Chapter 4). The most popular are the Wilson, NRTL, and Uniquac models, described in detail in many places [15, 36–40]. They contain two or three adjustable (and possibly temperature-dependent) parameters per binary. One cannot predict which model will be best for a given system; however, the Wilson equation is incapable of describing LLE.

For binary pairs where no data exist to which to fit parameters in activity-coefficient models, group-contribution methods have been developed to estimate these parameters based on molecular structure. The leading method, UNIFAC [46], usually provides reasonable estimates for mixtures of organic compounds.

A recent alternative to group-contribution activity-coefficient estimation methods is based on interactions between surface charge distributions (determined by quantum-mechanical calculations) of molecules in solution. The solvation model used for the charge-distribution calculation is known as COSMO; the most widely used method based on this technique is called COSMO-RS [47].

Equation (1.9) produces liquid-phase fugacities, but vapor-phase fugacities are also required for phase-equilibrium calculations. At low pressures, one can usually assume ideal-gas behavior for the vapor, in which case the fugacity of each component is equal to its partial pressure. At higher pressures, the virial expansion or another equation of state may be used. Correction for vapor-phase nonideality is essential in systems with strong vapor-phase associations, such as those containing carboxylic acids. The leading such method is that of Hayden and O'Connell [48]. If vapor-phase fugacity corrections are to be used in phase-equilibrium calculations, they must be included in the same manner when fitting parameters in the activity-coefficient model.

For systems containing dissolved supercritical gases, Equation (1.10) cannot be used directly because the pure-component vapor pressure p_i^{sat} is undefined for the gaseous component. If the solubility of the gas is small, Henry's law may be used to describe the fugacity of the dissolved gas. The Henry's constant k_{H} of a solute in a solvent is defined by

$$k_{\text{H}} = \lim_{x_2 \to 0} \frac{f_2}{x_2} \tag{1.11}$$

where subscript 2 designates the solute. Equation (1.11), without the infinite-dilution limit, may be used to describe solute fugacity f_2 when the pressure is relatively low and x_2 is small (less than 0.01 for typical systems). Values of Henry's constant k_{H} for solute-solvent pairs may be derived from experimental solubility data. If the solvent is a mixture of liquids, methods exist [15, 36] for estimating k_{H} in the mixture from its value in each component of the solvent.

A prerequisite for successful use of activity-coefficient models is accurate knowledge of the vapor pressure of each pure component (see Section 1.2); this is the dominant factor in Equation (1.10) and provides the pure-component endpoints that anchor the mixture calculations. The second most important factor is the binary interaction parameters, which must be fitted to reliable binary data or estimated with a reliable method. Some activity-coefficient models also require molar volumes of the pure components. Additional parameters such as critical constants and acentric factors may be required if vapor-phase fugacity corrections are used.

1.4.4 Choosing a Method

Whether to use an EOS or an activity-coefficient method is sometimes just a matter of convenience (for example, which method is easily available in software), but there are some general principles to consider. Perhaps the most important is that activity-coefficient methods require the vapor pressure of each component at the temperature of interest; this renders these methods unsuitable for systems containing supercritical gases (unless the gas can be treated with Henry's law, as mentioned above). This makes EOS methods preferable for mixtures containing light components, such as methane-containing mixtures in hydrocarbon processing. Equations of state typically have difficulty representing highly nonideal systems, such as mixtures of polar and nonpolar fluids. Activity-coefficient models (or EOS with sophisticated mixing rules that incorporate a g^{E} model) are normally preferred for such systems.

An important consideration when using either method for VLE is the importance of correct prediction of the pure-component vapor pressures. For activity-coefficient models, this requires the direct use of a correlation for p_i^{sat}; for EOS models, it may require (especially for polar fluids) fitting the $a(T)$ term in the EOS to vapor-pressure data.

For LLE, the equilibrium is dominated by the activity coefficients. While VLE for simple systems can be approximated by setting activity coefficients equal to unity (Raoult's law), LLE always requires binary interaction parameters. In liquid-liquid extraction systems, parameters based on binary data alone may be insufficient for accurate design; a few experimental ternary data for LLE tie-lines often provide significant improvement.

When using binary interaction parameters, it is best to use parameters fitted to binary data at or near the temperature of interest. If data are available at multiple temperatures, it is possible to include limited temperature dependence. It is also possible to fit parameters for a binary pair to ternary data, but only if parameters for the other two binary pairs in the ternary system are already known. Binary interaction parameters are not interchangeable between methods, so it is important to use exactly the same EOS or activity-coefficient model in both data regression and phase-equilibrium calculations.

Finally, VLLE calculations can sometimes be simplified in systems containing water and hydrocarbons. Because the solubility of hydrocarbons in water is very small, simplified calculations can be made by assuming a pure liquid water phase. Methods exist [4] to estimate the amount of water present in the vapor and dissolved in the liquid hydrocarbon phase. Such a simplification could not be performed if the amount of hydrocarbon in the water were important (for example, if wastewater contamination were a key design variable), but it is often adequate for calculations in petroleum refining.

1.4.5 Sources of Data

Both EOS and activity-coefficient methods require binary interaction parameters. In process simulation software, the necessary parameters may already be built into a data bank. Sometimes, parameters for the system of interest may be found in the literature. If not, however, the parameters must be fitted to mixture data.

The Dortmund Data Bank (DDB) [13] contains a large amount of mixture VLE and LLE data. A large collection of printed data is the DECHEMA Chemistry Data Series [31]; another printed source is the *International Data Series: Selected Data on Mixtures* [49]. Knowledge of an azeotrope (where the coexisting vapor and liquid have the same composition) can be an important piece of VLE data; azeotropic data may be found in the DDB [13] and in a printed compilation [50]. Extensive data for solubility, primarily of gases in various solvents, are in the *IUPAC Solubility Data Series* [51]; some data from this series are now available on the Internet [52]. Solubility data for organic compounds in water are collected in the AQUASOL database [53]; a large subset of these data is available in book form [54]. Some Henry's constants of solutes in water are available in the *NIST Chemistry Webbook* [5], and high-quality correlations have been produced [55] for the Henry's constants of common gases in water over a wide range of temperatures. The compilation of Linke and Seidell [56], while old, is still a valuable source of data for solubilities of inorganic compounds (including salts and other solids) in various liquids.

1.5 TRANSPORT PROPERTIES

1.5.1 Kinetic Theory for Transport Properties

For simple approximations to intermolecular interactions, the kinetic theory of gases has been well developed for the computation of transport properties at low densities. Theory and theory-based correlations are reviewed in references [15] and [57]. If the molecules are modeled as hard spheres of diameter σ and molar mass M, kinetic theory gives the following relations for the viscosity η, thermal conductivity λ, and diffusivity D of dilute gases:

$$\eta = C_\eta \frac{T^{1/2} M^{1/2}}{\sigma^2} \tag{1.12}$$

$$\lambda = C_\lambda \frac{T^{1/2}}{M^{1/2} \sigma^2} \tag{1.13}$$

$$D = C_D \frac{T^{1/2}}{M^{1/2}\rho\sigma^2} \tag{1.14}$$

where T is the absolute temperature, ρ is the density, and the multiplying constants can be computed by the theory at varying levels of approximation.

Unfortunately, real molecules differ significantly from hard spheres, so Equation (1.12) to (1.14) are not directly useful for real fluids. Additional correction factors can be added to these equations for fairly realistic spherically symmetric interactions; these can represent nonpolar fluids that are roughly spherical, such as the noble gases and CH_4. However, most molecules of interest are far from spherical, and kinetic theory is still intractable for molecular interactions that are not spherically symmetric. Therefore, the direct applicability of kinetic theory for calculating transport properties of real fluids is limited. However, kinetic theory plays an important role in guiding the functional form of semiempirical correlations such as those discussed below.

1.5.2 Viscosity

At low and moderate pressures, the viscosity of a gas is nearly independent of pressure and can be correlated for engineering purposes as a function of temperature only. Equations have been proposed based on kinetic theory and on corresponding-states principles; these are reviewed in *The Properties of Gases and Liquids* [15], which also includes methods for extending the calculations to higher pressures. Most methods contain molecular parameters that may be fitted to data where available. If data are not available, the parameters can be estimated from better-known quantities such as the critical parameters, acentric factor, and dipole moment. The predictive accuracy for gas viscosities is typically within 5%, at least for the sorts of small- and medium-sized, mostly organic, molecules used to develop the correlations.

For gas mixtures, the available methods are similar [15]. Some interpolate between pure-component viscosity values, while others utilize mixing rules to produce mixture correlation parameters from properties of each component. Predictive accuracy is somewhat worse than for pure components, but still usually within 10%. Simplistic combinations of pure-component viscosities (such as a linear mole-fraction average) can be quite inaccurate for gas mixtures, especially if the components differ greatly in polarity or in molar mass.

For liquid viscosity, theory is lacking and correlations are largely empirical. The main variation is with temperature; the effect of pressure is small for liquids well removed from the critical point. It is common to correlate the viscosity (or sometimes the kinematic viscosity, $\nu = \eta/\rho$) with a logarithmic dependence in reciprocal temperature:

$$\ln \eta = A + \frac{B}{T} \tag{1.15}$$

Equation (1.15) can accurately represent the viscosity only in limited temperature ranges of tens of Kelvins. For wider temperature ranges (particularly at low temperatures), an additional constant may be added, putting the correlation in the form of the Antoine equation, Equation (1.1), which in the context of viscosity is called the Vogel–Tammann–Fulcher equation. These correlations often extrapolate poorly, especially at temperatures above about $0.7T_c$. Predictive methods, as described in *The Properties of Gases and Liquids* [15], typically make use of group contributions and some thermodynamic information (critical properties, etc.) to estimate parameters in a correlating equation. These predictions can be subject to large errors on occasion, but often are accurate to within 15%.

For liquid mixtures, the available methods interpolate between pure-component viscosities, which may be known from experiment or estimated with a predictive method. Unfortunately, there is no clearly best method for interpolation. The most commonly used form is

$$\ln \eta_{mix} = \sum_i x_i \ln \eta_i + \frac{1}{2}\sum_i \sum_j x_i x_j G_{ij} \tag{1.16}$$

where the sums extend over all species. The G_{ij} parameter may be fitted to binary data where available or else set to zero; structure-based estimation techniques for G_{ij} have also been developed. *The Properties of Gases and Liquids* [15] discusses the merits of this and similar mixing rules. All obtain reasonable results (within about 10% if the pure-component viscosities are accurately known) for most classes of fluids *if* all the mixture components are liquids well below their critical temperatures. Such mixing rules are notoriously unreliable for mixtures of light and heavy components, such as crude oil containing dissolved methane.

The methods in the preceding paragraphs are effective for gases at moderately low densities and for dense liquids well below the critical temperature. For intermediate densities (high-temperature liquids, compressed gases, supercritical fluids), a corresponding-states approach is preferred. In this approach, the properties of the fluid are mapped onto those of a well-known reference fluid such as propane. The mapping parameters may depend on the fluid's critical properties, acentric factor, and/or vapor-pressure curve; one-fluid mixing rules for these quantities are used to map mixtures onto the reference fluid. The most commonly used such approach, SUPERTRAPP [58], has been implemented in NIST databases [9, 59].

For a few fluids (water, air components, light hydrocarbons, common refrigerants), extensive viscosity data exist and have been fitted to comprehensive equations. These reference-quality correlations are available in the pure-fluid property databases mentioned in Section 1.2.4.

For completeness, we mention that the viscosity of a fluid diverges to infinity in the limit as the critical point is approached. The effects of this viscosity divergence are confined to such a tiny region around the critical point that it can usually be ignored.

Viscosity data for pure components are available in several places [11–14, 60–64], and some collections of mixture data (mostly for binaries) also exist [31, 63, 65]. Some additional data references are cited in *The Properties of Gases and Liquids* [15].

1.5.3 Thermal Conductivity

Kinetic theory is useful for vapor-phase thermal conductivities, but a complication (compared to the viscosity) is that molecules can store thermal energy in internal modes. Almost always, an approach due to Eucken is used in which the correlated quantity is $(\lambda M/\eta C_V)$, where λ is the thermal conductivity, M is the molar mass, η is the viscosity (computed as described in Section 1.5.2), and C_V is the constant-volume heat capacity that contains contributions from molecular rotation and vibration. *The Properties of Gases and Liquids* [15] reviews several methods for estimating this factor, and also a group-contribution corresponding-states method that is useful for predictions for some classes of organic compounds. Methods exist [15] for extending the low-density results to somewhat higher pressures.

As with the viscosity, simplistic mole-fraction averaging of pure-component values is not advisable for gas-phase thermal conductivities. The most common method for predicting mixture values has the form

$$\lambda_{mix} = \sum_i \frac{y_i \lambda_i}{\sum_j y_j A_{ij}} \tag{1.17}$$

where various methods exist [15] for estimating A_{ij} (which is unity if $i = j$). A corresponding-states approach, similar to that for pure components, can also be used.

Correlations and estimation methods for liquid thermal conductivities are mostly empirical. At low temperatures (below or near the normal boiling point), the thermal conductivity is roughly linear in temperature over short temperature ranges; more complex temperature functions are required to cover a larger range of temperatures. Predictive methods are summarized in *The Properties of Gases and Liquids* [15].

For the thermal conductivity of liquid mixtures well below the critical point of each component, a linear mass-fraction average of the pure-component values is often a reasonable approximation. Such an average usually somewhat overpredicts the mixture value, and more complex mixing rules have been proposed [15] that give better quantitative results.

For high-temperature liquids, compressed gases, and other systems at intermediate densities, a corresponding-states treatment is preferable. The SUPERTRAPP model for thermal conductivity is similar to that described for viscosity in Section 1.5.2, and is available in the same NIST databases [9, 59].

Reference-quality correlations exist for the thermal conductivity of a few well-measured fluids such as water. These are available in the pure-fluid databases mentioned in Section 1.2.4.

An additional complication in describing the thermal conductivity at intermediate densities is its divergence to infinity in the critical region. Unlike viscosity, the divergence of the thermal conductivity manifests itself in a wide region around the critical point (contributing more than 1% for densities roughly within 50% of ρ_c at temperatures up to roughly $1.4T_c$). Calculations of thermal conductivity in this region require consideration of the near-critical divergence, either explicitly or by a corresponding-states approach where the formulation for the reference fluid has the near-critical contribution built in. A recent engineering-oriented correlation [66] incorporates this divergence.

There are collections of thermal conductivity data for pure components [11–14, 67] and mixtures [31, 65]. Some additional data references are cited in *The Properties of Gases and Liquids* [15].

1.5.4 Diffusivity

Diffusion coefficients are important for mass-transfer operations (see Chapter 8, "Mass Transfer"). There are several differently defined diffusion coefficients (self-diffusion coefficient, interdiffusion [or mutual diffusion] coefficient, intradiffusion [or tracer diffusion] coefficient); this can be a source of confusion. These are delineated in standard references [15, 68, 69].

For gases at low and moderate pressures, correlations and predictive methods are based on kinetic theory [15]. Because of the similarity in molecular mechanisms between viscosity and diffusivity, molecular parameters derived from viscosity data may often be successfully used to predict gas-phase diffusivities.

In liquids, predictive methods for diffusivity are typically semiempirical, relating the diffusivity of a solute at infinite dilution to the solvent viscosity, the molar volumes of the components, and sometimes other quantities [15]. For finite concentrations, the manner in which the diffusion coefficients pass from one infinite-dilution limit to the other is sometimes complex, and the models that exist [15] typically have a parameter that must be fitted to data.

Several sources of experimental diffusivity data are mentioned in the corresponding chapter of *The Properties of Gases and Liquids* [15].

1.6 AQUEOUS ELECTROLYTE SOLUTIONS

1.6.1 Vapor–Liquid Equilibria and Activity Coefficients

For systems with electrolytes dissolved in water, the methods discussed in previous sections are usually not appropriate, due to the presence of charged species. We will focus on aqueous electrolytes, but most methods discussed may be applied to electrolytes dissolved in other solvents. The

modeling of electrolytes in mixed solvents is especially difficult and is beyond the scope of this chapter. The thermodynamics of electrolyte solutions is discussed in most physical chemistry textbooks. The key quantities are the osmotic coefficient (which describes the effect of the dissolved electrolyte on the vapor pressure of the solvent) and the activity coefficient (which is related to the chemical potential of the solute).

Correlations for the activity and osmotic coefficients of aqueous electrolytes begin with the theoretically rigorous Debye-Hückel limiting law for dilute solutions. Because the Debye-Hückel theory is accurate only at very low concentrations, it is supplemented by semiempirical terms. The most widely used are the Pitzer model and the electrolyte-NRTL model, both of which may be extended (perhaps with additional parameters) to systems containing multiple salts. A thorough description of the Pitzer model and a listing of parameters is in the monograph edited by Pitzer [70]. Sources for the electrolyte-NRTL model include the original journal article [71] and the book by Zemaitis et al. [72].

Several sources exist [72–74] containing evaluated data for the activity and/or osmotic coefficients of single electrolytes in water at 25°C. Data at other temperatures, or for mixed salts, are more scarce, but some compilations and databases exist [13, 74–76].

If data are lacking on the system of interest, it is often a fair approximation (especially at low and moderate concentrations) to use a "model-substance" approach. The behavior of an electrolyte is assumed to be similar to that of a known electrolyte of the same charge type. For example, NaCl is a model substance for 1:1 salts. This approach is particularly useful in estimating the temperature dependence of activity and osmotic coefficients; when these coefficients are known only at 25°C, the model-substance approach may be used to estimate the effect of temperature.

1.6.2 Density and Enthalpy

The methods described in Section 1.3 are generally unsuitable for electrolyte solutions. Electrolytes cannot be simply incorporated into equations of state, and simple mixing rules or corresponding-states approaches do not work because the properties of the pure electrolyte have little relationship to the contributions their ions make to mixture properties.

Typically, density and enthalpy are modeled by starting with a definition of ideal mixing in which each solute contributes as it does at infinite dilution:

$$v^{\mathrm{id}} = x_1 v_1 + \sum_i x_i v_i^\circ \tag{1.18}$$

where subscript 1 denotes the solvent, the sum includes all the solutes, and v_i° is the *standard-state* volume of solute *i*, which is the infinite-dilution limit of the solute's partial molar volume. Additional multiplicative factors appear in the equations if, as is commonly the case for electrolytes, concentration is expressed in molality (moles per kilogram of solvent) instead of mole fraction. An analogous equation applies for the enthalpy:

$$h^{\mathrm{id}} = x_1 h_1 + \sum_i x_i h_i^\circ \tag{1.19}$$

For dilute solutions, Equation (1.18) and Equation (1.19) are sufficient to describe the density and enthalpy. For more concentrated solutions, corrections must be applied. The corrections to the density are obtained from the pressure derivative of an activity-coefficient expression, while those for enthalpy are obtained from a temperature derivative. Details are given by Zemaitis et al. [72] and Pitzer [70]; the latter also tabulates parameters for temperature dependence in the Pitzer activity-

coefficient model. Since it is rare to have activity-coefficient data over a wide range of temperature or pressure, the usual approach for applying these expressions is to treat the parameters for temperature dependence or pressure dependence as adjustable and fit them to data for enthalpies and densities, respectively.

Some fairly well-validated estimation techniques exist for the standard-state properties of electrolytes in water. The one in widest use is the Helgeson–Kirkham–Flowers (HKF) correlation, as implemented in software known as SUPCRT92. Versions of the software may be found with a Web search, and a site [77] provides access to the most current set of parameters.

Experimental data for densities and enthalpies of electrolyte solutions are found in some compilations [75, 78] and in the ELDAR database [76]. The book by Zaytsev and Aseyev [74] contains extensive tables based on smoothed experimental results; some caution is needed with such tables because smoothing procedures can introduce artifacts. The *CRC Handbook of Chemistry and Physics* [26] also contains density data for many electrolytes in water at 20°C.

1.6.3 Transport Properties

The viscosity of aqueous electrolyte solutions is typically modeled as the relative viscosity η_r:

$$\eta_r = \eta/\eta_0 \tag{1.20}$$

where η_0 is the viscosity of pure water at the same temperature and pressure (which may be obtained from the sources mentioned in Section 1.2.3). At low concentrations (up to 0.1 molal and sometimes as much as 1 molal), the viscosity is described by the Jones-Dole equation:

$$\eta_r = 1 + AI^{1/2} + \sum_i c_i B_i \tag{1.21}$$

where c_i is the concentration (molality) of ionic species i, I is the ionic strength defined by

$$I = 0.5\sum_i c_i z_i^2$$

z_i is the charge on species i, coefficient A depends on various solute and solvent properties, and the coefficients B_i are specific to the individual ions. Parameters for the Jones-Dole equation at room temperature are tabulated by Marcus [79]. A semiempirical extension of the Jones-Dole equation to higher concentrations, and also a method for extrapolating room-temperature parameters to higher temperatures, are described by Lencka et al. [80]. Jiang and Sandler [81] have developed a different method, based on liquid-state theory, that also appears promising for correlation and limited prediction of electrolyte solution viscosities.

The thermal conductivity of aqueous electrolyte solutions is typically described at room temperature by the following empirical equation:

$$\lambda = \lambda_0 + \sum_i \alpha_i c_i \tag{1.22}$$

where λ_0 is the thermal conductivity of pure water and α_i is a parameter specific to ion i. Values of α_i for common ions are tabulated by McLaughlin [82], who also gives an extension of the method to other temperatures.

Experimental data for the transport properties of aqueous electrolytes are found in several sources [29, 75, 76]. Tables based on smoothed data are in the book by Zaytsev and Aseyev [74]. Values of the viscosity for many electrolyte solutions at 20°C are tabulated in the *CRC Handbook* [26]. While now somewhat dated, the book by Horvath [83] discusses additional correlation methods, data sources, and parameters for transport properties of electrolyte solutions, including material on diffusion coefficients and electrical conductivity.

1.7 PROPERTIES FOR CHEMICAL REACTION EQUILIBRIA

The thermodynamic equilibrium constant for a chemical reaction is a function of temperature only and is related to the standard-state Gibbs energy change for the reaction. The standard state for each component is typically that of the pure substance at the temperature of interest and 0.1 MPa. The standard-state Gibbs energy for each component is taken as that corresponding to the formation of each compound from its elements. Standard-state Gibbs energies are typically tabulated at 298.15 K. Values of the standard-state enthalpy of formation and the heat capacity are used to calculate the standard-state Gibbs energy (and thence the thermodynamic equilibrium constant) at other temperatures.

For many species, thermochemical properties (Gibbs energy and enthalpy of formation, heat capacity) can be found in the *NIST Chemistry Webbook* [5]. A good written source, especially for small molecules, is the *JANAF Tables* [30]. The *NBS Tables of Chemical Thermodynamic Properties* [84] provides thermochemical properties at 298.15 K for many species, including ions in aqueous solution. Many pure-component thermodynamic databases include enthalpy and Gibbs energy of formation for the compounds included [11–14]. For vapor species, ideal-gas properties are often adequate; these may be obtained from the sources described in Section 1.2.7.

It is also possible to estimate standard-state thermodynamic properties from molecular structures, particularly for gas-phase species. Group-contribution methods for such estimations are reviewed in *The Properties of Gases and Liquids* [15]. The most widely used method is that of Benson, for which software is available [85]; more limited calculations are available in the *NIST Chemistry Webbook* [5].

For relatively small molecules, it is becoming routine to calculate thermochemical properties in the ideal-gas state with computational quantum mechanics. For organic species with fewer than about 10 nonhydrogen atoms, the methods are sufficiently well developed that they can rival or even surpass the accuracy that can be obtained from experiment.

Reaction equilibria in solution (acid-base neutralization, etc.) significantly affect phase equilibria and other properties mentioned in previous sections, rendering those calculations much more difficult. In many aqueous electrolyte systems, properly accounting for the speciation in solution is the most important part of the problem.

1.8 MEASUREMENT OF FLUID THERMOPHYSICAL PROPERTIES

1.8.1 When Experiments Are Necessary

When data are needed, the option of measurement should always be considered. Even for those without experimental facilities, there is the option of contracting the work. Experiments may be more time-consuming than computerized estimation techniques, but if the data are of sufficient importance, the effort may be a good investment.

When deciding whether experiments are needed when data are lacking, one must weigh the merits of measurement versus estimation. One important factor is the reliability of available estimation methods. If a method has been demonstrated to be reliable for systems very similar to the one of interest, then measurement may be unnecessary. On the other hand, if the only available

estimation method is of dubious reliability and/or was not developed for similar substances, experiments may be needed.

A second important factor is the difficulty of the experiment. Some measurements, such as liquid densities at ambient temperatures, provide accurate data easily, but in other cases experiments may be difficult or infeasible. Complications that would argue against experiments include high temperatures and/or pressures (or very low temperatures or pressures requiring cryogenic or vacuum equipment); chemicals that are unstable, corrosive, or toxic; and chemicals that are not available in sufficient purity or quantity. Some properties, such as high-pressure phase equilibria and the thermal conductivity of polar fluids, are more difficult to measure accurately. A few laboratories do have capabilities for more difficult measurements, so the option of contracting with such a lab for measurements may be considered.

A third important factor is the degree of accuracy to which the information is required. Often, estimation techniques provide reasonable "rough" answers, while experimental measurements (if done well) reduce the uncertainty significantly. It may be preferable to use estimates for screening calculations and even preliminary design, and to make measurements only for components and mixtures that are of vital importance in the final design. Often, several measurement techniques exist for a property, and more accurate results can be obtained at greater expense and effort. For some applications, a simple, inexpensive measurement may be adequate, even for final design. For others, more painstaking measurements may be needed to obtain the required accuracy.

In the remainder of this section, we will briefly discuss the measurement of fluid thermophysical properties and the level of accuracy that can be obtained for a given property. More detailed information may be found in a series of books from the International Union of Pure and Applied Chemistry (IUPAC) [69, 86–90].

1.8.2 General Considerations

An essential consideration in experimental work is *safety*. This includes issues of toxicity, flammability, etc., for all chemicals involved, and also hazards created by interactions within mixtures. Safety must be considered at all stages in the design and construction of experiments.

Another important factor is *experience*. While some instruments may be used successfully with little training, in many cases considerable skill is needed to measure data safely and accurately. Especially for more precise and specialized measurements, there is no substitute for hands-on experience with the apparatus. Companies that do not maintain experimental expertise may need to turn to outside consultants or contractors when the need for data arises.

The control and measurement of *temperature* and *pressure* are essential for accurate experimental work, especially at temperatures and pressures differing significantly from ambient conditions. Sometimes, a 0.1 K deviation in temperature can change a property by an amount larger than the precision of the measuring apparatus. Two of the IUPAC books mentioned above [87, 89] discuss the measurement of temperature and pressure. In most cases, the farther one goes from ambient temperatures and pressures, the larger the experimental uncertainty and/or the more complex and expensive is the apparatus required to maintain accuracy.

Purity may be an important factor. Purification procedures are discussed in reference [91]. The fluid being measured may be available in different grades; the purity (and expense) required will depend on the accuracy needed and the property being measured. Some properties (density, heat capacity) are in most cases not significantly affected by small amounts of impurities. The vapor pressure and vapor-liquid equilibria are quite sensitive to impurities, particularly if the impurity is much more volatile (e.g., dissolved air) than the fluids being measured.

Many experimental apparatus require *calibration* with substances whose properties are accurately known. Water (see Section 1.2.3) is the most common calibration fluid for liquid-phase properties, but other fluids such as toluene are sometimes used. Vapor-phase properties are often calibrated with helium, argon, nitrogen, or air. An IUPAC book [92] describes recommended

reference materials for different property measurements. Many reference materials for calibrations are available through the NIST Standard Reference Materials program [http://www.nist.gov/srm/] and other national metrology laboratories.

1.8.3 Density

For liquids at ambient conditions, one can obtain a reasonably accurate density simply by weighing a known volume of the liquid. For rough work, one can use something as simple as a volumetric flask; for more precise work, calibrated volumes (known as pycnometers) are used. One can easily obtain 1% accuracy, and careful pycnometry can obtain 0.1%.

More accurate density measurements may be made by instruments that take advantage of the principle of Archimedes, where the apparent weight of an object immersed in a fluid is diminished by that of the fluid displaced. In the simplest version of this experiment, a "sinker" of known mass and volume is immersed in the fluid while suspended by a wire from an analytical balance. More sophisticated versions may use a magnet to suspend the sinker or measure the difference between two sinkers of similar mass and surface area but different volume. With care and good control of temperature and pressure, such instruments can achieve uncertainties of 0.02% or lower for both vapor and liquid densities.

Another method of measuring density relies on the change in the resonant frequency of a tube (often U-shaped) when it is filled with a fluid. Vibrating-tube densimeters are commercially available; they can be a convenient measuring tool in many circumstances. These instruments must be calibrated (usually with water if liquids are being measured, although for liquids whose density is significantly different from water a calibration fluid with a similar density is preferable) at the temperature and pressure of interest. While the precision of these instruments is often better than 0.01%, very careful calibration and temperature control are required to obtain better than 0.1% uncertainty in practice.

Another alternative, particularly for high-pressure measurements, is the isochoric method. A cell of known volume is filled with the fluid, and then the pressure is measured as the temperature of the cell is changed. This provides data along curves of approximately constant density, known as isochors. Corrections are made for the expansion of the vessel due to temperature and pressure. This method is most useful for supercritical fluids and other situations where the fluid is fairly compressible. Uncertainties with this method can be on the order of 0.1%, but are often higher at elevated temperatures and pressures.

Expansion methods are often used for measuring gas densities. In these methods, a sample is expanded from a small volume to a larger volume (where the ratio of volumes is accurately known), holding the temperature constant and measuring the pressure ratio. Typically, multiple expansions are used (a successive expansion technique known as the Burnett method is popular), with the final state being at a pressure sufficiently low that the density is accurately known by other means (such as correction of the ideal-gas law by the second virial coefficient). The Burnett expansion method may achieve uncertainties in density as low as 0.01%.

1.8.4 Heat Capacity and Caloric Properties

The measurement of heat capacity and related quantities is known as *calorimetry*. Most often the constant-pressure heat capacity C_p is measured; some instruments measure the constant-volume heat capacity C_V. Often, what is actually measured is not the derivatives C_p and C_V but an energy change divided by a small but finite temperature change. In some cases, the original "enthalpy increment" data may be more useful than the approximate heat capacities derived from them. In addition to the IUPAC books referenced in Section 1.8.1, the monograph of Hemminger and Höhne [93] has extensive information about calorimetry.

One category of calorimetric measurements is *batch* or *static calorimetry*, where, in the simplest implementation, the sample is contained in a vessel, a measured amount of energy is

added (usually electrically), and the temperature change is measured. Corrections are required for the heat capacity of the calorimeter itself; sometimes parallel measurements are made with identical calorimeters (one full, one empty) to determine this correction. For liquids, this method usually yields not C_p but C_σ, where the path of the derivative is along the vapor-liquid saturation curve. This quantity is negligibly different from C_p as long as the amount of vapor in the cell is small and the experiment is conducted far from the critical point. For vapors and supercritical fluids, batch calorimeters most naturally yield C_V. Batch calorimetry can achieve accuracy of about 1% (or even 0.1% for some research instruments); the uncertainty typically increases at high temperatures and pressures.

Flow calorimetry has become the leading method for fluids and fluid mixtures. In a flow calorimeter, energy is added (or removed) at a known rate while fluid is flowing through the instrument at a known rate. Once steady state is reached, measurement of the temperature before and after the heating section yields the heat capacity C_p. Sometimes, to cancel out sources of error, measurements are made of the difference between a fluid and a well-known reference such as water. Flow instruments may also measure heats of mixing; the instrument can have two inputs and one output and measure either the temperature change upon mixing or the rate of energy input (or removal) to keep the temperature at its initial value. Commercial instruments are available for flow calorimetry on liquids near room temperature; several laboratories have the capability for flow calorimetry at more extreme conditions. The accuracy of flow calorimetry depends on minimizing heat leaks and careful control and measurement of flow rate and temperature; uncertainties in measured heat capacities or heats of mixing are typically on the order of 1%.

The other common category of calorimetry is *differential* methods, in which the thermal behavior of the substance being measured is compared to that of a reference sample whose behavior is known. In *differential scanning calorimetry* (DSC), the instrument measures the difference in power needed to maintain the samples at the same temperature. In *differential thermal analysis* (DTA), the samples are heated in a furnace whose temperature is continuously changed (usually linearly), and the temperature difference between the sample and the reference sample as a function of time can yield thermodynamic information. DSC and DTA are most commonly used for determining the temperature of a phase transition, particularly for transitions involving solids. In addition, DSC experiments can yield values for the enthalpy of a phase transition or the heat capacity. Commercial DSC and DTA instruments are available.

1.8.5 Pure-Component Vapor Pressure

In the measurement of vapor pressure, it is essential that the sample be thoroughly degassed; even a small amount of dissolved air or other volatile component will distort the measurement. Degassing usually involves either distillation of the sample or placing the sample (sometimes after freezing) under vacuum.

The most straightforward method for vapor-pressure measurement is the *static* method, in which the pressure of the vapor above a pure liquid is measured directly with a manometer, pressure gauge, or pressure transducer. All parts of the apparatus must be maintained at a temperature at least as high as that of the sample in order to avoid condensation. Static techniques may be used at high temperatures and pressures with appropriate apparatus construction, but they become difficult at low vapor pressures due to the difficulty of pressure measurement and the effects of impurities. With good equipment and procedures, the accuracy of static vapor pressure measurements can be on the order of 0.1%.

Another conceptually simple method is *ebulliometry*, where the liquid is boiled under total reflux at a fixed pressure and the boiling temperature is measured. Because of the difficulty of accurately measuring the temperature of a boiling liquid, ebulliometers typically measure the temperature of the condensing vapor. An advantage to ebulliometry is that volatile impurities are purged as the system approaches steady state, so the need for degassing is reduced. The attainable

accuracy of ebulliometry can exceed that for static methods, but it is more difficult to extend ebulliometry to high pressures.

Sometimes *comparative* measurements are used, where a substance whose vapor pressure is well known (such as water) serves as a reference. This can be done either by measuring the temperatures of the sample and the reference fluid boiling under the same pressure (comparative ebulliometry), or by measuring the pressure difference between the sample and reference fluid at a common temperature. Comparative measurements can be relatively fast and convenient if a suitable reference fluid is available. With good temperature measurement and an accurately known reference fluid, the accuracy of comparative ebulliometry can be better than 0.1%.

In the *gas saturation* method, a carrier gas such as helium or air is bubbled slowly through the sample, coming to equilibrium with it. The material exiting the apparatus is collected, and the amount of sample dissolved can be measured at the end of the experiment. Knowledge of the number of moles carried away, the number of moles of carrier gas used, and the pressure of equilibration allows calculation of the partial pressure of the sample at equilibrium, which is approximately its vapor pressure. Care must be taken to ensure that all of the carrier gas is equilibrated with the sample and to prevent premature condensation before the solute is collected. This method is typically applied for vapor pressures below about 3 kPa, and may achieve 1% accuracy with careful use.

For very low vapor pressures (below about 10 Pa), the vapor pressure can be measured by the *Knudsen* method, in which the rate of escape of vapor through a small hole is measured. The kinetic theory of gases (with correction factors for hole geometry, etc.) is used to relate the rate of effusion to the vapor pressure. The attainable accuracy of such methods is around 1% to 10% at best, but it is often the only experimental option for substances of very low volatility.

1.8.6 Mixture Vapor-Liquid Equilibria

The experimental measurement of vapor-liquid equilibria in mixtures is a huge subject; space considerations dictate that we only briefly discuss the major categories of techniques. More information may be found in some books [87, 90, 94].

The *analytic* method involves confining a mixture in a two-phase state, measuring its temperature and pressure, and analyzing samples from each phase to obtain the equilibrium compositions. This is challenging in practice, largely due to the difficulty of sampling. Samples must be small to avoid disturbing the equilibrium, and they must be extracted without changing their composition. Often, internal stirring or mixing is needed to obtain equilibrium in a reasonable period of time. This approach is widely used and can provide accurate data if done carefully. Sometimes only the liquid composition is measured; while this provides less information, it may suffice if the vapor phase is predominantly a single component whose solubility in the liquid is the quantity of most interest. Sometimes measurement of the total pressure and the liquid composition are combined with approximate thermodynamic analysis of the vapor (for example, with the virial equation) to yield a complete picture of the vapor-liquid equilibrium.

In some cases, it is possible to measure the composition of one or both phases without withdrawing a sample. Techniques for *in situ* composition measurements include various forms of spectroscopy and measurements of other properties such as the refractive index.

A related *dynamic* method makes use of a recirculating still to produce equilibrated samples of vapor and liquid. This method is often used at low and moderate pressures; it is particularly suited for mixtures where the volatilities of the components are similar.

A dynamic technique known as *differential ebulliometry* can measure the effect of small amounts of solute on a solvent. The difference in temperature is measured between a pure fluid and a solution, both of which are boiling at the same pressure. Differential ebulliometry is a common technique for determining infinite-dilution activity coefficients, particularly when the solute is less volatile than the solvent.

The *synthetic* method is often used to determine phase boundaries (bubble points or dew points) at high pressure and/or temperature. In this method, the cell is filled with a mixture of a known composition in a single-phase region. Then, the temperature or the volume is changed until a second phase begins to form; in this manner the composition, temperature, and pressure at the bubble or dew point are known. The formation of the second phase may be detected visually or through measurement of some property such as heat capacity or density that exhibits a discontinuity or change in slope at a phase transition. A disadvantage of this technique is that the composition of the coexisting phase cannot be determined, but it is often used in situations where sampling is impractical.

While gas solubilities in a liquid may be measured by the analytic or synthetic techniques mentioned above, specialized methods have been developed for gas solubility measurements, especially near ambient conditions. The typical method is to place a known amount of gas in contact with a known amount of degassed liquid, allow the system to equilibrate, and then measure the amount of gas remaining (often by knowing the vapor-phase volume and measuring its pressure). The difference between initial and final amounts of gas is the amount dissolved in the liquid. It is common for such methods to achieve 1% accuracy in the solubility, and the best instruments can achieve 0.1%.

The solubility of relatively nonvolatile components (including solids) in a gas may be measured by the *gas saturation* method mentioned in Section 1.8.5. The gas is passed through the solute, and the amount of solute collected by a given amount of gas is measured. This method is commonly used to measure solubilities in supercritical fluids, where the effects of pressure and vapor-phase nonideality make the partial pressure of the solute in the vapor much larger than its vapor pressure. The major challenges are analysis of the solute collected, avoiding condensation of the solute before it is collected, and ensuring that all the gas is saturated with the solute.

1.8.7 Liquid-Liquid Equilibria

Liquid–liquid phase equilibria are most often measured by the analytic method mentioned above, although the synthetic method is used on occasion. Issues of sampling and equilibration are again important. If the densities of the liquid phases are similar, it can be difficult to achieve separation. Entrainment of one phase in the other is a particular problem in aqueous/organic systems, where emulsions can form. For nonpolar solutes like hydrocarbons in water, the solubility is so small that analysis becomes difficult, and even a tiny amount of contamination with the hydrocarbon phase cannot be tolerated. Reviews exist [87, 90, 95] describing apparatus for measuring liquid-liquid equilibria at near-ambient pressures.

1.8.8 Viscosity

The emphasis of this section is on Newtonian fluids whose viscosity is independent of shear rate. Most methods are discussed in an IUPAC volume [69]. Because most of these methods actually measure the kinematic viscosity (ratio of viscosity to density), knowledge of the density of the fluid is required to obtain the viscosity itself.

Perhaps the most familiar technique is the capillary-flow method. The working principle is the Hagen-Poiseuille relationship between the flow rate through a tube of fixed diameter, the pressure drop, and the viscosity. In practice, because the capillary diameter appears to the fourth power in the working equation and is difficult to determine accurately, capillary viscometers are usually calibrated with reference fluids such as water or reference oils that are available from viscometer manufacturers and some national laboratories.

There are two types of capillary viscometers. In gravitational instruments, gravity drives vertical flow through a capillary and a timer is used to measure the flow rate. For liquids with low vapor pressures, an open-ended viscometer is suitable; this design has been well studied, and commercial instruments are available. Accuracy of 1% or better can be achieved. For more volatile liquids,

sealed instruments may be used. A different analysis must be applied to obtain correct results with a sealed capillary viscometer [96]. Sealed capillary viscometers have not yet been commercialized, and the uncertainty is currently 2% at best.

A second type of capillary viscometer generates a constant volumetric flow rate with a pumping device, and the viscosity is determined by measuring the pressure drop. Such viscometers have been used mostly in research, but some commercial instruments are available. These viscometers may be used over a wide range of conditions for both gases and liquids, and in some cases the uncertainty can be reduced to less than 0.1%.

Another simple method is to measure the falling or rolling of a sphere through a liquid; this motion is described by Stokes's law under certain simplifying assumptions. This method is commonly used for viscous liquids, with an accuracy on the order of 3%. It can also be used for liquids at high pressures, with some loss of accuracy.

A more sophisticated technique involves measuring the damping of the oscillations of a body immersed in a fluid. The oscillating body may be a sphere, a thin disk, or a cylinder. Research instruments of this type can attain better than 0.5% accuracy (0.05% in the best cases) for both vapors and liquids over a wide range of conditions. In a variant known as the oscillating-cup method, the fluid is contained inside a hollow body; this method is more often used for high-temperature measurements on fluids such as molten metals or molten salts.

Three techniques related to oscillating-body methods can be mentioned. One involves measuring the torsional oscillations of a piezoelectric crystal immersed in a fluid; it can achieve accuracies of about 2% and has been used in a variety of conditions. A second involves measuring the drag on a rotating cylinder magnetically suspended in the fluid; it can achieve uncertainties as low as 0.15% in the dilute-gas region and 0.4% for higher densities. A third technique involves measuring the damping of a vibrating wire due to shear and to its inertia; this can yield simultaneous measurements of density and viscosity, with uncertainties in viscosity near 4% if both properties are being measured, or near 0.5% if the density is already accurately known. The first two techniques have been implemented in commercially available viscometers.

Finally, there are industrial rheological instruments in common use that allow determination of viscosities for liquids to within a few percent, which is sufficient for many purposes. These involve measuring the torque required to maintain a given velocity for a fluid confined in the annulus between two concentric cylinders, one of which is rotated (*Couette* viscometer), or a fluid confined between a flat plate and a rotating cone (*cone-and-plate* viscometer).

1.8.9 Thermal Conductivity

The traditional way to measure thermal conductivity is with *steady-state* instruments, in which a measured heat flux is compared to a temperature difference between surfaces. Most often the geometry is coaxial cylinders, a thin wire inside a cylinder, or parallel plates. In such instruments, eliminating convection currents is crucial; many old data taken with steady-state instruments are unreliable because of convection. Multiple experiments at different heat fluxes are often performed to verify the absence of convection. With good design and operation, such instruments may achieve accuracy in the 1% to 3% range.

A newer method is the *transient hot-wire* method, where an electric current is passed through a metal wire immersed in the fluid. The resistance of the wire is affected by its temperature, which in turn is affected by the dissipation of heat from the wire's surface, which depends on the thermal conductivity of the fluid. These instruments require sophisticated data analysis, but that is no longer an obstacle with the ready availability of personal computers. The absence of convection is relatively easy to verify. The best research instruments can achieve an accuracy of better than 1%. Measurements on conducting fluids (such as polar liquids) are more difficult because of the need to electrically insulate the wire. Other geometries, such as needle-shaped cylinders and thin strips, are also sometimes used for transient measurements.

Commercial instruments exist for cylindrical probes for transient measurements and for steady-state parallel-plate measurements. These generally require calibration with reference fluids of known thermal conductivity.

1.8.10 Electrolyte Solutions

Most of the techniques mentioned above can be applied to electrolyte solutions in a straightforward manner. It may be necessary to use different apparatus materials due to the corrosive nature of some electrolyte systems, especially at high temperatures. In addition, special techniques exist to measure activity and osmotic coefficients in electrolyte solutions. These methods are discussed in more detail in reference [70].

In the *isopiestic* method, the vapor pressure of a solution is determined by equilibrating it with that of a reference solution (aqueous NaCl is often used) whose vapor pressure as a function of salt concentration and temperature is well known. This method can provide osmotic coefficients accurate to better than 1% over a wide range of conditions, but it is accurate only for electrolyte molalities above approximately 0.1 $mol \cdot kg^{-1}$. The necessary equilibration may take several days, and specialized apparatus is required for measurements significantly above room temperature.

Potentiometry may also be used to determine activity coefficients of electrolytes; the measured e.m.f. of an electrochemical cell is related to the activities of the ions. These measurements can yield very accurate values near room temperature for systems where reversible and reproducible electrodes have been developed. Potentiometry at high temperatures is much more difficult; this is an area of active research.

1.9 OVERVIEW OF MAJOR DATA SOURCES

1.9.1 Introductory Comments

Table 1.2 lists major data sources by property for both pure components and mixtures. It is also useful to organize the information by database; that is the purpose of this section. We will describe a number of major databases and compilations and how they may be accessed. It is impossible for such a list to be complete; we have tried to list the most comprehensive sources we are aware of. Sources that are confined to one or two properties can be found in the section corresponding to that property (and in Table 1.2). Failure to mention a particular data source should not be taken as an indication that the source is not valuable.

TABLE 1.2
Major Sources of Thermophysical Property Data for Pure Fluids and Mixtures

Property	Pure-Component Data Sources	Mixture Data Sources
Vapor pressure	[5, 11, 12, 13, 14, 15, 16, 17]	N/A
Caloric properties	[11, 12, 13, 14, 19, 20, 21, 22]	[13, 31, 33, 35]
Density	[11, 12, 13, 14, 15, 18]	[13, 33, 34]
Ideal-gas properties	[5, 11, 12, 13, 14, 15, 28, 29, 30]	N/A
Viscosity	[11, 12, 13, 14, 60, 61, 62, 63, 64]	[31, 63, 65]
Thermal conductivity	[11, 12, 13, 14, 67]	[31, 65]
Mixture-phase equilibria	N/A	[13, 31, 49, 50, 51, 52]

Sources: Numbered as listed in References section.

1.9.2 NIST (Including TRC)

One of the mandates of the U.S. National Institute of Standards and Technology (NIST) is to provide reliable data to meet the needs of industry, including the physical and chemical property data that are the subject of this chapter.

One of the main sources of data from the NIST is the Standard Reference Database program [http://www.nist.gov/srd/]. Computer databases are available for the thermophysical properties of a variety of industrially important fluids and fluid mixtures, including water, air, cryogenic fluids, common refrigerants (including refrigerant blends), and natural gas [8,9]. These are available as stand-alone programs or as source code for integration into other software.

The *NIST Chemistry Webbook* [5] provides information on a large number of chemical compounds. This includes thermophysical property information (a subset of that available in the Standard Reference Databases) for several important pure fluids. Structural information is available for a large number of compounds, and for many of these data are given for vapor pressure, heats of formation and phase change, and/or ideal-gas heat capacity.

The NIST's Thermodynamics Research Center (TRC) has a large collection of pure-fluid thermodynamic and transport properties; tables of recommended values and correlations exist both in paper form and in a computer database [12]. The TRC has also produced books with comprehensive compilations for organic compounds (sometimes also available as software) for vapor pressure [17], liquid density [18], and ideal-gas heat capacity [29], in addition to a compilation on virial coefficients [32]. Their major archival database of experimental pure-component and mixture data is called Source [97]; it is currently available only to members of their consortium. Some data for mixtures of organic compounds are published in the periodical *Selected Data on Mixtures* [49]. More information is at http://trc.nist.gov.

Other sources of data from the NIST include the *JANAF Tables* for standard-state properties of small molecules [30], *The NBS Tables of Chemical Thermodynamic Properties* for species (including aqueous ions) at 298.15 K [84], and the *Journal of Physical and Chemical Reference Data* (jointly published by NIST and the American Institute of Physics).

1.9.3 DIPPR

The Design Institute for Physical Properties (DIPPR) of the American Institute of Chemical Engineers (AIChE) sponsors a variety of projects to provide data for the chemical industries. The DIPPR's Project 801 produces a database containing pure-component thermodynamic and transport properties for over 1900 industrially important chemicals. Recommended values are given for a number of single-valued properties (such as critical parameters, normal boiling point, standard-state Gibbs energy, and enthalpy of formation), and correlations are given for 15 temperature-dependent properties (such as vapor pressure, heat of vaporization, and transport properties for the saturated liquid and vapor). Evaluated experimental data are used where possible, but sometimes estimation techniques are used to fill in missing values so that a complete set of recommended and evaluated data is given for each compound included in the database. The original data used to develop the recommended values are also available. DIPPR 801 data are available in both book and electronic form [11]. The most recent data are restricted to the project's industrial sponsors; the version available to the general public lags behind by about two years.

DIPPR Project 911 compiles and evaluates data for environmental and health purposes. This includes data on flammability, toxicity, biological oxygen demand, and related properties, and data for air/water and octanol/water partitioning. A discontinued project compiled several volumes of data for transport properties of mixtures [65]. Information about the DIPPR, including other projects relevant to physical and chemical properties, may be found at http://www.aiche.org/dippr/.

1.9.4 DECHEMA

Beginning in the 1970s, the German chemical engineering society DECHEMA has produced the *Chemistry Data Series*, containing thermophysical property data for fluids and fluid mixtures. Many volumes are devoted to mixture phase equilibria, and other volumes cover critical properties, heats of mixing, infinite-dilution activity coefficients, mixture transport properties, electrolyte solutions, polymer solutions, and solubilities. A complete listing is available [31]. Many of these (and additional) data are available in their DETHERM database [http://www.dechema.de/detherm.html], which can also be accessed through the STN system of the Chemical Abstracts Service [http://www.cas.org/stn.html].

1.9.5 DDB

Some of the compilers of the *DECHEMA Chemistry Data Series* expanded their work into a comprehensive data bank for thermophysical property data. The Dortmund Data Bank (DDB) historically concentrated on mixture data, and it contains tens of thousands of datasets both for mixture phase equilibria (including electrolytes) and for excess properties of mixing. In recent years, a large amount of pure-component property data has also been added.

More information about the DDB, including a list of distributors, may be found at their Web site [13]. One notable feature is a free lookup program that allows one to search the database and see whether or not the DDB contains data for a particular system. Much of the data in the DDB is also available through the DETHERM database mentioned in Section 1.9.4.

1.9.6 NEL

In Great Britain, the National Engineering Laboratory (NEL, formerly a government agency but now privatized) has produced a database for thermodynamic and transport properties. PPDS contains correlations for properties of a large number of pure components; these are based on evaluated experimental data where possible but also include some estimated properties. For mixtures, the database contains binary interaction parameters fitted to data for use with common equation-of-state and liquid-activity methods for calculating phase equilibria. Information is available at their Web site [14].

1.9.7 Landolt-Börnstein

Since the late 1800s, the Landolt-Börnstein series, published in Germany, has provided important critical compilations of data for physics and related fields. Several volumes of the physical chemistry group have already been cited [17, 18, 32, 34]. Additional compilations include data on static dielectric constants and vapor-liquid surface tension. Further information on the Landolt-Börnstein series may be found at http://www.landolt-boernstein.com. Most of their current volumes may also be accessed on-line; information about on-line access may be found at the Web site.

1.9.8 Beilstein

Beilstein's Handbook of Organic Chemistry, greatly updated and expanded since its original German publication in the late 1800s, has long been the standard reference for information on organic chemistry. While its focus is on chemical aspects (structure, reactions, spectra, analysis), thermodynamic property information (boiling points, critical properties, thermochemical data) is also reported for some compounds, with references to the original literature. Because *Beilstein* contains millions of compounds, it is a good place to search for information on organic chemicals that are not common enough to be included in other databases.

While many technical reference libraries have *Beilstein* in print form, it is more convenient to search for information in the electronic form of the database. In addition, the printed series is no longer being updated. The electronic database allows a variety of searches on compounds and properties. Access to the electronic database is offered through CrossFire Beilstein [see http://www.mdl.com] or through the STN database system of the Chemical Abstracts Service [http://www.cas.org/stn.html]. Some details given in the print version (such as experimental methods) were not carried over to the electronic version, so in some cases it may be necessary to consult the print version or the literature citation for further information.

1.9.9 Gmelin

Gmelin's Handbook of Inorganic and Organometallic Chemistry, first published in German in the 1700s, is to inorganic and organometallic chemistry what *Beilstein* is to organic chemistry. Like *Beilstein*, it is more focused on chemical aspects, but contains some thermodynamic property information. Also like *Beilstein*, much of the data (without some supplementary information) has been carried over into an electronic database that continues to be updated. Access to the electronic database is offered through CrossFire Gmelin [see http://www.mdl.com] or the STN database system of the Chemical Abstracts Service [http://www.cas.org/stn.html].

1.9.10 Process Simulation Software

In chemical process design, it is common to obtain property data via process simulation software. This is sometimes a good option; the major simulation packages incorporate data from NIST, DIPPR, and other reliable sources. Caution is in order, however, especially for temperature-dependent properties and for mixture quantities such as binary interaction parameters in activity-coefficient models or equations of state. The danger is that the parameters in the simulation software may be fitted at conditions other than those of interest, and often it is difficult to tell where the parameters came from or under what conditions they are applicable. It is important to verify that the parameters in the software are appropriate for the conditions in which they are being used; that might involve a query to the vendor or doing some sample calculations to validate them against data.

ACKNOWLEDGMENTS

This chapter is a contribution of the National Institute of Standards and Technology, not subject to copyright in the United States. The identification of certain commercial products in this chapter neither constitutes nor implies recommendation or endorsement by the U.S. government or the National Institute of Standards and Technology. Material for some sections was supplied by Dr. Arno Laesecke of NIST (Section 1.8.8) and Dr. Song Yu of Columbia University (Sections 1.9.8 and 1.9.9). Several members of the NIST Experimental Properties of Fluids Group provided helpful input for Section 1.8.

2.1 INTRODUCTION

Chemical engineering is concerned with the study of systems in which matter undergoes changes in composition, energy, and morphological structure brought about by physicochemical processes spanning a wide spectrum of spatio-temporal scales. The methodology of chemical engineering consists of analysis and synthesis.

1. Analysis comprises mainly
   Observation aided by all available tools of scientific instrumentation
   Investigation based on the use of physical conservation principles together with phenomenological equations of material behavior within the framework of continuum and statistical mechanics, chemical kinetics, and thermodynamics
2. Synthesis comprises
   Design and control of processes using the methods of optimization, control theory, and artificial intelligence
   Design of products of chemical origin using the methods of molecular theory, artificial intelligence, and practical experience so as to satisfy specified physicochemical properties

Because of the complexity of chemical engineering systems, the use of theory is often admixed with economic use of empiricism founded on the methods of dimensional analysis. With increasingly available software for symbolic manipulations and numerical computations, it is not difficult to obtain solutions to mathematical problems. As a result, a large amount of tedious and detailed calculation is often relegated to such software programs, which may be insensitive to specific oddities of the physical process. Consequently, the software can only provide correct solutions if the problems are correctly formulated.

The correct formulation of the physical problem means that the resulting mathematical problem be well-posed. Well-posedness requires that a unique solution exists and that it be continuous with respect to small perturbations in the parameters of the governing equations, which are due to uncertainties in measurements and fluctuations in operations. These requirements are not always satisfied in reality.

From the engineering standpoint, existence of a solution is relegated to finding it either analytically or computationally. In the latter case, care should be exercised to ensure that results of computation are bona fide solutions to the problems, since it has been documented (Skufca, 2004) that numerical instability in a well-tested initial-value problem solver, Runge-Kutta-Felberg, can induce chaos under certain conditions.

Uniqueness of a solution is not assured for a certain class of problems, particularly nonlinear steady-state problems. Thus one frequently encounters multiple solutions, requiring strategies for finding them.

When multiple steady states exist, the stability of these solutions and the startup condition must be contemplated to ensure that the desired steady state is attained.

Continuity with respect to small perturbations in the governing equations is more difficult to ascertain. It can arise in problems where the mathematical equations are structurally unstable. Typical examples of these problems are systems undergoing bifurcation. In structurally unstable systems, small perturbations in system parameters lead to large changes in the solution. For example, slight perturbations can alter the stability characteristics of the solutions. In addition to these structurally unstable systems, there is a class of engineering problems that is sensitive with respect to small errors due to, perhaps, uncertainties in measurements or other fluctuations in the surrounding environments. These problems arise in determining unknown functions of interest from experimental data. They are known broadly as inverse problems.

A particular class of problems whose solutions are sensitive to initial conditions is known as chaotic problems. The phenomenon of chaos has been observed in fluid mechanics, chemical reactions, and biological systems (Cvitanocic, 1987). A special feature of these systems is unpredictability. The chaotic solutions are so sensitive to initial conditions that two systems with minute differences in their initial states can eventually diverge from each other. Thus their long-term dynamics are unpredictable.

The foregoing issues are clearly important, since understanding them can affect the engineering designs and operations, but they have not received adequate attention from practicing engineers. In this chapter, various mathematical tools for investigation and computation of chemical engineering problems are introduced to help the practicing engineer to adapt to the modern approach to the design and operation of chemical engineering equipment. The special features of this chapter are to bring these issues to the attention of the readers and address some of them in sections where they are encountered using the techniques currently available in the literature. Special focus is placed on (a) simple analyses of equations to ensure that numerical solutions are reliable and (b) the formulation of a class of ill-posed problems, the inverse problems.

The specific objectives of this chapter are to

1. Sensitize the reader to the issues of well-posedness of a mathematical problem
2. Provide concise coverage of solution techniques in linear and nonlinear problems and provide directions for more detailed treatment
3. Introduce the engineer briefly to symbolic and numerical software for solving mathematical problems of interest. It should be noted that we have not cited literature in the text, however, pertinent references are included in the bibliography.

The organization of this chapter preserves the hierarchy of topics generally followed in the applied mathematics literature. However, the reader is encouraged to refer to Table 2.1 for general guidelines on what chemical engineering activity would lead to each of the itemized sections.

2.2 EQUATIONS ENCOUNTERED IN CHEMICAL ENGINEERING

The mathematical equations arising in chemical engineering are obtained by applying the conservation principles of mass, energy, and momentum to chemical reaction systems. These equations express the accumulation of mass, energy, or momentum in the system as a result of the combined effects of net fluxes across the boundary and the consumption or production of these quantities in the system. These equations can be classified as algebraic equations, ordinary differential equations, partial differential equations, integral equations, and integrodifferential equations. The reader is referred to various free Web sources (e.g., http://en.wikipedia.org/wiki/Trigonometry, etc.) for the details pertaining to the trigonometry that has not been covered in this chapter.

Algebraic equations arise in systems that are independent of space and time variations, and ordinary differential equations govern systems that either vary with space or vary with time. In

TABLE 2.1
Chemical Engineering Activities Related to Mathematics Employed and Relevant Sections in Chapter 2

Chemical Engineering Activity	Mathematics Employed	Section
1. Primer to mathematics	Number system	2.3
	Differential and integral calculus	2.4
	Vector analysis	2.5
	Complex variables	2.12
	Integral transforms	2.13, Appendix 2.C
	Calculus of variations	2.14
	Linear algebra	2.7
2. Material and energy balances (filtration, drying, crystallization, extraction, distillation, and absorption)	Algebraic equations	2.7
	Ordinary differential equations	2.9
	Partial differential equations	2.7, 2.9, 2.10, 2.11

other words, algebraic equations govern steady-state systems that are spatially uniform. Examples are steady-state equations for a continuous stirred-tank reactor (CSTR).

Differential equations are equations that contain the derivatives of the unknown functions. They must be supplemented with auxiliary conditions to completely specify a problem. Auxiliary conditions must be prescribed at one or more points in the domain of the independent variables representing the boundary of the domain interface between different regions, and so on. Those equations with prescribed conditions at one point are called initial-value problems, and those with prescribed conditions on the boundary of the domain are appropriately called boundary-value problems. Initial-value problems generally govern the dynamics of the systems, while boundary-value problems describe the systems in steady state.

Ordinary differential equations govern systems that vary either with time or space, but not both. Examples are equations that govern the dynamics of a CSTR or the steady state of tubular reactors. Both the dynamics of a CSTR and the steady state of a plug-flow reactor are governed by first-order ordinary differential equations with prescribed initial conditions. The steady-state tubular reactors with axial dispersion are governed by a second-order differential equation with the boundary conditions spec-

ified at the entrance and exit of the reactor (boundary-value problems). The existence and uniqueness of a solution for an initial-value problem are guaranteed by a general theorem. Partial differential equations arise in steady-state systems with variations in more than one spatial coordinate. Unsteady-state systems may include temporal variations. Transient equations for tubular reactors are examples of partial differential equations.

Integral equations are equations that contain the integral of the unknown functions. There are two types of integral equations: Volterra and Fredholm integral equations. Fredholm equations feature integrals with *fixed* limits, while Volterra equations have integrals in which the limits of integration are the independent variables. These equations can be obtained by direct formulation or by the reduction of differential equations. Volterra equations are reduced from initial-value problems, and Fredholm equations from boundary-value problems.

Integrodifferential equations involve both derivatives and integrals of the unknown functions. These equations arise in radiative transport problems in weakly absorbing media and naturally arise in the modeling of particulate systems. For more information, see the monograph by Ramkrishna (2000).

There are many systems that can fluctuate randomly in space and time and cannot be described by deterministic equations. For example, Brownian motion of small particles occurs randomly because of random collisions with molecules of the medium in which the particles are suspended. It is useful to model such systems with what are known as stochastic differential equations. Stochastic differential equations feature "noise" terms representing the behavior of random elements in the system. Other examples of stochastic behavior arise in chemical reaction systems involving a small number of molecules, such as in a living cell or in the formation of particles in emulsion drops, and so on. A useful reference on stochastic methods is Gardiner (2003).

The different equations encountered in mathematical modeling can be further classified as linear and nonlinear equations. Linear equations arise in systems where the unknowns in the equations are present in the first power. Linear equations enjoy the principle of superposition, i.e., the sum of the solutions is also a solution of the equations. Linearity allows the original problem to be partitioned into simpler component problems that can be solved separately and superimposed to obtain the solution to the original problem.

In what follows, we present representative chemical engineering applications arising in each of the foregoing classes of equations so as to familiarize the reader with their scope. Introductory discussion is deferred to the individual sections covering each topic.

2.2.1 Processes Governed by Difference Equations

We may classify the difference equations encountered in chemical engineering applications into two types, namely, scalar and vector difference equations. The unknowns in difference equations are functions of discrete independent variables.

2.2.1.1 Scalar Difference Equations

Dissolution of a species: We consider the dynamics of dissolution of a solid mounted on a revolving assembly to show that the mathematical description of its dissolution gives rise to a simple scalar difference equation.

Let x_0 = initial concentration of the dissolved solid in the solution; x_s = solubility of the solid species in a solvent; x_n = concentration of dissolved species at time $t_n = (\Delta t)n$, where n stands for the number of discrete time steps, (Δt). For dissolution to occur, we must of course assume that $x_0 < x_s$. The rate law for the concentration of dissolved solid in the solution follows the equation

$$\frac{x_{n+1} - x_n}{\Delta t} = K_{La}(x_s - x_n) \tag{2.1}$$

where K_{La} is the overall mass transfer coefficient (s^{-1}), which can be determined experimentally for a given speed of rotation and a fixed area of exposure. This equation can be put in the form

$$y_{n+1} = y_n(1-\lambda)+\lambda \tag{2.2}$$

where

$$y_n = \frac{x_n}{x_s},\ \lambda = K_{La}\Delta t \tag{2.3}$$

and

$$0 < \lambda \ll 1 \tag{2.4}$$

Thus Equation (2.2) represents the dissolution process in terms of a scalar difference equation that has a straightforward solution.

2.2.1.2 Vector Difference Equations

We present here how vector difference equations arise in one of the most classical chemical engineering operations, i.e., distillation. Methods to solve the difference equations are presented in subsection 2.8.

Multicomponent rectification: Consider a multicomponent mixture of m-species continuously fed into a distillation column (Acrivos and Amundson, 1955; Amundson, 1966; Ramkrishna and Amundson, 1985). Let $x_{n,i}$ and $y_{n,i}$ be the compositions of the ith species on the nth plate for the liquid phase and the vapor phase, respectively. Based on constant molal overflow of liquid with a downflow rate L and a vapor upward flow rate V, the steady-state mass balance for the ith species in the rectifying section above the nth plate leads to the equation

$$y_{n+1,i} = \frac{R}{R+1}x_{n,i} + \frac{x_{0,i}}{R+1},\ i = 1,2,\ldots,m \tag{2.5}$$

where $R \equiv L/(V-L)$ is the reflux ratio and $x_{0,i}$ is the known mole fraction of the ith species in the product. The standard assumption of equilibrium between the liquid and the vapor leaving the plate is expressed by a relationship of the form

$$x_{n,i} = \frac{p_i y_{n,i}}{\sum_{j=1}^{m} p_j y_{n,j}},\ p_i > 0 \tag{2.6}$$

where p_i (i = 1,2,3,…,m) are constants representing relative volatilities. The relationship satisfies the requirement that the mole fractions must be summed to unity. To solve for the nth plate composition, it is necessary to calculate the composition on all the intermediate plates.

The following procedure is useful to calculate the composition just above the feed plate. Let $\{X_{n,i}\}$ be defined iteratively as

$$X_{n,i} = Rp_iX_{n-1,i} + p_i\sum_{j=1}^{m} X_{n-1,j}x_{0,j} \tag{2.7}$$

Also, we have

$$X_{0,i} = p_i, \quad i = 1, 2, \ldots, m \tag{2.8}$$

If $X_{n,i}$ are known, the original variables $x_{n,i}$ are then recovered from

$$x_{n,i} = \frac{X_{n,i} x_{0,i}}{\sum_{j=1}^{m} X_{n,j} x_{0,j}} \tag{2.9}$$

To solve for $X_{n,i}$, it is convenient to define the vector $\mathbf{X}_n = (X_{n,1}, X_{n,2}, \ldots, X_{n,m})$ and the matrix operator A, whose elements are given by

$$a_{ij} \equiv R p_i \delta_{ij} + p_i x_{0,j} \tag{2.10}$$

$\mathbf{X}_n$ is then satisfied by a difference equation of the form

$$\mathbf{X}_n = \mathbf{A}\mathbf{X}_{n-1} \tag{2.11}$$

The solution of Equation (2.11) is given by

$$\mathbf{X}_n = \mathbf{A}^n \mathbf{X}_0 \tag{2.12}$$

where $\mathbf{X}_0 = (p_0, p_1, \ldots, p_m)$. The solution of the vector difference Equation (2.12) is expressed in terms of the eigenvalues of the eigenvectors of the matrix **A** (for details, see Amundson, 1966 or Ramkrishna and Amundson, 1985). Similarly, one can obtain a vector difference equation for the stripping section.

2.2.2 Processes Governed by Linear Equations

2.2.2.1 Steady-State Continuous Countercurrent Staged Extraction

Consider a sequence of n equilibrium extraction stages, which are countercurrently fed with the extracting solvent phase entering stage 1, and the raffinate stream entering stage n (Ramkrishna and Amundson, 1985). The flow rates of the solute-free extract and raffinate are denoted as S and R, respectively. The solute concentration in the jth stage measured in mole ratios is Y_j in the extract phase and X_j in raffinate. The equilibrium relationship between Y and X is assumed to be $Y = KX$. The steady-state mass balance is given by the following equations:

$$\textit{Stage } 1\text{: } SY_0 - (SK + R)X_1 + RX_2 = 0 \tag{2.13}$$

$$\textit{Stages } 2, 3, \ldots, n-1\text{: } SKX_{j-1} - (SK + R)X_j + RX_{j+1} = 0,\ j = 2, 3, \ldots, n-1 \tag{2.14}$$

$$\textit{Stage } n\text{: } SKX_{n-1} - (SK + R)X_n + RX_{n+1} = 0 \tag{2.15}$$

which are clearly the linear equations that can be concisely written as

$$\mathbf{Ax} = \mathbf{b}$$

where

$$\mathbf{A} = \begin{bmatrix} \beta_1 & \gamma_1 & 0 & 0 & \cdots & 0 & 0 \\ \alpha_2 & \beta_2 & \gamma_2 & 0 & \cdots & 0 & 0 \\ \vdots & & & \cdots & & & \vdots \\ 0 & 0 & \cdots & 0 & \alpha_{n-1} & \beta_{n-1} & \gamma_{n-1} \\ 0 & 0 & \cdots & 0 & 0 & \alpha_n & \beta_n \end{bmatrix} \tag{2.16}$$

and

$$\mathbf{x} = (X_1, X_2, \ldots, X_{n+1})^T \quad \mathbf{b} = (-SY_0, 0, \ldots, -RX_{n+1})^T \quad \alpha_j = SK \quad \beta_j = -(SK + R) \quad \gamma_j = R$$

2.2.2.2 Steady-State First-Order Reactions in a Stirred-Tank Reactor

Consider the sequence of reversible first-order reactions (Ramkrishna and Amundson, 1985)

$$A_1 \underset{k_1'}{\overset{k_1}{\rightleftarrows}} A_2 \underset{k_2'}{\overset{k_2}{\rightleftarrows}} \cdots \underset{k_{n-1}'}{\overset{k_{n-1}}{\rightleftarrows}} A_n$$

in the continuous stirred-tank reactor. Let F be the volumetric flow rate of the feed, V be the volume of the reactor, and $\mathbf{x_f}$ and $\mathbf{x} = (x_1,\ldots,x_n)$ are the vectors comprising the mole fractions of species A_i in the feed and exit streams, respectively. The steady-state mass balance can be concisely represented by the set of linear equations as

$$\mathbf{Kx} + \frac{F}{V}(\mathbf{x}_f - \mathbf{x}) = \mathbf{0} \tag{2.17}$$

where the rate constants, i.e., the elements $k_{i,j}$ of the matrix $\mathbf{K}$, are given by

$$k_{1,1} = -k_1, \quad k_{1,2} = k_1', \quad k_{n-1,n} = k_{n-1}, \quad k_{n,n} = -k_{n-1}'$$

$$k_{ij} = k_{i-1}\delta_{i-1,j} - (k_{i-1}' + k_i)\delta_{i,j} + k_i'\delta_{i,j-1}$$

2.2.3 Processes Governed by Nonlinear Equations

2.2.3.1 Concentration of a Species in a Chemical Reaction at Equilibrium

Consider the following equilibrium chemical reaction wherein the reactants are present in stoichiometric proportion:

$$N_2 + 3H_2 \rightleftarrows 2NH_3$$

Let the total pressure of the gases be P_t, and let x be the equilibrium partial pressure of NH_3 whose value is desired at equilibrium:

$$P_{N_2} + P_{H_2} + P_{NH_3} = P_t$$

By stoichiometry $P_{H_2} = 3P_{N_2}$. Hence

$$P_{N_2} = \frac{1}{4}(P_t - x), \;\; P_{H_2} = \frac{3}{4}(P_t - x)$$

The equilibrium constant for the chemical reaction is given by

$$\frac{P_{NH_3}^2}{P_{N_2}P_{H_2}^3} = K$$

Substituting the partial pressure in terms of equilibrium partial pressure gives

$$\frac{256x^2}{27(P_t - x)^4} = K$$

or

$$x = \frac{3}{16}\sqrt{3K}\,(P_t - x)^2$$

that is a quadratic equation in x.

2.2.3.2 Vapor-Liquid Equilibria

Consider one mole per hour of a stream consisting of n volatile liquids with known compositions, and $x_{f,i}$ to be continuously separated into vapor and liquid streams at a given temperature and pressure (Reklaitis, 1983). It is desired to determine the steady-state flow rates of the vapor stream and of the liquid stream and their compositions. Let K_i be the vapor-liquid equilibrium constants, $K_i = y_i/x_i$, where x_i and y_i are the liquid and vapor fractions, respectively. K_i is calculated from Raoult's law, $K_i = p_i(T)/P$, where p_i is the vapor pressure obtained from the Antoine equation. The flow rate of vapor stream, V, is obtained by solving the following nonlinear equation resulting out of the material balance on each of the species:

$$\sum_{i=1}^{n} \frac{x_{f,i}(1 - K_i)}{1 + V(K_i - 1)} = 0 \tag{2.18}$$

The flow rate of the liquid stream is

$$L = 1 - V$$

The mole fractions are obtained from

$$x_i = \frac{x_{f,i}}{1 + V(K_i - 1)} \tag{2.19}$$

and the mole fractions in the vapor phase are given by

$$y_i = K_i x_i$$

2.2.3.3 Steady State of a Continuous Stirred-Tank Reactor

Consider a general chemical reaction occurring in a single phase and transforming a particular reactant into products in a CSTR having volume V, with an inlet volumetric flow rate F of the feed at temperature T_f containing reactant at concentration C_f. The reactor is cooled by a heat exchanger whose heat-transfer coefficient and surface area are U and A, respectively. The temperature of the coolant is maintained at T_c. Let C_p be the capacity of the reaction mixture, ρ be the mixture density, $r(C,T)$ be the reaction rate per unit volume of the reactor, and $-\Delta H$ be the heat of reaction. The steady-state mass and energy balances in the CSTR are given by the following equations:

$$F(C_f - C) - Vr(C,T) = 0 \tag{2.20}$$

$$\rho C_p F(T_f - T) - UA(T - T_c) + (-\Delta H)Vr(C,T) = 0 \tag{2.21}$$

The above system of nonlinear equations can be combined into a single equation by eliminating the reaction term to obtain T in terms of C:

$$T = \frac{F(-\Delta H)(C_f - C)}{\rho C_p F + UA} + \frac{\rho C_p F T_f + UAT_c}{\rho C_p F + UA} \tag{2.22}$$

Substituting T into the mass balance equation yields a nonlinear equation in C.

2.2.4 Processes Governed by Ordinary Differential Equations

2.2.4.1 Dynamics of a Continuous Stirred-Tank Reactor

We consider here the same continuous reactor of Section 2.2.3.3 under unsteady-state conditions. Assuming that all temperature dependent parameters remain constant at some average values, the mass and energy balances in the CSTR are governed by the following equations:

$$\frac{dC_A}{dt} = \frac{F}{V}(C_f - C_A) - r(C,T) \tag{2.23}$$

$$\frac{dT}{dt} = \frac{F}{V}(T_f - T) - \frac{UA}{\rho C_p V}(T - T_c) + \frac{(-\Delta H)}{\rho C_p} r(C,T) \tag{2.24}$$

$$C(0) = C_0$$

$$T(0) = T_0$$

The above equations constitute a system of first-order nonlinear differential equations whose steady-state versions are given in the previous section.

2.2.4.2 Steady State of a Tubular Reactor

Consider the reaction in Section 2.2.3.3 occurring in a homogeneous tubular reactor of length l, cross-sectional area A, and the perimeter P. The reactant is fed into the reactor with velocity v, which is assumed to be uniform over the tube cross section. The constant mass-dispersion coefficient and the thermal conductivity are denoted by D_m and k, respectively. Heat exchange takes place through the wall of the reactor maintained at the coolant temperature of T_c with the heat-transfer coefficient U. We assume here no radial variation of temperature, i.e., $T \equiv T(z)$. The mass and energy balance are given by the following differential equations:

$$D_m \frac{d^2C}{dz^2} - v\frac{dC}{dz} - r(C,T) = 0, \quad 0 < z < l \tag{2.25}$$

$$k\frac{d^2T}{dz^2} - v\rho C_p \frac{dT}{dz} - \frac{UP}{A}(T - T_c) + (-\Delta H)r(C,T) = 0, \quad 0 \leq z < l \tag{2.26}$$

The boundary conditions are

$$-D_m \frac{dC}{dz} = v(C_f - C), \quad z = 0$$

$$\frac{dC}{dz} = 0, \quad z = l$$

$$-k\frac{dT}{dz} = \rho C_p v(T_f - T), \quad z = 0$$

$$\frac{dT}{dz} = 0, \quad z = l$$

For an adiabatic reactor, i.e., $U = 0$, T can be solved in terms of C, and these equations are combined into one nonlinear differential equation to be solved for C.

2.2.5 Processes Governed by Partial Differential Equations

2.2.5.1 Dynamics of a Tubular Reactor

We reflect on the more involved case of a tubular reactor described in Section 2.2.4.2, where we will consider the radial variation of temperature in addition to its axial variation. Thus $T \equiv T(r,z)$. Furthermore, we also assume that the diffusion coefficient D_m is constant. Consequently, the mass and energy balance are given by the following partial differential equations:

$$\frac{DC}{Dt} = D_m \nabla^2 C - r(C,T) = 0, \quad 0 < z < l, \quad 0 < r < R \tag{2.27}$$

$$\rho C_p \frac{DT}{Dt} = k\nabla^2 T + (-\Delta H)r(c,T) = 0, \quad 0 < z < l, \quad 0 < r < R \tag{2.28}$$

where

$$\nabla^2 = \frac{1}{r}\frac{\partial}{\partial r}\left(r\frac{\partial}{\partial r}\right) + \frac{\partial^2}{\partial z^2}$$

$$\frac{D}{Dt} = \frac{\partial}{\partial t} + \boldsymbol{v}\cdot\nabla$$

$$\boldsymbol{v} = v_r\boldsymbol{\delta}_r + v_z\boldsymbol{\delta}_z$$

and

$$\nabla = \boldsymbol{\delta}_r\frac{\partial}{\partial r} + \boldsymbol{\delta}_z\frac{\partial}{\partial z}$$

The boundary conditions are given by the following equations:

$$-D_m\frac{\partial C}{\partial z} = v_z(C_f - C), \quad z = 0$$

$$\frac{\partial C}{\partial z} = 0, \quad z = l$$

$$\frac{\partial C}{\partial r} = 0, \quad r = R$$

$$-k\frac{\partial T}{\partial z} = \rho C_p v_z(T_f - T), \quad \text{at } z = 0$$

$$\frac{\partial T}{\partial z} = 0, \quad z = l$$

$$-k\frac{\partial T}{\partial r} = U(T - T_w), \quad r = R$$

where C_f and T_f are the concentration of a species in a feed and the temperature of the feed, respectively, while T_w is the wall temperature.

2.2.5.2 Dynamics of Chromatography

Chromatographic separation is achieved by selective adsorption of chemical species in a packed column. Consider a one-dimensional, isothermal chromatographic column, which is fed with a mixture of m-species at axial velocity v, uniform across the cross-section. Let c_i be the moles per unit volume concentration of species i in liquid phase, and n_i be the concentration of the species in the moles per unit volume. The local mass balances for each of the species result in the following set of first-order partial differential equations (Rhee et al., 1986):

$$\varepsilon\frac{\partial c_i}{\partial t} + \varepsilon\frac{\partial v c_i}{\partial z} + (1-\varepsilon)\frac{\partial n_i}{\partial t} = 0 \tag{2.29}$$

where ε is the porosity. The concentrations of species i in the liquid phase and particle phase are assumed to be in equilibrium, which is given by a relationship (Langmuir isotherms) such as

$$n_i = f_i(c_i)$$

Differentiating this relationship gives

$$\frac{\partial n_i}{\partial t} = f'(c_i)\frac{\partial c_i}{\partial t} \tag{2.30}$$

Substituting the above equation in the mass balances yields the partial differential equation for the concentration dynamics:

$$\frac{\partial c_i}{\partial t}[\varepsilon+(1-\varepsilon)f'(c_i)]+\varepsilon\frac{\partial v c_i}{\partial z}=0 \tag{2.31}$$

2.2.6 Processes Governed by Integral Equations

2.2.6.1 Particle Size Distribution in Continuous Comminution Process

Consider a continuous comminution process in which the feed consists of large particles and the smaller comminuted particles are being removed at the same mass flow rate as the feed. Following Ramkrishna (2000), the population balance equation may be written as

$$\frac{\partial n(x,t)}{\partial t} = \frac{n_f(x)-n(x,t)}{\theta} + \int_x^\infty \nu(y)g(y)P(x|y)n(y,t)dy - g(x)n(x,t) \tag{2.32}$$

where $n(x,t)$ is the number density (assumed to be spatially uniform), $n_f(x,t)$ is the number density in the feed and θ is the mean residence time. The comminution process is described by the breakage frequency $g(x)$ and the size distribution of particles of size x formed from the breakage of a particle size y is defined by $P(x|y)$. The steady state integro-differential equation may be written in terms of the so-called "breakage kernel," $K(x,y) \equiv \nu(y)g(y)P(x|y)$ as follows.

$$g(x)n_s(x) = \frac{n_f(x)-n_s(x)}{\theta} + \int_x^\infty K(x,y)n_s(y)dy \tag{2.33}$$

where $n_s(x)$ is the steady-state exit number density.

2.2.6.2 Determination of Pore Size Distribution in Porous Media

The pore size distribution in a porous medium is determined by measuring the counterdiffusion rates of two gases across the medium in a Wicke-Kallenbach experiment (Brown and Travis, 1983). The experiments are carried out without a temperature or pressure gradient across the pellet.

The thickness of the porous medium is L. The mole fractions of a gaseous species A at the near face and a distant face at L are denoted by y_{A0} and y_{AL}, respectively. Define α as a function of molecular weights of the gases A and B as follows:

$$\alpha = \frac{M_A + M_B}{M_B}$$

For diffusion through a cylindrical pore, an equation describing the dependence of diffusion rate on the porosity (ε), temperature (T), pressure (P), and pore size (r) is given as

$$N_A(P,T) = \frac{\varepsilon D_{AB}^0 P_0}{RTL\alpha} \int_{r_{\min}}^{r_{\max}} \left\{ \ln\left[\frac{1-\alpha y_{AL} + (3D_{AB}^0 P_0)/[(2rP)(8RT/\pi M_A)^{1/2}]}{1-\alpha y_{A0} + (3D_{AB}^0 P_0)/[(2rP)(8RT/\pi M_A)^{1/2}]} \right] \right\} \frac{f(r)}{\tau(r)} dr \quad (2.34)$$

where $f(r)$ and $\tau(r)$ are the pore size distribution and the tortuosity factor, respectively. D_{AB}^0 is the binary diffusion coefficient at the atmospheric pressure, P_0. Notwithstanding the fact that pressure and pore radius may have different ranges, we may loosely define Equation (2.34) as a Fredholm equation of the first kind, where the unknown function to be determined is $f(r)/\tau(r)$, given the diffusion measurements of N_A at a fixed temperature and various pressures.

2.2.6.3 Integral Equations Resulting Out of the Boundary-Value Problems with Mixed Derivative Boundary Condition

While descriptions of some of the chemical engineering systems may directly yield integral equations as illustrated in the above examples, for some systems one can transform the governing differential equations into integral equations with computational advantage for their solution. An example of such a transformation follows.

Consider a two-dimensional slab of length l (along x direction) and width b (along y direction) with its insulated ends consisting of heat generation defined by $f(x,y)$, cooled by the liquid flowing along its boundary (Ramkrishna and Amundson, 1979). Let k, h, P, t, C_p, and W be the thermal conductivity of the slab, heat transfer coefficient through the wall, heat transfer area per unit length of the slab at the cooled surface, coolant temperature, specific heat of the coolant, and coolant flow rate, respectively. The boundary-value problem describing the two-dimensional variation of slab temperature, $T(x,y)$, can be completely described as follows:

$$\frac{\partial^2 T}{\partial x^2} + \frac{\partial^2 T}{\partial x^2} = -f(x,y), \quad 0 < y < b, \quad 0 < x < l \quad (2.35)$$

subjected to the boundary conditions given by

$$y = 0, \quad \frac{\partial T}{\partial y} = 0, \quad 0 < x < l \quad (2.36)$$

$$y = b, \quad = -k\frac{\partial T}{\partial y} = h(T - t) = \frac{WC_p}{P}\frac{dt}{dx}, \quad 0 < x < l \quad (2.37)$$

$$x = 0, \quad x = l, \quad \frac{\partial T}{\partial x} = 0, \quad 0 < y < b \quad (2.38)$$

The solution to Equation (2.35), i.e., the temperature distribution in the slab, can be written in terms of Green's function as follows:

$$T(x,y) = \int_0^1 d\xi \int_0^b d\eta G(x,y,\xi,\eta) f(\xi,\eta) + \frac{h}{k}\int_0^1 d\xi t(\xi) G(x,y,\xi,b) \quad (2.39)$$

The boundary condition in Equation (2.37) represents a mixed derivative boundary condition, which can be written in the form

$$\frac{dt}{dx} = \beta[T(x,b) - t], \; t(0) = t_0, \; \beta \equiv \frac{hP}{WC_p} \tag{2.40}$$

and can be rewritten as

$$t(x) = t_0 e^{-\beta x} + \beta \int_0^x T(\xi,b) e^{-\beta(x-\xi)} d\xi \tag{2.41}$$

Substitution for $T(\xi,b)$ from Equation (2.39) results in the Fredholm integral equation:

$$t(x) = g(x) + \lambda \int_0^1 K(x,\xi) t(\xi) d\xi \tag{2.42}$$

where the expressions for the functions $g(x)$ and $K(x,\xi)$ can be readily obtained from Equations (2.41) and (2.39). Thus, solution of the integral Equation (2.42) completely specifies the solution to the boundary-value problem of Equation (2.39).

2.2.7 Processes Governed by Integrodifferential Equations

Most chemical systems involve multiple phases. The description of the interaction between them leads to both the differential as well as integral terms. The *population balance equations* form an important class of integrodifferential equations.

The population balance equation is a framework for the modeling of particulate systems. These include dispersions involving solid particles, liquid drops, and gas bubbles spanning a variety of systems of chemical engineering interest. The detailed derivation of the population balance equation and its applications can be found in Ramkrishna (1985, 2000). Publications pioneering the general application of population balance are by Hulburt and Katz (1964), Randolph and Larson (1964), and Frederickson et al. (1967).

Let $f(\mathbf{x},\mathbf{r},t)$ be the number density of particles with the particle state, $\mathbf{x}$, called as internal coordinate at a spatial location $\mathbf{r}$ at time t. Let $\dot{\mathbf{X}}(\mathbf{x},\mathbf{r},\mathbf{Y},t)$ and $\dot{\mathbf{R}}(\mathbf{x},\mathbf{r},\mathbf{Y},t)$ be the velocities along the internal and external coordinates, respectively, at time t in an environment of state $\mathbf{Y}$. Let $P(\mathbf{x},\mathbf{r},\mathbf{Y},t)$ and $D(\mathbf{x},\mathbf{r},\mathbf{Y},t)$ be the rates of production and destruction of particles. Then, following Ramkrishna (2000), the population balance equation for the number density is written as

$$\frac{\partial f}{\partial t} + \nabla \cdot \dot{\mathbf{X}} f + \frac{1}{V_0} \int_{A_i} f \dot{\mathbf{R}} \cdot d\mathbf{A} + \frac{1}{V_0} \int_{A_o} f \dot{\mathbf{R}} \cdot d\mathbf{A} = P - D$$

where V_0 is the system volume, and A_i and A_o are the areas of inlet and outlet, respectively. The production and destruction terms most commonly resulting out of aggregation and breakage involve integral terms imparting population balance equations as a class of the integrodifferential equations.

2.2.8 Processes Governed by Stochastic Differential Equations

In industrial operations, there often exist random fluctuations in the operating conditions from a variety of sources. Aris and Amundson (1958) show how fluctuations in the outputs of a continuous reactor caused by specified fluctuations in the input variables can be estimated by linearization.

For dynamic effects, stochastic differential equations pose a reasonable alternative to model such situations. A stochastic differential equation is written in the following form:

$$\frac{dX_t}{dt} = a(t, X_t) + b(t, X_t)\xi(t) \tag{2.43}$$

where $\xi(t)$ is the random fluctuations. The alternative to Equation (2.43) is

$$X_t = X_0 + \int_0^t a(s, X_s)ds + \int_0^t b(s, X_a)\xi(s)ds \tag{2.44}$$

The fluctuations are often modeled as a Wiener process, i.e., $\xi(t)dt = dW(t)$ (Gardiner, 2003); the function is known as *white* noise. For its precise mathematical definition and that of the Wiener process, the reader is referred to Gardiner (2003). Then Equation (2.44) is replaced by

$$X_t = X_0 + \int_0^t a(s, X_s)ds + \int_0^t b(s, X_s)dW(s) \tag{2.45}$$

Equation (2.45) is called the Îto stochastic equation.

For information on how stochastic differential equations can be used to analyze the effect of the fluctuations in operating conditions, see Rao et al. (1974a). The actual method of solving nonlinear stochastic equations can be found in Rao et al. (1974b). Algorithms simpler than Rao et al. (1974b) are reported elsewhere (e.g., Pardoux and Talay, 1985).

2.3 THE NUMBER SYSTEM

A prerequisite for engineering calculations is the understanding of the number system. The reader may refer to the free on-line Web source http://mathworld.wolfram.com/topics/NumberTheory.html for the details.

2.3.1 The Real Number System

Integers are whole numbers spanning both positive and negative numbers including zero, while natural numbers consist of only positive numbers excluding zero. In addition to integers, rational numbers or fractional numbers are the ratios of integers. Irrational numbers are the numbers not representable by a ratio of integers. An example of an irrational number is π, the ratio of circumference of a circle to its diameter. The real number system consists of rational and irrational numbers (integers are special cases of rational numbers). Apart from addition, subtraction, multiplication, and division, operations on real numbers involving powers, roots, and logarithms are necessary for solving equations governing the engineering systems.

2.3.1.1 Powers and Roots

The nth power of a real number is defined as

$$a^n = \underbrace{a \cdot a \cdot a \cdots a}_{n \text{ times}}$$

where a is called the base and n is called the exponent. Powers with negative exponents are defined as

$$a^{-n} = \frac{1}{a^n}, \quad a \neq 0$$

The *n*th root of a real number is defined as

$$x = a^{1/n} = \sqrt[n]{a} \text{ if and only if } x^n = a$$

Properties of powers and roots are as follows:

$$a^n a^m = a^{m+n}; \quad \frac{a^n}{a^m} = a^{n-m}; \quad (ab)^n = a^n b^n; \quad \left(\frac{a}{b}\right)^n = \frac{a^n}{b^n}$$

$$a^{n/m} = \sqrt[m]{a^n} = (\sqrt[m]{a})^n; \quad \sqrt[m]{\sqrt[n]{a}} = \sqrt[mn]{a}; \quad \sqrt[n]{ab} = \sqrt[n]{a}\sqrt[n]{b}$$

$$\sqrt[n]{\frac{a}{b}} = \frac{\sqrt[n]{a}}{\sqrt[n]{b}} (b \neq 0)$$

2.3.1.2 Logarithm

The logarithm to the base $c > 0$,

$$x = \log_c a$$

is defined by

$$c^x = a \quad \text{or} \quad c^{\log_c a} = a$$

Properties of logarithms:

$$\log_c a = 1; \quad \log_c c^p = p$$

$$\log_c (ab) = \log_c a + \log_c b; \quad \log_c \left(\frac{a}{b}\right) = \log_c a - \log_c b$$

$$\log_c (a^n) = n \log_c a; \quad \log_c (\sqrt[n]{a}) = \frac{1}{n} \log_c a$$

2.3.2 Sequences and Series

A sequence is a function that maps integers to a subset of real numbers. A sequence can be viewed as a set of numbers indexed by integers. A finite sequence terminates after a finite number of terms. The following is an example of a finite sequence:

$$\{a_i\}_{i-0}^{5} = \{2i+1\}_{i=0}^{5} = \{1, 3, 5, 7, 9, 11\}$$

A sequence that extends indefinitely is an infinite sequence. For example, $\{a_i\}_{i=1}^{\infty} = \{2i+1\}_{i=0}^{\infty}$ is a sequence of odd integers that is an example of a divergent sequence. The following is an example of a real sequence:

$$\{a_i\}_{i=1}^{\infty} = \left\{\frac{1}{i}\right\}_{i=1}^{\infty}$$

If an infinite sequence approaches a definite number, then the sequence is convergent. Thus the real sequence represented above is a convergent sequence that converges to zero.

A sequence is called increasing (decreasing) if $a_{n+1} > a_n(a_{n+1} < a_n)$ and is called nondecreasing (nonincreasing) if $a_{n+1} \geq a_n(a_{n+1} \leq a_n)$. A sequence is called strictly monotone if it is either increasing or decreasing. A sequence is bounded if there is a number M such that $|a_n| \leq M$. A bounded strictly monotone sequence converges.

A series is the sum of a sequence. Thus, given a sequence, one can form a series by summing the sequence. A finite sequence generates a finite series, and an infinite sequence generates an infinite series.

From a series, one can form an infinite sequence by defining the partial sum as follows:

$$A_n = \sum_{i=1}^{n} a_i$$

The sequence formed from this series is $A_1, A_2, A_3, \ldots$, where

$$A_2 + a_1 + a_2, \quad A_3 = a_1 + a_2 + a_3, \quad A_4 = a_1 + a_2 + a_3 + a_4 \ldots$$

However, the criteria for convergence of a sequence and of a series are different. A convergent sequence may not generate a convergent series. A sequence formed by partial sums of a convergent series is convergent.

2.3.3 Tests for Convergence of Sequence and Series

We list here some of the tests that can be used to determine the convergence of series without having to evaluate the series:

$$\sum_{n=1}^{\infty} a_n$$

2.3.3.1 Integral Test

The series converges if and only if the integral

$$\int_1^{\infty} f(x)dx$$

converges, where $f(k) = a_k \geq 0$. For example, the harmonic series

$$\sum_{n=1}^{\infty}\frac{1}{n}$$

is divergent because

$$\int_{1}^{\infty}\frac{1}{x}dx=\infty$$

2.3.3.2 Ratio Test

$$\rho=\lim_{n\to\infty}\frac{a_{n+1}}{a_n}$$

The series is convergent if $\rho < 1$; divergent if $\rho > 1$. It is indeterminate if $\rho = 1$. For example, the series

$$\sum_{n=0}^{\infty}\frac{1}{n!}$$

is convergent because

$$\lim_{n\to\infty}\frac{a_{n+1}}{a_n}=\lim_{n\to\infty}\frac{1}{n+1}=0<1$$

2.3.3.3 Root Test

$$\rho=\lim_{n\to\infty}\sqrt[n]{a_n}$$

The series is convergent if $\rho < 1$; divergent if $\rho > 1$. It is indeterminate if $\rho = 1$. For example, the series

$$\sum_{n=1}^{\infty}\frac{1}{n^n}$$

is convergent because

$$\lim_{n\to\infty}\sqrt[n]{a_n}=\lim_{n\to\infty}\frac{1}{n}=0<1$$

2.3.3.4 Comparison Test

If $0 < a_n < (>) b_n$ and the series

$$\sum_{n=1}^{\infty} b_n$$

is convergent (divergent), then the series

$$\sum_{n=1}^{\infty} a_n$$

is convergent (divergent).

For example, the series

$$\sum_{n=1}^{\infty} \frac{1}{n^2+n}$$

is convergent because

$$\frac{1}{n^2+n} < \frac{1}{n^2}$$

and the latter series is convergent by integral test. Thus the former series is convergent.

2.3.3.5 Limit Comparison Test

$$\rho = \lim_{n\to\infty} \frac{a_n}{b_n}$$

If $0 < \rho < \infty$, then both the series converge or diverge. For example, the series

$$\sum_{n=1}^{\infty} \frac{n}{n^2+n}$$

is divergent because the harmonic series is divergent, and by the limit comparison test, both the series diverge.

2.3.4 Taylor Series

If $f(x)$ is analytic within and on a circle C centered at x_0 of radius R, then the Taylor series representation of $f(x)$ is given by

$$f(x) = \sum_{n=0}^{\infty} \frac{f^{(n)}(x_0)}{n!}(x - x_0)^n$$

2.3.5 Binomial Theorem

For any positive integer n,

$$(a+b)^n = a^n + na^{n-1}b + \frac{n(n-1)}{2!}a^{n-2}b^2 + \frac{n(n-1)(n-2)}{3!}a^{n-2}b^3 + \cdots +$$
$$= \sum_{m=0}^{n} C_m^n a^{n-m} b^m$$

where

$$C_m^n = \frac{n!}{(n-m)!m!} = C_{n-m}^n$$
$$n! = n(n-1)(n-2)\cdots 1, \quad 0! = 1$$

C_m^n satisfies the following identity:

$$2^n = 1 + C_1^n + C_2^n + \cdots + C_n^n$$

that is obtained by letting $a = b = 1$. The expansion of binomial terminates when n is an integer. A similar expansion holds for $b = 1$ and noninteger n,

$$(1+a)^n = 1 + na + \frac{n(n-1)}{2!}a^2 + \frac{n(n-1)(n-2)}{3!}a^3 + \cdots +$$

2.3.6 Inequalities

We list here some of the important inequalities followed by an example showing the use of one of the inequalities in the context of a chemical reaction. Let $\{a_i\}_{i=1}^n$ and $\{b_i\}_{i=1}^n$ be sequences of real numbers and $p, q \geq 1$.

2.3.6.1 Algebraic Inequalities

$$\text{Triangular inequality:} \quad \left|\sum_{i=1}^{n} a_i\right| \leq \sum_{i=1}^{n} |b_i| \tag{2.46}$$

$$\text{Hölder's inequality:} \quad \sum_{i=1}^{n} |a_i b_i| \leq \left(\sum_{i=1}^{n} |a_i|^p\right)^{1/p} \left(\sum_{i=1}^{n} |b_i|^q\right)^{1/q}, \quad \frac{1}{p} + \frac{1}{q} = 1 \tag{2.47}$$

For $p = q = 2$, Holder's inequality is known as the Cauchy–Schwartz inequality.

$$\text{Minkowski's inequality:}\quad \left(\sum_{i=1}^{n}|a_i+b_i|^p\right)^{1/p} \le \left(\sum_{i=1}^{n}|a_i|^p\right)^{1/p} + \left(\sum_{i=1}^{n}|a_i|^p\right)^{1/p} \quad (2.48)$$

$$\text{Arithmatic-geometric means inequality:}\quad \frac{1}{n}\sum_{i=1}^{n} a_i \ge \left(\prod_{i=1}^{n} a_i\right)^{1/n},\ a_i \ge 0 \quad (2.49)$$

$$\text{Chebyshev's inequality:}\quad \frac{1}{n}\sum_{i=1}^{n} a_i b_i \ge \left(\frac{1}{n}\sum_{i=1}^{n} a_i\right)\left(\frac{1}{n}\sum_{i=1}^{n} b_i\right),\ a_1 \ge \cdots \ge a_m, b_1 \ge \cdots \ge b_m \quad (2.50)$$

2.3.6.2 Integral Inequalities

$$\text{Modulus inequality:}\quad \left|\int_a^b f(x)dx\right| \le \int_a^b |f(x)|dx \quad (2.51)$$

$$\text{Hölder inequality:}\quad \int_a^b |f(x)g(x)|dx \le \left(\int_a^b |f(x)|^p dx\right)^{1/p}\left(\int_a^b |g(x)|^q\right)^{1/q} \quad (2.52)$$

For $p = q = 2$,

$$\text{Arithmatic-geometric inequality:}\quad \frac{1}{b-a}\int_a^b f(x)dx \ge \exp\left[\frac{1}{b-a}\int_a^b \ln f(x)dx\right],\ f(x) \ge 0 \quad (2.53)$$

$$\left(\frac{1}{b-a}\int_a^b f(x)dx\right)\left(\frac{1}{b-a}\int_a^b g(x)dx\right) \le \frac{1}{b-a}\int_a^b f(x)g(x)dx,\ f'(x),\ g'(x) \ge 0 \quad (2.54)$$

Example 2.1: Application of Inequalities

Consider a reactant undergoing an nth-order reaction with rate kc^n in dispersed-phase droplets. The concentration c is assumed to vary between 0 and c_0. If the distribution of solute concentration is denoted $f(c)$, which is nonnegative and such that $\int_0^{c_0} f(c)dc = 1$, the average concentration in the drop phase is then

$$\bar{c} = \int_0^{c_0} f(c)dc$$

The reaction rate in the drop phase is then

$$k\overline{c^n} = k\int_0^{c_0} c^n f(c)dc$$

On the other hand, the reaction rate in terms of the average concentration is given by

$$k\bar{c}^n = k\left[\int_0^{c_0} cf(c)dc\right]^n$$

It is easy to show that the rate of reaction as described by the lumped dispersed phase analysis underestimates the actual rate by using the Hölder's inequality. Let $g(c) = cf^{1/p}$ and $h(c) = f^{1/q}$. Thus,

$$\int_0^{c_0} c[f(c)]^{1/p+1/q}dc \le \left(\int_0^{c_0} c^p f(c)\right)^{1/p}\left(\int_0^{c_0} f(c)dc\right)^{1/q}$$

The second integral on the right-hand side of the inequality is unity by definition. Hence, with $p = n$ and $q = 1/(n - 1)$,

$$k\bar{c}^n \le k\overline{c^n}, \ n > 1$$

2.4 DIFFERENTIAL AND INTEGRAL CALCULUS

2.4.1 Functions, Limits, and Continuity

A function $y = f(x)$ is a rule that assigns a unique value of y for each of the given values of x in the definition of a domain of f, and x is said to be an independent variable and y the dependent variable. There may exist more than one value of x for a given value of y. The set of values of x is called the domain of a function, and the corresponding set of y is called the range of a function.

A function $f(x)$ approaches a limit y_0 as x approaches x_0; for any given $\varepsilon > 0$, then there exists a $\delta > 0$ such that $|f(x) - y_0| < \varepsilon$ for $|x - x_0| < \delta$. Symbolically,

$$\lim_{x \to x_0} f(x) = y_0$$

The limits follow simple arithmetic operations, e.g., the sum of the limits is the limit of the sums, etc.

A function is said to be continuous at x_0 if

$$\lim_{x \to x_0} f(x) = f(x_0)$$

For example,

$$f(x) = \begin{cases} \dfrac{1}{x}, & x > 0 \\ 0, & x = 0 \end{cases}$$

is not continuous at $x = 0$ because

$$\lim_{x \to 0} f(x) = \infty \ne f(0) = 0$$

2.4.2 The Derivative

The derivative is the rate of change of the function with respect to its argument. It follows that if the derivative is positive, then the function is increasing, and if the derivative is negative, then the function is decreasing.

A function is said to be differentiable at $x = a$ if

$$f'(a) \equiv \frac{df(a)}{dx} \equiv \lim_{x \to a} \frac{f(x) - f(a)}{x - a}$$

exists. The derivative of $f(x)$ at $x = a$ is the instantaneous rate of change of $f(x)$ with respect to x at $x = a$. Graphically, it is the slope of a tangent line to the curve $f(x)$ at the point $(a, f(a))$.

Following are the rules of differentiation for the differentiable functions $f(x)$ and $g(x)$:

$$\frac{dc}{dx} = 0, \quad c \neq f(x)$$

$$\frac{d[cf(x)]}{dx} = c\frac{df(x)}{dx}, \quad c = \text{constant}$$

$$\frac{d}{dx}[f(x) \pm g(x)] = \frac{df(x)}{dx} \pm \frac{dg(x)}{dx}$$

$$\frac{d}{dx} f(x)g(x) = f(x)\frac{dg(x)}{dx} + g(x)\frac{f(x)}{dx}$$

$$\frac{d}{dx}\frac{f(x)}{g(x)} = \frac{f(x)\dfrac{dg(x)}{dx} - g(x)\dfrac{df(x)}{dx}}{[g(x)]^2}$$

$$\frac{d}{dx} f(g(x)) = \frac{df(g)}{dg}\frac{dg(x)}{dx}$$

$$\frac{d^n}{dx^n} f(x)g(x) = \sum_{m=0}^{n} C_m^n \frac{d^{n-m}}{dx^{n-m}} f(x) \frac{d^m}{dx^m} g(x)$$

$$\frac{d}{dx}[f(x)]^n = n[f(x)]^{n-1}\frac{df(x)}{dx}$$

A higher-order derivative of a function is defined recursively in terms of the lower-order derivative.

The second-order derivative is the concavity of the function at x. If the second derivative of a function at x_0 is negative, then the function is concave down at x_0. The function is concave up at x_0 if its second derivative is positive. If the second derivative vanishes at x_0, then it is called as an inflection point, where the function essentially changes its concavity.

When the derivative is zero, the function reaches its local extremum. Whether this local extremum is a maximum or minimum depends on additional information. If, in addition, the second derivative is negative, then the function attains maximum at x_0; if the second derivative is positive at the local extremum, then it is a minimum.

2.4.2.1 An Example Application of the Derivatives

The concentration of the intermediate product, B, at any time, t, as a result of the following reactions in series

$$A \xrightarrow{k_1} B \xrightarrow{k_2} C$$

with first-order reaction kinetics with respect to A and B and with the initial concentration of the reactant, A, equal to C_{A0}, is given by

$$C_B(t) = \frac{k_1 C_{A0}}{k_2 - k_1}[e^{-k_1 t} - e^{-k_2 t}]$$

To find out the space-time, τ, that maximizes the concentration of B, the derivative of C_B with respect to time t is set equal to zero at $t = \tau$ to yield

$$\left.\frac{dC_B}{dt}\right|_{t=\tau} = 0 \Rightarrow \tau = \frac{\ln k_2 - \ln k_1}{k_2 - k_1}$$

$$\left.\frac{d^2 C_B}{dt^2}\right|_{t=\tau} < 0, \text{ at } t = \tau$$

Hence, the maximum concentration of the species B, $C_{B,m}$ is given by

$$C_{B,m} = \frac{k_1 C_{A0}}{k_2 - k_1}\left[\left(\frac{k_1}{k_2}\right)^{k_1/k_2 - k_1} - \left(\frac{k_1}{k_2}\right)^{k_2/k_2 - k_1}\right]$$

2.4.3 The Mean Value Theorem

Let $f(x)$ and $g(x)$ be the differentiable functions on $[a,b]$. If $g(b) \neq g(a)$ and $g'(x) \neq 0$, then there exists $c \in (a,b)$ such that

$$\frac{f'(c)}{g'(c)} = \frac{f(b) - f(a)}{g(b) - g(a)}$$

In particular, if $g(x) = x$, then

$$f'(c) = \frac{f(b) - f(a)}{b - a}$$

which is the familiar form of the mean value theorem.

2.4.3.1 An Example Application of the Mean Value Theorem

To account for the effects of transport resistance in a catalyst pellet, effectiveness factors (defined as the ratio between the observed reaction rate to that obtained when neither concentration nor temperature gradients exist between the ambient phase and any point in the catalyst pellet) are used

in modeling chemical reactors. It is very important that the effectiveness factors do not change the nature of the reactions. One of the properties that the effectiveness factors must possess is positive definiteness. This property ensures that the transport resistance does not change the direction of a reaction. Here we illustrate the use of the mean value theorem to show that the overall effectiveness factor is positive.

Reactions in series were discussed in Section 2.4.2.1. For reactions occurring in a spherical catalyst pellet with the pore radius R, the concentration of the intermediate product, B, is proportional to the overall effectiveness factor given by

$$\bar{\eta} = \frac{\eta_2\phi_2^2 - \eta_1\phi_1^2}{\phi_2^2 - \phi_1^2}$$

where effectiveness factors for each of the reactions are given by

$$\eta_i = \frac{3\phi_i \coth(3\phi_i) - 1}{3\phi_i^2} \text{ and the Thiele moduli as, } \phi_i = \frac{R}{3}\sqrt{\frac{a_p k_i}{D_B}}, \quad i = 1, 2$$

where D_B is the diffusivity of the product B. Thus,

$$\bar{\eta} = \frac{\phi_2 \coth(3\phi_2) - \phi_1 \coth(3\phi_1)}{\phi_2^2 - \phi_1^2}$$

Setting $f(c) \equiv \sqrt{c}\coth(3\sqrt{c})$, $g(c) \equiv c$ and applying the mean value theorem,

$$\bar{\eta} = \frac{f'(c)}{g'(c)}, \quad \phi_1^2 < c < \phi_2^2$$

that ensures that the overall effectiveness factor is positive if

$$f(x) = x\coth(3x)$$

is positive. It can be readily shown that $f'(x)$ is indeed positive for all positive x.

2.4.4 L'Hôspital's Rule

The limit of a function as its independent variable approaches a value is indeterminate if it has one of the following forms:

$$\frac{0}{0}, \ \frac{\infty}{\infty}, \ 0\cdot\infty, \ 0^0, \ \infty^0, \ 1^\infty, \ \infty - \infty \tag{2.55}$$

L'Hôspital's rule is applicable to the first two forms, namely, 0/0 or ∞/∞. The rest of the forms can be rewritten in terms of the first two.

For limits that yield 0/0 or ∞/∞, L'Hôspital's rule states

$$\lim_{x \to x_0} \frac{f(x)}{g(x)} = \lim_{x \to x_0} \frac{f'(x)}{g'(x)}$$

since ∞ – 1/0, 0 · ∞ can be stated as the first two forms. Limit of the form ∞ – ∞ is equivalent to 1 – ∞/∞.

Logarithms of the limits can be used to find the limits involving exponents using L'Hôspital's rule.

Example 2.2: Application of L'Hôspital's Rule

$$\lim_{x \to \infty} \left(\cos \frac{1}{x} \right)^x$$

Let

$$y = \left(\cos \frac{1}{x} \right)^x \Rightarrow \ln y = x \ln \cos \frac{1}{x}$$

$$\lim_{x \to \infty} \ln y = \lim_{x \to \infty} x \ln \cos \frac{1}{x} = \lim_{x \to \infty} \frac{\ln \cos \frac{1}{x}}{\frac{1}{x}} = -\lim_{x \to \infty} \frac{\sin \frac{1}{x}}{\cos \frac{1}{x}} = 0$$

$$\lim_{x \to \infty} \left(\cos \frac{1}{x} \right)^x = 1$$

2.4.5 Implicit Function Theorem

Given a function $f(x,y)$ such that

$$f(x_0, y_0) = 0, \quad \text{and} \quad \left. \frac{\partial f}{\partial y} \right|_{(x_0, y_0)} \neq 0$$

then there exists a neighborhood $B(x_0)$ and a unique function $g(x)$ such that $y = g(x)$ for $x \in B(x_0)$, $f(x,g(x)) = 0$.

2.4.6 The Integral

Given a bounded function $f(x)$ defined on a bounded interval $[a,b]$, the definite Riemann integral of $f(x)$ is defined as

$$\int_a^b f(x)dx = \lim_{\|\Delta x_i\|} \sum_{i=1}^{n} f(\xi_i)\Delta x_i$$

where

$$x_{i-1} < \xi_i < x_i, \quad \|\Delta x_i\| = \max_{i=1}^{n}(x_i - x_{i-1}), \quad a = x_0 < x_1 < \cdots < x_n = b$$

The term $f(x)$ is known as the integrand; a and b are the limits of integration. The interpretation of a definite integral is the area bounded by the function $f(x)$ and the x-axis between the lines $x = a$ and $x = b$.

The integral possesses the following properties:

$$\int_a^b f(x)dx = -\int_b^a f(x)dx$$

$$\int_a^c f(x)dx = \int_a^b f(x)dx + \int_b^c f(x)dx$$

$$\int_a^b [f(x)+g(x)]dx = \int_a^b f(x)dx + \int_a^b g(x)dx$$

Rules of integration:

1. Integration by parts,

$$\int_a^b f(x)g'(x)dx = f(x)g(x)\Big|_{x=a}^{x=b} - \int_a^b g(x)f'(x)dx$$

2. If $x = h(t)$, then $dx = h'(t)dt$ and

$$\int_a^b f(x)dx = \int_{h^{-1}(a)}^{h^{-1}(b)} f[h(t)]dt$$

3. Leibnitz's rule: If $p(y)$ and $q(y)$ are continuously differentiable functions of y,

$$\frac{\partial}{\partial y}\int_{p(y)}^{q(y)} f(x,y)dx = \frac{dq}{dy}f(q,y) - \frac{dp}{dy}f(p,y) + \int_{p(y)}^{q(y)} \frac{\partial}{\partial y} f(x,y)dx$$

The fundamental theorem of calculus: Given a continuous function $f(x)$ on the bounded interval $[0,x]$, then

$$\frac{d}{dx}\int_0^x f(\xi)d\xi = f(x)$$

2.4.6.1 Improper Integrals

There are two types of improper integrals. One type of improper integral is that where the integrand becomes infinite at one of the limits of integration. The other type is that where one or both of the limits of integration are infinite. The improper integral is defined as

$$\int_a^\infty f(x)dx = \lim_{b\to\infty}\int_a^b f(x)dx$$

If the limit exists, then the improper integral converges; otherwise, the improper integral diverges. Given $f(x)$ on $[a,b]$ such that $f(a) = \infty$, then the improper integral is defined as

$$\int_a^b f(x)dx = \lim_{x \to a} \int_x^b f(\xi)d\xi$$

The improper integrals are said to be convergent if and only if the limits are convergent.

The Riemann integral is convergent for a bounded function with a finite number of discontinuities. It is possible to construct a pathological function that has an infinite number of discontinuities. Although such a function is bounded, its Riemann integral does not exist. The Lebesgue integral is designed to overcome such a deficiency.

2.4.6.2 An Example Application of the Integrals

We reproduce here some useful formulae for the determination of area under the curve, the arc length, volume of solid revolution, and the surface area that are the results of the application of the integrals. Let $f(x)$ be a real valued function defined on an interval (a,b). Let A be the area bounded by the function, the x-axis, and the lines $x = a$ and $x = b$. Then

$$A = \int_a^b f(x)dx \tag{2.56}$$

and the arclength, S, of the curve defined by the function is

$$S = \int_a^b \sqrt{1+\left(\frac{df}{dx}\right)^2}\,dx \tag{2.57}$$

The volume of the solid generated by revolving the curve $f(x)$ about the x-axis is

$$\pi \int_a^b [f(x)]^2 dx$$

and the surface area of the solid body is given by

$$2\pi \int_a^b f(x)\sqrt{1+\left(\frac{df}{dx}\right)^2}\,dx \tag{2.58}$$

2.5 VECTOR ANALYSIS

2.5.1 Vector Algebra

A vector $\mathbf{v}$ in n-dimensional space is an array consisting of n scalar quantities, i.e., $\mathbf{v} = [v_1 \quad v_2 \quad \ldots \quad \ldots \quad v_n]^T$. In three-dimensional space, a vector, $\mathbf{v}$, can be represented geometrically as directed line segments with directions and magnitudes. The terms v_x, v_y, and v_z are the components of the vector $\mathbf{v}$ along the x-, y-, and z-axes, respectively. The magnitude of $\mathbf{v}$, $|\mathbf{v}|$, is $\sqrt{v_x^2 + v_y^2 + v_z^2}$, which measures the length of the vector or the distance from the origin to the tip of the vector. The angles α, β, and γ between the vector $\mathbf{v}$ and basis vectors δ_x, δ_y, and δ_y of the coordinate axes x, y, and z, respectively, are calculated from the direction cosines of the vector,

$$\cos\alpha = \frac{v_x}{\sqrt{v_x^2 + v_y^2 + v_z^2}} \quad \cos\beta = \frac{v_y}{\sqrt{v_x^2 + v_y^2 + v_z^2}} \quad \cos\gamma = \frac{v_z}{\sqrt{v_x^2 + v_y^2 + v_z^2}} \tag{2.59}$$

From these operations, it is clear that negating a vector is reversing its direction. It is possible to resolve a vector into its components, and vice versa, i.e.,

$$\mathbf{v} = [v_x \quad v_y \quad v_z]^T \quad \text{or} \quad \mathbf{v} = v_x\boldsymbol{\delta}_x + v_y\boldsymbol{\delta}_y + v_z\boldsymbol{\delta}_z$$

Addition of vectors is carried out componentwise. Given two three-dimensional vectors **a** and **b**,

$$\mathbf{a} \pm \mathbf{b} = [a_1 \pm b_1 \quad a_2 \pm b_2 \quad a_3 \pm b_3]$$

it follows that addition of vectors is commutative and associative:

$$\mathbf{a} + \mathbf{b} = \mathbf{b} + \mathbf{a} \tag{2.60}$$

$$(\mathbf{a} + \mathbf{b}) + \mathbf{c} = \mathbf{a} + (\mathbf{b} + \mathbf{c}) \tag{2.61}$$

Scalar product: The scalar product of two three-dimensional vectors **a** and **b** is defined as

$$\mathbf{a} \cdot \mathbf{b} = |\mathbf{a}||\mathbf{b}| \cos(\mathbf{a},\mathbf{b})$$

where cos(**a**,**b**) is the cosine of the angle between the vectors **a** and **b**. It is a componentwise operation,

$$\mathbf{a} \cdot \mathbf{b} = \sum_{i=1}^{3} a_i b_i$$

or it can be simply written as $a_i b_i$ using Einstein's convention of summation over repeated indices. It follows that scalar products are commutative and distributive.

Vector product: The vector product of two three-dimensional vectors **a** and **b** is

$$\mathbf{a} \times \mathbf{b} = \begin{vmatrix} \boldsymbol{\delta}_x & \boldsymbol{\delta}_y & \boldsymbol{\delta}_z \\ a_x & a_y & a_z \\ b_x & b_y & b_z \end{vmatrix}$$

Componentwise operation is defined as

$$\mathbf{a} \times \mathbf{b} = \sum_{i=1}^{3}\sum_{j=1}^{3}\sum_{k=1}^{3} \varepsilon_{ijk} a_i b_j \boldsymbol{\delta}_k$$

or it can be simply represented by $\varepsilon_{ijk} a_i b_j \delta_{\mathbf{k}}$, where

$$\varepsilon_{123} = \varepsilon_{231} = \varepsilon_{312} = 1 \tag{2.62}$$

$$\varepsilon_{132} = \varepsilon_{321} = \varepsilon_{213} = -1 \tag{2.63}$$

$$\varepsilon_{ijk} = \varepsilon_{ijj} = \varepsilon_{iji} = 0 \tag{2.64}$$

Scalar triple product:

$$(\mathbf{a}\times\mathbf{b})\cdot\mathbf{c} = \begin{vmatrix} a_x & a_y & a_z \\ b_x & b_y & b_z \\ c_x & c_y & c_z \end{vmatrix}$$

Vector triple product:

$$\mathbf{a} \times (\mathbf{b} \times \mathbf{c}) = (\mathbf{a} \cdot \mathbf{c})\mathbf{b} - (\mathbf{a} \cdot \mathbf{b})\mathbf{c}$$

Quadruple scalar product:

$$(\mathbf{a} \times \mathbf{b}) \cdot (\mathbf{c} \times \mathbf{d}) = (\mathbf{a} \cdot \mathbf{c})(\mathbf{b} \cdot \mathbf{d}) - (\mathbf{a} \cdot \mathbf{d})(\mathbf{b} \cdot \mathbf{c})$$

Quadruple vector product:

$$(\mathbf{a} \times \mathbf{b}) \times (\mathbf{c} \times \mathbf{d}) = [(\mathbf{a} \times \mathbf{b}) \cdot \mathbf{d}]\mathbf{c} - [(\mathbf{a} \times \mathbf{b}) \cdot \mathbf{c}]\mathbf{d}$$

2.5.2 Vector Calculus

We list here some of the useful vector operations in a differential setting that are generally encountered in chemical engineering:

$$\frac{d\mathbf{a}}{dt} = \frac{da_x}{dt}\boldsymbol{\delta}_x + \frac{da_y}{dt}\boldsymbol{\delta}_y + \frac{da_z}{dt}\boldsymbol{\delta}_z$$

$$\frac{d}{dt}(\mathbf{a}+\mathbf{b}) = \frac{d\mathbf{a}}{dt} + \frac{d\mathbf{b}}{dt}$$

$$\frac{d}{dt}(\phi\mathbf{a}) = \phi\frac{d\mathbf{a}}{dt} + \mathbf{a}\frac{d\phi}{dt}$$

$$\frac{d}{dt}(\mathbf{a}\cdot\mathbf{b}) = \frac{d\mathbf{a}}{dt}\cdot\mathbf{b} + \mathbf{a}\cdot\frac{d\mathbf{b}}{dt}$$

$$\frac{d}{dt}(\mathbf{a}\times\mathbf{b}) = \frac{d\mathbf{a}}{dt}\times\mathbf{b} + \mathbf{a}\times\frac{d\mathbf{b}}{dt}$$

$$\frac{d}{dt}(\mathbf{a}\times\mathbf{b}\cdot\mathbf{c}) = \frac{d\mathbf{a}}{dt}\times\mathbf{b}\cdot\mathbf{c} + \mathbf{a}\times\frac{d\mathbf{b}}{dt}\cdot\mathbf{c} + \mathbf{a}\times\mathbf{b}\cdot\frac{d\mathbf{c}}{dt}$$

$$\frac{d}{dt}(\mathbf{a}\times\mathbf{b}\times\mathbf{c}) = \frac{d\mathbf{a}}{dt}\times(\mathbf{b}\times\mathbf{c}) + \mathbf{a}\times\left(\frac{d\mathbf{b}}{dt}\times\mathbf{c}\right) + \mathbf{a}\times\left(\mathbf{b}\times\frac{d\mathbf{c}}{dt}\right)$$

2.5.3 Orthogonal Curvilinear Coordinate Systems

2.5.3.1 Scale Factors and Metric Tensors

Given a transformation of coordinate system from (x_1,x_2,x_3) to an orthogonal curvilinear coordinate system (ξ_1,ξ_2,ξ_3),

$$x_1 \equiv x_1(\xi_1,\xi_2,\xi_3) \quad x_2 \equiv x_2(\xi_1,\xi_2,\xi_3) \quad x_3 \equiv x_3(\xi_1,\xi_2,\xi_3)$$

we have

$$dx_i = \sum_{j=1}^{3} \frac{\partial x_i}{\partial \xi_j} d\xi_j$$

and

$$dl^2 = \sum_{i=1}^{3} dx_i^2 = \sum_{i=1}^{3}\sum_{j=1}^{3} g_{ij} d\xi_i d\xi_i$$

where the elements g_{ij} are given by

$$g_{ij} = \sum_{k=1}^{3} \frac{\partial x_k}{\partial x_i}\frac{\partial x_k}{\partial \xi_j} = \left[\sum_{k=1}^{3} \frac{\partial \xi_i}{\partial x_k}\frac{\partial \xi_i}{\partial x_k}\right]$$

provided the Jacobian of the transformation

$$J = \begin{vmatrix} \dfrac{\partial x_1}{\partial \xi_1} & \dfrac{\partial x_1}{\partial \xi_2} & \dfrac{\partial x_1}{\partial \xi_3} \\ \dfrac{\partial x_2}{\partial \xi_1} & \dfrac{\partial x_2}{\partial \xi_2} & \dfrac{\partial x_2}{\partial \xi_3} \\ \dfrac{\partial x_3}{\partial \xi_1} & \dfrac{\partial x_3}{\partial \xi_2} & \dfrac{\partial x_3}{\partial \xi_3} \end{vmatrix}$$

does not vanish.

Let the scale factors be defined by

$$h_1 = \sqrt{g_{11}} \quad h_2 = \sqrt{g_{22}} \quad h_3 = \sqrt{g_{33}}$$

then the differential volume element

$$dV = h_1 h_2 h_3 d\xi_1 d\xi_2 d\xi_3$$

and the elements of the area ds_i on the surfaces u_i = constant, for i = 1,2,3, are

$$ds_1 = h_2 h_3 d\xi_1 d\xi_3; \quad ds_2 = h_1 h_3 d\xi_1 d\xi_3; \quad ds_3 = h_1 h^2 d\xi^2$$

2.5.3.2 Differential Operators in Curvilinear Coordinate System

We present here the expressions for various differential vector operators that can be of great utility for transforming the equations in different coordinate systems. Given a curvilinear coordinate system with basis vectors ($h_1\boldsymbol{\delta}_1 \quad h_2\boldsymbol{\delta}_2 \quad h_3\boldsymbol{\delta}_3$),

$$\frac{\partial \boldsymbol{\delta}_1}{\partial \xi_1} = -\frac{\boldsymbol{\delta}_2}{h_2}\frac{\partial h_1}{\partial \xi_2} - \frac{\boldsymbol{\delta}_3}{h_3}\frac{\partial h_1}{\partial \xi_3} \qquad \frac{\partial \boldsymbol{\delta}_1}{\partial \xi_2} = \frac{\boldsymbol{\delta}_2}{h_1}\frac{\partial h_2}{\partial \xi_1} \qquad \frac{\partial \boldsymbol{\delta}_1}{\partial \xi_3} = \frac{\boldsymbol{\delta}_3}{h}\frac{\partial h_3}{\partial \xi_1}$$

$$\frac{\partial \boldsymbol{\delta}_2}{\partial \xi_2} = -\frac{\boldsymbol{\delta}_1}{h_1}\frac{\partial h_2}{\partial \xi_1} - \frac{\boldsymbol{\delta}_3}{h_3}\frac{\partial h_2}{\partial \xi_3} \qquad \frac{\partial \boldsymbol{\delta}_2}{\partial \xi_1} = \frac{\boldsymbol{\delta}_1}{h_2}\frac{\partial h_1}{\partial \xi_2} \qquad \frac{\partial \boldsymbol{\delta}_2}{\partial \xi_3} = \frac{\boldsymbol{\delta}_3}{h_2}\frac{\partial h_3}{\partial \xi_2}$$

$$\frac{\partial \boldsymbol{\delta}_3}{\partial \xi_3} = -\frac{\boldsymbol{\delta}_1}{h_1}\frac{\partial h_3}{\partial \xi_1} - \frac{\boldsymbol{\delta}_2}{h_2}\frac{\partial h_3}{\partial \xi_2} \qquad \frac{\partial \boldsymbol{\delta}_3}{\partial \xi_1} = \frac{\boldsymbol{\delta}_1}{h_3}\frac{\partial h_1}{\partial \xi_3} \qquad \frac{\partial \boldsymbol{\delta}_3}{\partial \xi_2} = \frac{\boldsymbol{\delta}_2}{h_3}\frac{\partial h_2}{\partial \xi_3}$$

let

$$\mathbf{f} = f_1\boldsymbol{\delta}_1 + f_2\boldsymbol{\delta}_2 + f_3\boldsymbol{\delta}_3$$

$$\nabla\Phi = \boldsymbol{\delta}_1\frac{\partial \Phi}{\partial \xi_1} + \boldsymbol{\delta}_2\frac{\partial \Phi}{\partial \xi_2} + \boldsymbol{\delta}_3\frac{\partial \Phi}{\partial \xi_3}$$

$$\nabla\cdot\mathbf{f} = \frac{1}{h_1 h_2 h_3}\left(\frac{\partial}{\partial \xi_1}(h_2 h_3 f_1) + \frac{\partial}{\partial \xi_2}(h_1 h_3 f_2) + \frac{\partial}{\partial \xi_3}(h_1 h_2 f_3)\right)$$

$$\nabla\times\mathbf{f} = \frac{1}{h_1 h_2 h_3}\begin{vmatrix} h_1\boldsymbol{\delta}_1 & h_2\boldsymbol{\delta}_2 & h_3\boldsymbol{\delta}_3 \\ \dfrac{\partial}{\partial \xi_3} & \dfrac{\partial}{\partial \xi_3} & \dfrac{\partial}{\partial i_3} \\ h_1 f_1 & h_2 f_2 & h_3 f_3 \end{vmatrix}$$

$$\nabla^2 = \frac{1}{h_1 h_2 h_3}\left(\frac{\partial}{\partial \xi_1}\left(\frac{h_2 h_3}{h_1}\frac{\partial}{\partial \xi_3}\right) + \frac{\partial}{\partial \xi_2}\left(\frac{h_1 h_3}{h_2}\frac{\partial}{\partial \xi_2}\right) + \frac{\partial}{\partial \xi_3}\left(\frac{h_1 h_2}{h_3}\frac{\partial}{\partial \xi_3}\right)\right)$$

$$\nabla(\nabla\cdot\mathbf{f}) = \sum_{i=1}^{3}\frac{1}{h_i}\frac{\partial}{\partial \xi_i}\left\{\frac{1}{h_1 h_2 h_3}\left[\frac{\partial f_1 h_2 h_3}{\partial \xi_1} + \frac{\partial f_2 h_1 h_3}{\partial \xi_2} + \frac{\partial f_3 h_1 h_2}{\partial \xi_3}\right]\right\}\delta_i$$

$$\nabla\times(\nabla\times\mathbf{f})=\frac{\boldsymbol{\delta}_1}{h_2h_3}\left\{\frac{\partial}{\partial\xi_2}\left[\frac{h_3}{h_1h_2}\left(\frac{f_2h_2}{\partial\xi_1}-\frac{f_1h_1}{\partial\xi_2}\right)\right]-\frac{\partial}{\partial\xi_3}\left[ach_2h_1h_3\left(\frac{f_1h_1}{\partial\xi_3}-\frac{f_3h_3}{\partial\xi_2}\right)\right]\right\}$$

$$+\frac{\boldsymbol{\delta}_2}{h_1h_3}\left\{\frac{\partial}{\partial\xi_3}\left[\frac{h_1}{h_2h_3}\left(\frac{\partial f_3h_3}{\partial\xi_2}-\frac{\partial f_2h_2}{\partial\xi_3}\right)\right]-\frac{\partial}{\partial\xi_1}\left[\frac{h_3}{h_1h_2}left\left(\frac{\partial f_2h_2}{\partial\xi_3}-\frac{\partial f_1h_1}{\partial\xi_2}\right)\right]\right\}$$

$$+\frac{\boldsymbol{\delta}_3}{h_1h_2}\left\{\frac{\partial}{\partial\xi_1}\left[\frac{h_2}{h_1h_3}\left(\frac{\partial f_1h_1}{\partial\xi_3}-\frac{\partial f_3h_3}{\partial\xi_1}\right)\right]-\frac{\partial}{\partial\xi_2}\left[\frac{h_1}{h_2h_3}\left(\frac{\partial f_3h_3}{\partial\xi_2}-\frac{\partial f_2h_2}{\partial\xi_3}\right)\right]\right\}$$

$$\nabla^2\mathbf{f}=\nabla(\nabla\cdot\mathbf{f})-\nabla\times(\nabla\times\mathbf{f})$$

In the following discussion, we list the coordinate transformations followed by the scaling factors for a variety of coordinate systems.

2.5.3.3 Circular Cylindrical Coordinates

$$\xi_1=r,\ \ \xi_2=\theta,\ \ \xi_3=z,\ \ x=r\cos\theta,\ \ y=r\cos\theta,\ \ z=z$$

$$h_1=1\qquad h_2=r\qquad h_3=1\tag{2.65}$$

$$\nabla\Phi=\frac{\partial\Phi}{\partial r}\boldsymbol{\delta}_r+\frac{1}{r}\frac{\partial\Phi}{\partial\theta}\boldsymbol{\delta}_\theta+\frac{\partial\Phi}{\partial z}\boldsymbol{\delta}_z$$

$$\nabla\cdot\mathbf{f}=\frac{1}{r}\frac{\partial rf_r}{\partial r}+\frac{1}{r}\frac{\partial f_\theta}{\partial\theta}+\frac{\partial f_z}{\partial z}$$

$$\nabla\times\mathbf{f}=\frac{1}{r}\begin{vmatrix}\boldsymbol{\delta}_r & r\boldsymbol{\delta}_\theta & \boldsymbol{\delta}_z\\ \frac{\partial}{\partial r} & \frac{\partial}{\partial\theta} & \frac{\partial}{\partial z}\\ f_r & f_\theta & f_z\end{vmatrix}$$

$$\nabla^2=\frac{1}{r}\frac{\partial}{\partial r}\left(r\frac{\partial}{\partial r}\right)+\frac{1}{r^2}\frac{\partial^2}{\partial\theta^2}+\frac{\partial^2}{\partial z^2}$$

2.5.3.4 Spherical Coordinates

$$\xi_1=r,\ \ \xi_2=\theta,\ \ \xi_3=\phi,\ \ x=r\sin\theta\cos\phi,\ \ y=r\sin\theta\sin\phi,\ \ z=r\cos\theta$$

$$h_1=1\qquad h_2=r\qquad h_3=r\sin\theta\tag{2.66}$$

$$\nabla \Phi = \frac{\partial \Phi}{\partial r}\boldsymbol{\delta}_r + \frac{1}{r}\frac{\partial \Phi}{\partial \theta}\boldsymbol{\delta}_\theta + \frac{1}{r\sin\theta}\frac{\partial \Phi}{\partial \phi}\boldsymbol{\delta}_\phi$$

$$\nabla \cdot \mathbf{f} = \frac{1}{r^2}\frac{\partial}{\partial r}(r^2 f_r) + \frac{1}{r\sin\theta}\frac{\partial}{\partial \theta}(f_\theta \sin\theta) + \frac{1}{r\sin\theta}\frac{\partial f_\phi}{\partial \phi}$$

$$\nabla \times \mathbf{f} = \frac{1}{r^2\sin\theta}\begin{vmatrix} \boldsymbol{\delta}_r & r\boldsymbol{\delta}_\theta & r\sin\theta\boldsymbol{\delta}_\phi \\ \frac{\partial}{\partial r} & \frac{\partial}{\partial \theta} & \frac{\partial}{\partial \phi} \\ f_r & rf_\theta & r\sin\theta f_\phi \end{vmatrix}$$

$$\nabla^2 = \frac{1}{r^2}\frac{\partial}{\partial r}\left(r^2\frac{\partial}{\partial r}\right) + \frac{1}{r^2\sin\theta}\frac{\partial}{\partial \theta}\left(\sin\theta\frac{\partial}{\partial \theta}\right) + \frac{1}{r^2\sin^2\theta}\frac{\partial^2}{\partial \phi^2}$$

2.5.3.5 Elliptic Cylindrical Coordinates

$$x = a\cosh\xi_1 \cos_2, \quad y = a\sinh\xi_1 \sin\xi_2$$

where ξ_1 = constant is a confocal ellipse described by

$$\left(\frac{x}{a\cosh\xi_1}\right)^2 + \left(\frac{y}{a\sinh\xi_1}\right)^2 = 1$$

and ξ_2 = constant is a confocal hyperbola described by

$$\left(\frac{x}{a\cos\xi_2}\right)^2 - \left(\frac{y}{a\sin\xi_2}\right)^2 = 1$$

$$h_1 = h_2 = a\sqrt{\cosh^2\xi_1 - \cos^2\xi_2} \qquad h_3 = 1$$

2.5.3.6 Prolate Spheroidal Coordinates

$$x = a\cosh\xi_1\cos\xi_2, \quad y = a\sinh\xi_1\sin\xi_2\sin\xi_3, \quad z = a\sinh\xi_1\sin\xi_2\cos\xi_3$$

where ξ_1 = constant is a prolate spheroid described by

$$\left(\frac{x}{a\cosh\xi_1}\right)^2 + \left(\frac{y}{a\sinh\xi_1}\right)^2 + \left(\frac{z}{a\sinh\xi_1}\right)^2 = 1$$

ξ_2 = constant is a hyperboloid two sheets described by

$$\left(\frac{x}{a\cos\xi_2}\right)^2+\left(\frac{y}{a\sin\xi_2}\right)^2-\left(\frac{z}{a\sin\xi_2}\right)^2=1$$

and ξ_3 = constant is a half-plane described by

$$\tan\xi_3=\frac{y}{z}$$

$$h_1=h_2=a\sqrt{\sinh^2\xi_1+\sin^2\xi_2}\quad h_3=a\sinh\xi_1\sin\xi_2$$

2.5.3.7 Oblate Spheroidal Coordinates

$$x=a\cosh\xi_1\sin\xi_2\sin\xi_3,\;\; y=a\sinh\xi\cos\xi_2,\;\; z=a\cosh\xi_1\sin\xi_2\cos\xi_3$$

where ξ_1 = constant is an oblate spheroid described by

$$\left(\frac{x}{a\cosh\xi_1}\right)^2+\left(\frac{y}{a\sinh\xi_1}\right)^2+\left(\frac{z}{a\cosh\xi_1}\right)^2=1$$

ξ_2 = constant is a hyperboloid one sheet described by

$$\left(\frac{x}{a\sin\xi_2}\right)^2-\left(\frac{y}{a\cos\xi_2}\right)^2+\left(\frac{z}{a\sin\xi_2}\right)^2=1$$

and ξ_3 = constant is a half plane described by

$$\tan\xi_3=\frac{x}{z}$$

$$h_1=h_2=a\sqrt{\cosh^2\xi_1-\sin^2\xi_2}\quad h_3=a\cosh\xi_1\sin\xi_2$$

2.5.3.8 Parabolic Cylinder Coordinates

$$x=\frac{1}{2}(\xi_2^2-\xi_1^2),\quad y=\xi_1\xi_2$$

where ξ_1 = constant is a parabolic cylinder described by

$$y^2=\xi_1^2(\xi_1^2+2x)$$

and ξ_2 = constant is a parabolic cylinder described by

$$y^2 = \xi_1^2(\xi_1^2 - 2x)$$

$$h_1 = h_2 = \sqrt{\xi_1^2 + \xi_2^2} \quad h_3 = 1$$

2.5.3.9 Parabolic Coordinates

$$x = \frac{1}{2}(\xi_2^2 - \xi_1^2), \;\; y = \xi_1\xi_2 \sin\xi_3, \;\; z = \xi_1\xi_2 \cos\xi_3$$

where ξ_1 = constant is a paraboloid of revolution described by

$$y^2 + z^2 = \xi_1^2(\xi_1^2 + 2x)$$

and ξ_2 = constant is a paraboloid of revolution described by

$$y^2 + z^2 = \xi_1^2(\xi_1^2 - 2x)$$

$$\tan\xi_3 = \frac{y}{z}$$

$$h_1 = h_2 = \sqrt{\xi_1^2 + \xi_2^2} \quad h_3 = \xi_1\xi_2$$

2.5.3.10 Conical Coordinates

$$x^2 = \left(\frac{\xi_1\xi_2\xi_3}{bc}\right)^2 \quad y^2 = \frac{\xi_1^2(b^2 - \xi_2^2)(\xi_3^2 - b^2)}{b^2(c^2 - b^2)} \quad z^2 = \frac{\xi_1^2(c^2 - \xi_2^2)(c^2 - \xi_3^2)}{b^2(c^2 - b^2)}$$

$$0 < \xi_2^2 < b^2 < \xi_3^2 < c^2$$

where ξ_1 = constant is a sphere described by

$$x^2 + y^2 + z^2 = r^2 = \xi_1^2$$

ξ_2 = constant is an elliptic cone described by

$$\frac{x^2}{\xi_2^2} - \frac{y^2}{b^2 - \xi_2^2} - \frac{z^2}{c^2 - \xi_2^2} = 0$$

and ξ_3 = constant is an elliptic cone described by

$$\frac{x^2}{\xi_3^2} - \frac{y^2}{b^2 - \xi_3^2} - \frac{z^2}{c^2 - \xi_3^2} = 0$$

$$h_1 = 1 \quad h_2 = \sqrt{\frac{\xi_1^2(\xi_3^2 - \xi_2^2)}{(b^2 - \xi_2^2)(c^2 - \xi_2^2)}}, \quad h_3 = \sqrt{\frac{\xi_1^2(\xi_3^2 - \xi_2^2)}{(\xi_2^2 - b^2)(c^2 - \xi_3^2)}}$$

2.5.3.11 Ellipsoidal Coordinates

$$x^2 = \left(\frac{\xi_1\xi_2\xi_3}{bc}\right)^2 \quad y^2 = \frac{(\xi_1^2 - a^2)(\xi_2^2 - a^2)(a^2 - \xi_3^2)}{a^2(b^2 - a^2)} \quad z^2 = \frac{(\xi_1^2 - b^2)(b^2 - \xi_2^2)(b^2 - \xi_3^2)}{b^2(b^2 - a^2)}$$

$$0 \le \xi_3^2 < a^2 < \xi_2^2 < b^2 < \xi_1^2 < \infty$$

where ξ_1 = constant is an ellipsoid described by

$$\left(\frac{x}{\xi_1}\right)^2 + \frac{y^2}{\xi_1^2 - a^2} - \frac{z^2}{\xi_1^2 - b^2} = 1$$

ξ_2 = constant is a hyperbola one sheet described by

$$\left(\frac{x}{\xi_2}\right)^2 + \frac{y^2}{\xi_2^2 - a^2} - \frac{z^2}{b^2 - \xi_2^2} = 1$$

ξ_3 = constant is a hyperbola two sheets described by

$$\left(\frac{x}{\xi_3}\right)^2 - \frac{y^2}{a^2 - \xi_3^2} - \frac{z^2}{b^2 - \xi_3^2} = 1$$

$$h_1 = \left[\frac{(\xi_1^2 - \xi_2^2)(\xi_1^2 - \xi_3^2)}{(\xi_1^2 - a^2)(\xi_1^2 - b^2)}\right]^{1/2} \quad h_2 = \left[\frac{(\xi_1^2 - \xi_3^2)(\xi_1^2 - \xi_2^2)}{(\xi_2^2 - a^2)(b^2 - \xi_2^2)}\right]^{1/2} \quad h_3 = \left[\frac{(\xi_1^2 - \xi_3^2)(\xi_2^2 - \xi_3^2)}{(a^2 - \xi_3^2)(b^2 - \xi_3^2)}\right]^{1/2}$$

2.5.3.12 Paraboloidal Coordinates

$$x^2 = 4\frac{(\xi_2 - a)}{a - b}(a - \xi_1)(a - \xi_3), \quad y^2 = 4\frac{(\xi_2 - b)}{a - b}(b - \xi_1)(\xi_2 - b), \quad z = \xi_1 + \xi_2 + \xi_3 - a - b$$

$$0 < \xi_1 < b < \xi_3 < a < \xi_3$$

where ξ_1 = constant is an elliptic paraboloid described by

$$\frac{x^2}{a - \xi_1} + \frac{y^2}{b - \xi_1} = 4(z - \xi_1)$$

ξ_2 = constant is an elliptic paraboloid described by

$$\frac{x^2}{a - \xi_2} + \frac{y^2}{b - \xi_2} = 4(z - \xi_2)$$

ξ_3 = constant is a hyperbolic paraboloid described by

$$\frac{x^2}{a-\xi_3}-\frac{y^2}{\xi_3-b}=4(z-\xi_3)$$

$$h_1=\left[\frac{(\xi_2-\xi_1)(\xi_2-\xi_3)}{(\xi_2-a)(\xi_2-b)}\right]^{1/2}\quad h_2=\left[\frac{(\xi_2-\xi_1)(\xi_3-\xi_1)}{(a-\xi_1)(b-\xi_1)}\right]^{1/2}\quad h_3=\left[\frac{(\xi_3-\xi_1)(\xi_2-\xi_1)}{(a-\xi_3)(\xi_3-b)}\right]^{1/2}$$

2.5.3.13 Bispherical Coordinates

$$x=a\xi_3\frac{\sqrt{1-\xi_2^2}}{\xi_1-\xi_2};\quad y=a\frac{\sqrt{(1-\xi_2^2)(1-\xi_3^2)}}{\xi_1-\xi_2};\quad z=a\frac{\sqrt{\xi_1^2-1}}{\xi_1-\xi_2}$$

$$h_1=\frac{a}{(\xi_1-\xi_2)\sqrt{\xi_1^2-1}};\quad h_2=\frac{a}{(\xi_1-\xi_2)\sqrt{1-\xi_2^2}};\quad h_3=\frac{a}{\xi_1-\xi_2}\sqrt{\frac{1-\xi_2^2}{1-\xi_3^2}}$$

2.5.3.14 Toroidal Coordinates

$$x=a\frac{\sqrt{\xi_1^2-1}}{\xi_1-\xi_2};\quad y=a\frac{\sqrt{(\xi_1^2-1)(1-\xi_3^2)}}{\xi_1-\xi_2};\quad z=a\frac{\sqrt{1-\xi_2^2}}{\xi_1-\xi_2}$$

$$h_1=\frac{a}{(\xi_1-\xi_2)\sqrt{\xi_1^2-1}};\quad h_2=\frac{a}{(\xi_1-\xi_2)\sqrt{1-\xi_2^2}};\quad h_3=\frac{a}{\xi_1-\xi_2}\sqrt{\frac{\xi_2^2-1}{1-\xi_3^2}}$$

2.5.4 Vector Integral Theorems

Let V be a volume bounded by a closed surface S, and let $\mathbf{f}$ be a continuously differentiable vector field in V and S. If $d\mathbf{s}$ is an outward normal vector to the differential area, then we have the following equations as per various useful theorems.

Gauss's divergence theorem:

$$\iiint_V \nabla\cdot\mathbf{f}dv=\iiint_S \mathbf{f}\cdot d\mathbf{s}$$

Gradient theorem:

$$\iiint_V \nabla\mathbf{f}dv=\iint_S \mathbf{f}d\mathbf{s}$$

Curl theorem:

$$\iiint_V \nabla\times\mathbf{f}dv=-\iint_S \mathbf{f}\times d\mathbf{s}$$

Stokes's theorem: Let S be a surface bounded by a closed curve C and $d\mathbf{r}$ be the tangent vector. Then

$$\iint_S (\nabla \times \mathbf{f}) \cdot ds = \int_c \mathbf{f} \cdot dr$$

Generalized form of Gauss's divergence theorem:

$$\iiint_V (\mathbf{a} \cdot \nabla)\mathbf{f} + \mathbf{f}(\nabla \cdot \mathbf{a}) dv = \iint_S \mathbf{f}(\mathbf{a} \cdot d\mathbf{s})$$

Green's identities:

$$\iiint_V [\nabla\psi \cdot \nabla\phi + \psi\nabla^2\phi] dv = \iint_S \psi\nabla\phi \cdot d\mathbf{s}$$

$$\iiint_V [\psi\nabla^2\phi - \phi\nabla^2\psi] dv = \iint_S [\psi\nabla\phi - \phi\nabla\psi] \cdot d\mathbf{s}$$

Green's theorem: Let R be a region in a plane bounded by a closed curve C and P, and let Q be any two continuously differentiable functions in R and on C. Then

$$\iint_R \left[\frac{\partial Q}{\partial \xi_1} - \frac{\partial P}{\partial \xi_2} \right] d\xi_1 d\xi_2 = \oint_l [Q d\xi_2 + P d\xi_1]$$

Reynolds's transport theorem: Let f be a continuous function of space and time defined throughout the volume $V(t)$ bounded by a closed surface $S(t)$ moving with velocity $\mathbf{v}$. Then

$$\frac{D}{Dt} \iiint_{V(t)} f dv = \iiint_{V(t)} \frac{\partial f}{\partial t} dv + \iint_{S(t)} f\mathbf{v} \cdot d\mathbf{s} = \iiint_{V(t)} \left(\frac{Df}{Dt} + f\nabla \cdot \mathbf{v} \right) dv$$

where

$$\frac{D}{Dt} \equiv \frac{\partial}{\partial t} + \mathbf{v} \cdot \nabla$$

2.5.5 Gradients of Sum and Product

We list here some of the important formulae involving the gradients of the sum and the product:

$$\nabla(\phi + \psi) = \nabla\phi + \nabla\psi$$

$$(\mathbf{a} \cdot \nabla)(\mathbf{f} + \mathbf{g}) = (\mathbf{a} \cdot \nabla)\mathbf{f} + (\mathbf{a} \cdot \nabla)\mathbf{g}$$

$$\nabla \cdot (\mathbf{f} + \mathbf{g}) = \nabla \cdot \mathbf{f} + \nabla \cdot \mathbf{g}$$

$$\nabla \times (\mathbf{f} + \mathbf{g}) = \nabla \times \mathbf{f} + \nabla \times \mathbf{g}$$

$$\nabla(\phi\psi) = \psi\nabla\phi + \phi\nabla\psi$$

$$\nabla(\mathbf{f}\cdot\mathbf{g}) = (\mathbf{f}\cdot\nabla)\mathbf{g} + (\mathbf{g}\cdot\nabla)\mathbf{f} + \mathbf{f}\times(\nabla\times\mathbf{g}) + \mathbf{g}\times(\nabla\times\mathbf{f})$$

$$\nabla\cdot(\phi\cdot\mathbf{f}) = \phi(\nabla\cdot\mathbf{f}) + \mathbf{f}\cdot\nabla\phi$$

$$(\mathbf{a}\cdot\nabla)(\phi\mathbf{f}) = \phi[(\mathbf{a}\cdot\nabla)\mathbf{f}] + \mathbf{f}[(\mathbf{a}\cdot\nabla)\phi]$$

$$(\mathbf{a}\cdot\nabla)(\mathbf{f}\times\mathbf{g}) = \mathbf{f}\times[(\mathbf{a}\cdot\nabla)\mathbf{g}] + [(\mathbf{a}\cdot\nabla)\mathbf{f}]\times\mathbf{g}$$

$$\nabla\cdot(\phi\mathbf{f}) = \mathbf{f}\cdot\nabla\phi + \phi\nabla\cdot\mathbf{f}$$

$$\nabla\cdot(\mathbf{f}\times\mathbf{g}) = \mathbf{g}\cdot(\nabla\times\mathbf{f}) - \mathbf{f}\cdot(\nabla\times\mathbf{g})$$

$$\nabla\times(\phi\mathbf{f}) = \nabla\phi\times\mathbf{f} + \phi\nabla\times\mathbf{f}$$

$$\nabla\times(\mathbf{f}\times\mathbf{g}) = (\mathbf{g}\cdot\nabla)\mathbf{f} - (\mathbf{f}\cdot\nabla)\mathbf{g} + \mathbf{f}\nabla\cdot\mathbf{g} - \mathbf{g}\nabla\cdot\mathbf{f}$$

2.6 DIMENSIONAL ANALYSIS

Dimensional homogeneity is fundamental to equations relating variables in the description of natural processes. The recognition of this basic attribute is the substance of dimensional analysis, which results in the reduction of relevant parameters to the essential minimum. Physical quantities comprise combinations of one or more basic dimensions. Table 2.2 shows some commonly used physical quantities in engineering expressed in terms of basic dimensions (mass, M; length, L; time, T; temperature, θ).

2.6.1 Theory of Dimensional Analysis

Consider a specific process that involves n physical quantities comprising m basic dimensions among them. The dimension of each physical quantity is defined as the product of each of the basic dimensions raised to an appropriate exponent. For example, velocity can be expressed as LT^{-1}. Each physical quantity is then viewed as a vector of elements representing the respective exponents. Thus in the *MLT* system involving mass (M)-length (L)-time (T) as basic dimensions, velocity would be represented by the row vector [0 1 −1]. By lining up the vectors representing the different physical quantities (in columns), we obtain the *dimensional matrix*. A dimensionless group is a multiplicative combination of physical quantities with no net dimension and has the zero vector as its representative. Thus the formation of a dimensionless group can be identified with expressing the zero vector as a linear combination of vectors representing physical quantities in the group. From linear algebra, it follows that the number of independent dimensionless groups that can be formed is $n - r$, where r is the rank of the dimensional matrix, which is known as Buckingham's π-theorem. If the basic dimensions are independent, then $r = m$. Once the dimensionless groups $\pi_1,\pi_2,\ldots,\pi_{n-r}$ are determined, the physical process is described abstractly by an equation of the form $f(\pi_1,\pi_2,\ldots,\pi_{n-r}) = 0$. A couple of examples follow.

TABLE 2.2
Dimensions of Commonly Used Physical Quantities in Engineering

Physical Quantity	Dimension
Mass	M
Length	L
Time	T
Density	ML^{-3}
Curvature	L^{-1}
Moment of inertia	ML^2
Momentum	MLT^{-1}
Viscosity	$M(LT)^{-1}$
Kinematic viscosity	L^2T^{-1}
Frequency	T^{-1}
Acceleration	LT^{-2}
Force	MLT^{-2}
Pressure	$M(LT^2)^{-1}$
Angular acceleration	T^{-2}
Surface tension	MT^{-2}
Energy, Torque	ML^2T^{-2}
Power	ML^2T^{-3}
Temperature	θ
Heat capacity per unit mass	$L^2(T^2\theta)^{-1}$
Heat capacity per unit volume	$M(T^2L\theta)^{-1}$
Temperature gradient	$(L\theta)^{-1}$
Conductivity	$ML(T^3\theta)^{-1}$

2.6.2 Applications of Dimensional Analysis

Example 2.3

Here we illustrate the use of dimensional analysis to determine the relationship between the drag force, F, on a smooth sphere and the affecting physical quantities, namely, the diameter of the sphere, D, the fluid velocity, V, density, ρ, and viscosity, μ. It is assumed that $f(D,V,F,\rho,\mu)=0$.

The dimensional matrix is formed as follows:

	D	V	F	ρ	μ
M	0	0	1	1	1
L	1	1	1	–3	–1
T	0	–1	–2	0	–1

To make the groups of all the physical quantities dimensionless, it is convenient to form the products as $D^{k_1}V^{k_2}F^{k_3}\rho^{k_4}\mu^{k_5}$. From the matrix, the following equations are formed:

$$k_3 + k_4 + k_5 = 0$$

$$k_1 + k_2 + k_3 - 3k_4 - k_5 = 0 \tag{2.67}$$

$$-k_2 - 2k_3 - k_5 = 0$$

According to Buckingham's π-theorem, there exist two dimensionless groups. Thus there are two linearly independent solutions to Equation (2.67), and these are $k_1 = k_2 = -2$, $k_3 = 1$, $k_4 = -1$, $k_5 = 0$ and $k_1 = k_2 = k_4 = 1$, $k_3 = 0$, $k_5 = -1$. The resulting dimensionless groups are given by

$$\pi_1 = \frac{F}{\rho V^2 D^2} \quad \pi_2 = \frac{VD\rho}{\mu}$$

Experimental data are, however, correlated as $C_D = (8/\pi)\pi_1$, known as the drag coefficient, while π_2 is the well-known Reynolds number.

Example 2.4

The objective of this example is to show the utility of dimensional analysis in the interpretation of experimental data. Bose and coworkers (Barenblett, 1996) performed experiments with various fluids, namely, water, chloroform, bromoform, and mercury. The fluids were allowed to flow through a pipe in the turbulent regime. The times τ required for the fluids of density ρ and viscosity μ to attain a certain specified total discharge (volume) of Q under an imposed pressure drop P were measured. A graph of log P as a function of log(1/τ) showed four separate curves representing four different fluids. The same data can be plotted in terms of the new dimensionless groups, showing the collapse of all the data on a single curve through dimensional analysis, as was first shown by Von Kármán (1957):

The dimensional matrix may be written as

	P	τ	Q	ρ	μ
M	1	0	0	1	1
L	–1	0	3	–3	–1
T	–2	1	0	0	–1

The dimensionless groups are formed using $P^{k_1}\tau^{k_2}Q^{k_3}\rho^{k_4}\mu^{k_5}$:

$$\begin{aligned} k_1 + k_4 + k_5 &= 0 \\ -k_1 + 3k_3 - 3k_4 - k_5 &= 0 \\ -2k_1 + k_2 - k_5 &= 0 \end{aligned} \tag{2.68}$$

The two linearly independent solutions are $k_1 = 0$, $k_2 = -1$, $k_3 = 2/3$, $k_4 = 1$, $k_5 = -1$ and $k_1 = k_2 = 1$, $k_5 = -1$, $k_3 = k_4 = 0$. The two dimensionless groups are

$$\frac{\tau P}{\mu} \quad \text{and} \quad \frac{\rho Q^{2/3}}{\tau\mu}$$

The functional relation is

$$f\left(\frac{\tau P}{\mu}, \frac{\rho Q^{2/3}}{\tau\mu}\right)$$

Rearranging,

$$P = \frac{\mu}{\tau} g\left(\frac{\rho Q^{2/3}}{\tau\mu}\right) \tag{2.69}$$

When the experimental data were plotted using $\log(\tau P/m)$ as a function of $\log(\rho Q^{2/3}/\tau\mu)$, a single curve was indeed obtained for all the fluids. Thus the functional relationship in Equation (2.69) can be seen to be verified experimentally.

2.7 ALGEBRAIC EQUATIONS

We present here the solution methods for algebraic equations that may further be classified into linear and nonlinear equations.

2.7.1 System of Linear Equations

The subject of linear equations is best described in terms of concepts associated with linear algebra and matrix theory. The reader is referred to Amundson (1966) for details. We present here only the basic definitions and results that are important for the solution of linear algebraic equations.

Consider m equations in n unknowns $x_1, x_2, \ldots, x_n$ given by

$$\begin{aligned} a_{11}x_1 + a_{12}x_2 + \cdots + a_{1n}, x_n &= b_1 \\ a_{21}x_1 + a_{22}x_2 + \cdots + a_{2n}x_n &= b_2 \\ &\vdots \\ a_{m1}x_1 + a_{m2}x_2 + \cdots + a_{mn}x_n &= b_m \end{aligned} \tag{2.70}$$

It can be compactly represented by vector-matrix notation as

$$\mathbf{Ax} = \mathbf{b} \tag{2.71}$$

where **A** is a rectangular matrix array of (known) coefficients, **x** is a column vector of the n unknowns, and **b** is a column vector of known constants, as shown below:

$$\mathbf{A} = \begin{bmatrix} a_{11} & a_{12} & \cdots & a_{1n} \\ a_{21} & a_{22} & \cdots & a_{2n} \\ \vdots & \vdots & \ddots & \vdots \\ a_{m1} & a_{m2} & \cdots & a_{mn} \end{bmatrix}, \mathbf{x} = \begin{bmatrix} x_1 \\ x_2 \\ \vdots \\ x_n \end{bmatrix}, \quad \text{and} \quad \mathbf{b} = \begin{bmatrix} b_1 \\ b_2 \\ \vdots \\ b_m \end{bmatrix} \tag{2.72}$$

When the number of equations is less than the number of unknowns ($m < n$), at least $m - n$ of the unknowns must be assumed arbitrarily in terms of which the remaining unknowns can be calculated. When $m = n$, the number of equations is equal to the number of unknowns, a situation generally viewed to be sufficient for solving for all the unknowns. However, this issue is connected with situations when solutions exist in general. When $m > n$, the number of equations exceeds the number of unknowns, raising concerns about the consistency of the set of equations. The question of when a set of equations can be solved for the unknowns regardless of the relative values of m and n is answered elegantly by matrix theory. A few preliminary definitions are necessary before the necessary and sufficient conditions for the existence of the solution to a set of algebraic equations can be understood.

Vectors: The collection of all vectors containing n elements satisfying basic axioms (see, for example, Ramkrishna and Amundson (1985)) is called a linear space denoted by $\Re^n$. The basic axioms define scalar multiplication, vector addition (from which evolves the concept of linear combination), and a null vector that has all elements zero. Thus a linear combination of vectors $\mathbf{x_i}$, $j = 1,2,\ldots,k,$ is expressed as the vector $\Sigma_{j=1}^{k}\alpha_j\mathbf{x_j}$, where the α_j's are numbers. If the α_j's are all zero, the linear combination gives the zero vector, 0. Linear spaces contain (linear) subspaces that are subsets in which linear combinations are contained within the set. Linear subspaces are also linear spaces.

Linear dependence: A set of vectors such as $\mathbf{x_i}$, $i = 1,2,\ldots,k$, is said to be linearly dependent if it is possible to find scalars not all zeroes such that the linear combination gives the zero vector. If this is not possible, the set is said to be linearly dependent. No vector in a linearly independent set can be expressed as a linear combination of the remaining vectors.

The maximum number of linearly independent vectors in a linear space or subspace is said to be the dimension of the space. Such a linearly independent set of vectors is said to be a *basis* for that space, by which it is meant that any arbitrary vector in the space can be expressed as a linear combination of the basis set.

Matrices: We consider the matrix **A** defined in Equation (2.72). If it has only one column ($n = 1$), it is the same as a column vector. If it has only one row, then it is a row vector. Thus vectors may be regarded as matrices themselves. The following properties are of interest.

Rank of a matrix: The rank of matrix **A** is the largest order of square array whose determinant is nonzero. Clearly, the rank of the matrix above cannot exceed the minimum of m and n. The definition of a determinant can be found in Amundson (1966). The matrix **A** may be regarded as a *transformation* of vectors in $\Re^n$ into a range of vectors, denoted $R(\mathbf{A})$, a subspace of $\Re^m$. The rank of **A** may also be seen to be the dimension of $R(\mathbf{A})$. When $m = n$, **A** is said to be a *square* matrix of order n. If its rank is less than n, it is said to be *singular*. Clearly, the determinant of the singular matrix is zero.

A square matrix that has only nonzero elements along its diagonal is called a diagonal matrix. If the diagonal matrix has all its diagonal elements equal to unity, it is called the identity matrix, denoted by **I**. The diagonal matrix **D** and the identity matrix **I** are shown below:

$$\mathbf{D} = \begin{bmatrix} d_{11} & 0 & \cdots & 0 \\ 0 & d_{22} & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & d_{nn} \end{bmatrix}, \quad \mathbf{I} = \begin{bmatrix} 1 & 0 & \cdots & 0 \\ 0 & 1 & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & 1 \end{bmatrix}$$

Matrix addition/subtraction: Two matrices **A** and **B** are said to be compatible for addition/subtraction if both the matrices have the same numbers of rows and columns. The addition/subtraction of two matrices is carried out elementwise and simply follows

$$\mathbf{C} = \mathbf{A} \pm \mathbf{B} \Rightarrow c_{ij} = a_{ij} \pm b_{ij} \;\; (i = 1, \ldots, n; \; j = 1, \ldots, n)$$

Matrix multiplication: Two matrices, **A** and **B**, are said to be conformable for multiplication in the order **AB** if **A** has the same number of columns as **B** has rows. The multiplication is defined by

$$\mathbf{C} = \mathbf{AB} \Rightarrow c_{ik} = \sum_{i=1}^{n} a_{ij} b_{jk}$$

Thus square matrices can always be multiplied in any order. Also, we have **IA** = **A** for any matrix **A**, which also implies that an identity matrix raised to any exponent also gives **I**. A nonsingular matrix has an *inverse* matrix, denoted by $\mathbf{A}^{-1}$, with the property $\mathbf{A}^{-1}\mathbf{A} = \mathbf{A}\mathbf{A}^{-1} = \mathbf{I}$.

LU *decomposition*: For a square matrix **A** of order *n,* given that the determinants of the matrices $\mathbf{A}_p$ ($p = 1,2,\ldots,n - 1$) formed by the elements at the intersection of the first p rows and columns of **A** are nonzeroes, then there exists a unique lower triangular matrix **L** and a unique upper triangular matrix **U** such that

$$\mathbf{A} = \mathbf{LU}$$

2.7.1.1 Solution of Linear Equations

We will first address the question of when the set of linear equations in Equation (2.71) has a solution. Homogeneous equations always have a solution. This is also evident from the fact that **x** = **0** is always a solution. Whether nontrivial solutions also exist depends on the rank of the matrix **A**. If r is the rank of the matrix **A**, then there are $(n - r)$ linearly independent solutions obtained by assuming arbitrary values for suitably selected $(n - r)$ variables and solving for the remaining r variables. One way to do this is as follows. Assume that the equations are so arranged that the rth-order upper left-hand matrix is nonsingular. Set *one* of the $(n - r)$ variables $x_{r+1}, x_{r+2}, \ldots x_n$ to be unity and all others equal to zero. Solve for the variables $x_1, x_2, \ldots x_r$. This generates one of the linearly independent solutions. The others can be generated similarly. Clearly, the nontrivial solution exists when $n = r$.

Equation (2.71) has a unique solution when its homogeneous version has only the zero solution. Since the latter occurs only when $r = n$, we conclude that, for the case of $m = n$, i.e., the number of equations is the same as the number of unknowns, a unique solution occurs regardless of **b** when **A** is nonsingular. When $m \neq n$ and $r = n$, a unique solution exists for **Ax** = **b** as long as the ranks of matrices **A** and [**A**|**b**] are the same, where the *augmented* matrix [**A**|**b**] is defined by

$$[\mathbf{A} \,|\, \mathbf{b}] = \begin{bmatrix} a_{11} & a_{12} & \cdots & a_{1n} & b_1 \\ a_{21} & a_{22} & \cdots & a_{2n} & b_2 \\ \vdots & & & & \\ a_{m1} & a_{m2} & \cdots & a_{mn} & b_m \end{bmatrix}$$

For $r < n$, the solution for **Ax** = **b** exists when **b** satisfies the condition

$$\mathbf{b}^{\mathbf{T}}\mathbf{z_j} = 0 \quad j = 1, 2, \ldots, (m - r) \tag{2.73}$$

where $\mathbf{z_j}$ are the $(m - r)$ linearly independent solutions of the homogeneous equation $\mathbf{b^T z_j = 0}$. In this case, the solution to the inhomogeneous Equation (2.71) is not unique, since a particular solution to the inhomogeneous equation plus an arbitrary nontrivial solution of its homogeneous version is also a solution to the inhomogeneous Equation (2.71).

It should be noted that the calculation of an inverse matrix requires considerable computational time, and hence various methods have been proposed for the solution of a set of linear equations that take advantage of the structure of the matrix **A**. The methods may be divided into two classes, namely, direct and iterative methods.

Cramer's rule, LU decomposition, and Gauss elimination methods form the class of *direct methods*, whereas Jacobi, Gauss-Seidel, and successive overrelaxation methods constitute the class of *iterative methods*. Among the direct methods, the Gauss elimination method, especially its partial pivoting variant, is the preferred method for large problems when sufficient computer memory is available for matrix storage. It relies on the transformation of the coefficient matrix into an upper triangular matrix problem and solving it by back substitution.

Iterative methods are sometimes used due to ease of computer coding and lesser computational storage requirements. The Jacobi method is the simplest iterative method but has slower convergence in comparison with the Gauss-Seidel method. In the Gauss-Seidel method, the $(k+1)$th iteration of the value of the unknown x_i is given by

$$x_i^{(k+1)} = \left(-\sum_{j=1}^{i-1} a_{ij} x_j^{(k+1)} - \sum_{j=i+1}^{i-1} a_{ij} x_j^{(k)} + b_i \right) \Bigg/ a_{ii}, \quad i = 1, 2, \ldots, m$$

The successive overrelaxation method is a variant of the Gauss-Seidel method, wherein the $(k+1)$th iteration is a weighted average of the Gauss Seidel kth and $(k+1)$th estimates x_i and $x_i^{(k+1)}$, respectively. The reader is referred to Jensen and Jeffreys (1977) for a detailed account on the matrices and solution methods.

Generalized inverse (pseudoinverse): To obtain an approximate solution of an overdetermined system of linear equations, i.e., when the number of equations is greater than the number of unknowns $(m > n)$, a vector $\mathbf{x}$ is sought to minimize the square of residuals, $\mathbf{r}^T\mathbf{r}$, where

$$\mathbf{r} = \mathbf{Ax} - \mathbf{b}$$

The condition for minimization can be written as

$$d\mathbf{r}^T\mathbf{r} = 0$$

than implies

$$\mathbf{A^T A x} = \mathbf{A^T b}$$

The matrix $\mathbf{B} = \mathbf{A^T A}$ is symmetric and positive definite. If its inverse exists, then the least square solution is given by

$$\mathrm{x} = \mathbf{B^{-1} A^T b} = (\mathbf{A^T A})^{-1}\mathbf{A^T b}$$

The matrix $(\mathbf{A}^T\mathbf{A})^{-1}\mathbf{A}^T$ is called a pseudoinverse of **A**, which becomes the actual inverse $\mathbf{A}^{-1}$ for $m = n$.

2.7.2 Nonlinear Equations

In what follows, we discuss the solution methods for polynomial equations, followed by the most commonly used iterative solution methods.

2.7.2.1 Polynomial Equations

A polynomial of degree n, $P_n(x)$, is represented as

$$P_n(x) = \sum_{k=0}^{n} a_k x^k = a_n x^n + a_{n-1}x^{n-1} + \cdots + a_1 x + a_0$$

where $a_n \neq 0$. A corresponding polynomial equation is written as

$$\sum_{k=0}^{n} a_k x^k = a_n x^n + a_{n-1}x^{n-1} + \cdots + a_1 x + a_0 = 0$$

A number r is called a root of the polynomial if

$$P_n(r) = 0$$

The fundamental theorem of algebra states that a polynomial of degree n has n number of roots, although some of the roots may be complex numbers. If a root of a polynomial of degree n is known to be, say r, then a polynomial of degree $n - 1$ is given by

$$P_{n-1}(x) = \frac{P_n(x)}{x - r}$$

In what follows, we provide a list of some of the important rules and formulae pertaining to polynomial equations.

Routh-Hurwitz criterion: The number of roots with positive real parts of a real polynomial equation is the number of sign changes in the following sequence:

$$\{D_1,\ D_1D_2,\ D_2D_3,\ \ldots,\ D_{n-1}D_{n-2},\ a_0\}$$

where

$$D_1 = a_1 D_2 = \begin{vmatrix} a_1 & a_0 \\ a_3 & a_2 \end{vmatrix} \quad D_3 = \begin{vmatrix} a_1 & a_0 & 0 \\ a_3 & a_2 & a_1 \\ a_5 & a_4 & a_3 \end{vmatrix} \quad D_4 = \begin{vmatrix} a_1 & a_0 & 0 & 0 \\ a_3 & a_2 & a_1 & a_0 \\ a_5 & a_4 & a_3 & a_2 \\ a_7 & a_6 & a_5 & a_4 \end{vmatrix} \cdots$$

$$D_n = \begin{vmatrix} a_1 & a_0 & 0 & 0 & \cdots & 0 \\ a_3 & a_2 & a_1 & 0 & \cdots & 0 \\ \cdots & \cdots & \cdots & \cdots & \cdots & \cdots \\ a_{2n-1} & a_{2n-2} & a_{2n-3} & a_{2n-4} & \cdots & a_n \end{vmatrix}$$

Descartes's rule of signs: The number of positive real roots of a real polynomial equation is either equal to the number of sign changes in the sequence of coefficients $\{a_n, a_{n-1}, \ldots, a_0\}$, or it is less by an even number. Application of this rule to $P(-x)$ gives the number of negative real roots.

Budan's rule of signs: The number of zeroes in the interval (a,b) is either equal to $V(a) - V(b)$ or less by an even number, where $V(x)$ is the number of sign changes in the sequence

$$\{P_n(x), P_n'(x), P_n''(x), \ldots, P_n^n(x)\}$$

Bounds on real roots: If the first k coefficients $(a_n, a_{n-1}, \ldots, a_{k-1})$ of a real polynomial are nonnegative, then all the real roots are less than U where

$$U = 1 + \sqrt[k]{\frac{M}{a_n}}$$

$$M = \max_{0 \le j \le k} |a_j|, \quad a_j < 0$$

Application of this bound to $P_n(-x)$ gives the lower bound L on the roots. Thus, all the real roots of a real polynomial are located in the interval (L,U).

Polynomials of degree $n \le 4$ can be solved by the following formulae.

Quadratic formula: The roots of a polynomial of degree $n = 2$ are given by the quadratic formula

$$x_1 = \frac{-a_1 + \sqrt{D}}{2a_2}$$

$$x_2 = \frac{-a_1 - \sqrt{D}}{2a_2}$$

where

$$D = a_1^2 - 4a_2 a_0$$

If $D > 0$, then there are two distinct real roots. If $D < 0$, then there are two distinct complex roots. If $D = 0$, then the repeated roots are given by

$$x_1 = x_2 = \frac{-a_1}{2a_2}$$

Cardano's formula: The roots of a polynomial of degree $n = 3$ are given by the cubic formula. The number of real roots of a cubic equation depends on the sign of the polynomial discriminant

$$D = \left(\frac{p}{3}\right)^3 + \left(\frac{q}{2}\right)^2$$

where

$$p = \left(\frac{3a_1 - a_2^2}{3}\right)$$

and

$$q = \left(\frac{9a_1 - a_2 27a_0 - 2a_2^3}{27}\right)$$

If $D > 0$, there is one real root and two complex roots.
If $D < 0$, there are three real roots.
If $D = 0$, there is one real root and a real double root or a triple real root.

For $D \geq 0$, the roots are given by

$$x_1 = u_1 + u_2 - \frac{a_2}{3a_3} \tag{2.74}$$

$$x_2 = m_1u_1 + m_2u_2 - \frac{a_2}{3a_3} \tag{2.75}$$

$$x_3 = m_2u_1 + m_1u_2 - \frac{a_2}{3a_3} \tag{2.76}$$

where

$$u_{1,2} = \sqrt[3]{\left(-\frac{q}{2} \pm \sqrt{D}\right)} \quad m_{1,2} = \frac{1}{2}\left(-1 \pm i\sqrt{3}\right)$$

For $D < 0$, let

$$\rho = \sqrt{-\left(\frac{p}{3}\right)^3} \quad \text{and} \quad \cos\phi = -\frac{q}{2\rho}$$

Then the roots are given by

$$x_1 = 2\sqrt[3]{\rho}\cos\left(\frac{\phi}{3}\right) - \frac{a_2}{3a_3} \tag{2.77}$$

$$x_2 = 2\sqrt[3]{\rho}\cos\left(\frac{\phi}{3} + \frac{2\pi}{3}\right) - \frac{a_2}{3a_3} \tag{2.78}$$

$$x_3 = 2\sqrt[3]{\rho}\cos\left(\frac{\phi}{3} + \frac{4\pi}{3}\right) - \frac{a_2}{3a_3} \tag{2.79}$$

Quartic formula: For $n = 4$, the roots are obtained by solving the cubic resolvent equation (Harris and Stocker, 1998):

$$8y^3 - 4\frac{a_2}{a_4}y^2 + \frac{2a_3a_1 - 8a_0}{a_4}y + 4\frac{a_2a_0 - a_3^2a_0 - a_1^2}{a_4} = 0$$

The roots to the quartic equation are obtained by solving

$$x^2 + \frac{a_3 + a_4D}{2a_4} + \left(y + \frac{a_3y - a_1}{a_4D}\right) = 0$$

where

$$D = \pm\sqrt{8y + \frac{a_3^2}{a_4} - 4\frac{a_2}{a_4}}$$

If $a_3 = a_1 = 0$, then the quartic equation is reduced to a quadratic equation by substituting $y = x^2$.

2.7.2.2 Numerical Solutions of Nonlinear Equations

We discuss here the use of two most prominent iterative methods of solutions of nonlinear equations through illustrations that are relevant to chemical engineers.

2.7.2.2.1 Successive Substitution

The steady-state mass and energy balances in a CSTR are given by Equations (2.20) and (2.21), respectively, which are reproduced here for ready reference:

$$F(C_f - C) - Vr(C,T) = 0 \tag{2.80}$$

$$\rho F C_p(T_f - T) - UA(T - T_c) + (-\Delta H)Vr(C,T) = 0 \tag{2.81}$$

These equations are written in nondimensionalized form as

$$1 - u - DaR(u,u) = 0 \tag{2.82}$$

$$1 - v + \beta DaR(u,u) = 0 \tag{2.83}$$

with the following dimensionless parameters (Morbidelli et al., 1986):

$$u = \frac{C}{C_f} \quad v = \frac{T}{T_m} \quad Da = \frac{Vr(C_f,T_m)}{FC_f} \quad \delta = \frac{UA}{F\rho C_p}$$

$$\beta = \frac{(-\Delta H)C_f}{\rho C_p T_m(1+\delta)} \quad R = \frac{r(C,T)}{r(C_f,T_m)} \quad T_m = \frac{T_f + \delta T_c}{1+\delta}$$

These can be combined by eliminating the reaction term to express the relationship between the dimensionless concentration and the dimensionless temperature as

$$u = \frac{1+\beta - v}{\beta} \tag{2.84}$$

to give the dimensionless energy equation,

$$1 - v + \beta DaR\left(\frac{1+\beta-v}{v}, v\right) = 0 \tag{2.85}$$

The equation is rewritten as

$$v = 1 + \beta DaR\left(\frac{1+\beta-v}{v},\right) \tag{2.86}$$

so that it exhibits the form $x = g(x)$. This equation is solved by the following nonlinear recurrence equation (e.g., Reklaitis, 1983):

$$x_{n+1} = g(x_n) \tag{2.87}$$

Given an initial guess x_0, $g(x_0)$ is evaluated to give x_1. The process is repeated to obtain a sequence $\{x_0, x_1, \ldots, \}$ that may converge to the solution. The condition for the convergence of a sequence is given by

$$\left|g'(x)\right|_{x=x_\infty} < 1$$

where x_∞ is the solution. Thus, the condition ensures that the iteration converges to a stable solution.

In general, the system of n equations in n unknowns is written in vector form as

$$\mathbf{f}(\mathrm{x}) = \mathbf{0} \tag{2.88}$$

which can be solved by iterating the following equation:

$$\mathbf{x}_{n+1} = \mathbf{g}(\mathbf{x}_n)$$

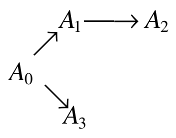
The criterion for the convergence of such a sequence is that the absolute eigenvalues of the following Jacobian matrix evaluated at the root are less than 1:

$$\mathbf{Jg}(\mathbf{x})\Big|_{\mathbf{x}=\mathbf{x}_\infty} = \begin{bmatrix} \dfrac{\partial g_1}{\partial x_1} & \dfrac{\partial g_1}{\partial x_2} & \cdots & \dfrac{\partial g_1}{\partial x_n} \\ \dfrac{\partial g_2}{\partial x_1} & \vdots & \cdots & \dfrac{\partial g_2}{\partial x_n} \\ \dfrac{\partial g_n}{\partial x_1} & \dfrac{\partial g_n}{\partial x_2} & \cdots & \dfrac{\partial g_n}{\partial x_n} \end{bmatrix}_{\mathbf{x}=\mathbf{x}_\infty}$$

The convergence condition stated above is difficult to ascertain, since it requires eigenvalues of the Jacobian to be evaluated at the root. A relatively loose condition is to ensure that the eigenvalues of the Jacobian are less than unity in the interval where the expected root is located. Using this condition and the application of the Gershgorin theorem (Bell, 1965), the condition for the convergence of iterations can be ensured for the function $g(x)$.

Example 2.5: Application of the Convergence Condition

Consider first-order reactions represented by



The first-order rate constants k_1 and k_3 associated with the reactions producing A_1 and A_3, respectively, are determined by measuring the rate of consumption of the reactant A_0 and the production of A_3. The rate constant, k_2, for the reaction producing A_2 is determined by solving a nonlinear equation that is derived as follows.

The concentrations of A_0, A_1, and A_3 as functions of time are obtained by integrating the following equations:

$$\frac{dA_0}{dt} = -(k_1 + k_3)A_0 \tag{2.89}$$

$$\frac{dA_1}{dt} = k_1 A_0 - k_2 A_1 \tag{2.90}$$

$$\frac{dA_3}{dt} = k_3 A_0 \tag{2.91}$$

$$A_0(0) = A_i \tag{2.92}$$

$$A_1(0) = A_2(0) = A_3(0) = 0 \tag{2.93}$$

to give

$$A_0 = A_i e^{-(k_1+k_3)t} \tag{2.94}$$

$$A_1 = \frac{k_1 A_i (e^{-(k_1+k_3)t} - e^{-k_2 t})}{k_2 - k_1 - k_3} \tag{2.95}$$

$$A_3 = \frac{k_3 A_i (1 - e^{-(k_1+k_3)t})}{k_1 + k_3} \tag{2.96}$$

Determination of k_2 involves the measurement of the concentration of A_1. Because A_1 is an intermediate product, the maximum concentration of A_1 occurs at t_{max} when

$$(k_1 + k_3)e^{-(k_1+k_3)t_{max}} = k_2 e^{-k_2 t_{max}} \tag{2.97}$$

In Equation (2.97), k_1, k_3, and t_{max} are known from experimental measurements. The unknown k_2 is obtained by solving this equation.

This equation admits two solutions. One solution occurs at the time less than t_{max} and the other at time greater than t_{max}. When the method of successive substitution is applied to the equation

$$k_2 = (k_1 + k_3)e^{k_2 - (k_1+k_3)t_{max}}$$

the condition for convergence for this equation is satisfied when $k_2 < 1/t_{max}$. The second solution cannot be obtained from this equation. By rewriting Equation (2.97) as

$$k_2 = (k_1 + k_3) + \frac{\ln[k_2/(k_1 + k_3)]}{t_{max}}$$

the second solution with $k_2 > 1/t_{max}$ can now be obtained, since the condition for convergence is satisfied.

2.7.2.2.2 Newton-Raphson Iteration

The convergence of the successive substitution method is slow, i.e., it may require many iterations for the sequence to converge. The Newton-Raphson method has a faster rate of convergence, which is given as follows:

$$\mathbf{Jf}(\mathbf{x}_n)[\mathbf{x}_{n+1}-\mathbf{x}_n]=\mathbf{f}(\mathbf{x}_n) \tag{2.98}$$

where

$$\mathbf{Jf}(\mathbf{x})=\begin{bmatrix} \frac{\partial f_1}{\partial x_1} & \frac{\partial f_1}{\partial x_2} & \cdots & \frac{\partial f_1}{\partial x_n} \\ \frac{\partial f_2}{\partial x_1} & \vdots & \cdots & \frac{\partial f_2}{\partial x_n} \\ \frac{\partial f_n}{\partial x_1} & \frac{\partial f_n}{\partial x_2} & \cdots & \frac{\partial f_n}{\partial x_n} \end{bmatrix}$$

The sequence $\mathbf{x}_{n+1}$ is generated by solving the system of linear equations defined by Equation (2.98). This sequence converges faster but requires a more accurate initial guess for x_0.

2.8 DIFFERENCE EQUATIONS

Difference equations are discrete analogues of differential equations. In this section, we present the methods of solving linear difference equations.

2.8.1 Method of Solution for Homogeneous Equations

Given a homogeneous kth-order linear difference equation

$$a_k y_{n+k} + a_{k-1} y_{n+k-1} + \cdots + a_0 y_n = 0 \tag{2.99}$$

the general solution of Equation (2.99) is determined by the solutions of the characteristic equation

$$a_k r^k + a_{k-1} r^{n+k-1} + \cdots + a_0 = 0 \tag{2.100}$$

If $r_1, r_2, \ldots, r_k$ are distinct roots of the characteristic equation, then the general solution is given by

$$y_n = \sum_{m=1}^{k} C_m r_m^n \tag{2.101}$$

where C_m's are constants to be determined from the boundary conditions.

If $r_1, r_2, \ldots, r_{m-p}$ are real but not distinct, and if r_p is a root of p-multiplicity, then the general solution is

$$y_n = \sum_{m=1}^{m} \sum_{k_j=0}^{k_{p-1}} C_{m,k_j} r_{m-p}^n k^m r_p^n \tag{2.102}$$

2.8.2 Method of Solution for Inhomogeneous Equations

Given the following inhomogeneous linear equations:

TABLE 2.3
Functional Form of Particular Solutions for y_p Depending on p_n

p_n	y_p
a^n	Aa^n
k^m	$\sum_{j=0}^{m} A_j k^j$
sin(bn) or cos(bn)	A sin(bn) + B cos(bn)
a^n sin(nb) or cos(bn)	a^n[A sin(bn) + B cos(bn)]

$$a_k y_{n+k} + a_{k-1} y_{n+k-1} + \cdots + a_0 y_n = p_n \tag{2.103}$$

the general solution of Equation (2.103) is given by

$$y_n = y_h + y_p$$

where y_h satisfies the homogeneous Equation (2.99) and y_p is a particular solution that depends on the functional form of p_n. The method of undetermined coefficients is used to solve for the particular solution y_p. This method assumes that the particular solution y_p depends on the form of p_n, as shown in Table 2.3.

Example: Application of the Solution Method

Consider the difference equation given by

$$8y_{n+2} - 6y_{n+1} + y_n = 2^n$$

The characteristic equation is

$$8r^2 - 6r + 1 = 0$$

The roots are $r_1 = 0.25$ and $r_2 = 0.5$. The particular solution has the functional form

$$y_p = A2^n$$

$$8y_{p,n+2} - 6y_{n+1} + y_n = 8A2^{n+2} - 6A2^{n+1} + A2^n = 2^n(32A - 12A + A) = 2^n$$

$$11A = 1 \quad \text{or} \quad A = \frac{1}{11}$$

The general solution is

$$y_n = C_1\left(\frac{1}{4}\right)^n + C_2\left(\frac{1}{2}\right)^n + \frac{1}{11}2^n$$

The constants C_1 and C_2 can be calculated through the application of boundary conditions, enabling the complete specification of the solution.

2.8.3 Numerical Solutions to Ordinary Differential Equations

In this subsection, some commonly used numerical schemes that involve difference equations to solve ordinary differential equations are presented along with their stability characteristics. Simple examples to illustrate the effects of step size on the convergence of numerical methods are shown.

A simple discretization of the first-order linear differential equation

$$\frac{dy}{dz} = -\lambda y, \quad a \le x \le b, \quad y(a) = y_0$$

by a straightforward discretization using Euler's rule yields the following difference equation:

$$y_{n+1} = y_n - h\lambda y_n = (1 - h\lambda) y_n$$

where $h = (b - a)/n$. The solution is given by

$$y_n = (1 - h\lambda)^n y_0$$

The solution of the differential equation approaches zero as x approaches infinity. The solution of the difference equation clearly depends on h, and it approaches zero only if $h\lambda < 1$. For $h\lambda > 1$, the solution of the difference equation oscillates between very large positive and negative values for large n. Thus, the solution of the difference equation converges only for values h that satisfy $h\lambda < 1$.

For a nonlinear equation,

$$\frac{dy}{dx} = f(x, y), \quad a \le x \le b, \quad y(a) = y_0$$

the necessary and sufficient condition through convergence of Euler's rule is (Lambert, 1973)

$$\sup_{x \in (a,b); y \in (-\infty,\infty)} \left(h \left| \frac{\partial f}{\partial y} \right| \right) < 1$$

This example illustrates that the step size, h, plays a crucial role in the convergence of the numerical solution of a differential equation. Depending on the equation to be solved and the method of discretization, h can be adjusted to obtain convergence of a numerical solution.

A general method of solving a differential equation is to divide the interval of integration into n subintervals and then approximate the derivative by a one-step difference quotient, as in the Euler method or k-step difference quotient:

$$\frac{dy}{dx} = \frac{1}{h} \sum_{i=0}^{k} \alpha_i y_i \qquad (2.104)$$

where α_i's are constants with values ensuring the limit of the right-hand side of Equation (2.104) to the derivative of y at $x = 0$. Such an approximation introduces errors in computation. It also introduces

an extraneous parameter h. The example shows that the growth or decay of the error is related to this parameter. Hence the strategy is to use the step length to control the growth or decay of the error. To derive conditions for controlling the error, a few notations and definitions are introduced.

The order of a method is the integer p such that the difference between the term on the right-hand side of Equation (2.104) and y' is proportional to h^{p+1}. The solution of the difference equation converges to that of the differential equation if the difference between the two solutions vanishes as the step size, h, approaches zero. A difference scheme is said to be zero-stable if the numerical solution of the equation for $f(x,y) = 0$ is zero.

In general, for $f(x,y) \neq 0$, the solution of the differential equation is approximated by the solution of the following difference equation:

$$\sum_{i=0}^{k} \alpha_i y_i = h \sum_{i=0}^{k} \beta_i f_i \tag{2.105}$$

where α_k's and β_k's are the constants. If $\beta_k = 0$, the method is explicit; if $\beta_k \neq 0$, the method is implicit. The k-step methods require $k - 1$ starting values before they can be used to calculate the solution at the k-step. Explicit methods are easier to implement but are generally less stable. For nonlinear equations, implicit methods require iterative solutions, since the values of the unknown function at subsequent steps are not known.

The stability of a method leads to the condition that the modulus of the root, r, of the equation below should be less than unity:

$$\sum_{i=0}^{k} (\alpha_i - \bar{h}\beta_i) r^i = 0 \tag{2.106}$$

where $\bar{h} \equiv h\frac{\partial f}{\partial y}$. Methods that satisfy this condition are absolutely stable. It is shown (Lambert, 1973) that for every consistent, zero-stable method, one root of Equation (2.106) is greater than unity in magnitude for positive and small $\bar{h}$. However, for positive $\bar{h}$, the solution of the differential equation also grows. Thus, for the solutions to be meaningful, it is required that the rate of growth of the error be less than that of the solution. If r_1 is the root with the largest magnitude, then the condition for convergence is

$$|r_i| < |r_1| \quad i = 2, 3, \ldots \tag{2.107}$$

Methods that satisfy the conditions of Equation (2.107) are said to be relatively stable.

Often, the step size is chosen to increase the accuracy of the numerical solution. More importantly, the step size controls not only the error, but also the stability of the numerical scheme. The following problem is selected to illustrate the stability characteristics of the numerical method:

$$\frac{dy}{dx} = -50y^2 \quad y(0) = 1 \tag{2.108}$$

The theoretical solution is

$$y_t(x) = \frac{1}{1 + 50x} \tag{2.109}$$

TABLE 2.4
Theoretical and Numerical Solutions of Equation (2.108) by Four-Stage Runge-Kutta Method (y_{rk})

x	y_t, Equation (2.109)	y_{rk}, $h = 0.02$	y_{rk}, $h = 0.04$
0	1	1	1
0.04	0.3333	0.326900	–0.3333
0.08	0.2	0.197676	–0.958119
0.12	0.142857	0.141669	–578.994

The interval of absolute stability for four-stage Runge-Kutta is (–2.78,0). If the numerical solution is to converge to the theoretical solution, the step size h must be selected such that $-2.78 < \bar{h} < 0$. Because $dy/dx < 0$, the solution is a monotonically decreasing function of x, the maximum value of y is $y(0) = 1$, and the minimum of $\bar{h} = -100h < 2.78$. For $h = 0.01$ and 0.02, $\bar{h} = -1, -2$, respectively, which remain in the interval of absolute stability. For $h = 0.04$, $\bar{h} = -4$, which falls outside of the interval of absolute stability. Hence, the numerical solution diverges for $h = 0.04$.

The extension of a single equation to a system is accomplished with vector-dependent variables. In principle, the stability condition is still valid with the replacement of $\bar{h}$ by $h\rho$, where ρ is the maximum among all the absolute eigenvalues of the Jacobian of the vector $\mathbf{f}(x,\mathbf{y})$.

The reader is referred to Lambert (1973) for an excellent treatise on the computational methods for ordinary differential equations.

In what follows, we list the explicit and implicit methods for ready reference. The differences will be obvious through the formulations.

2.8.3.1 Explicit Methods

2.8.3.1.1 Runge-Kutta Methods

There exists a family of Runge-Kutta methods that differs by the number of functional evaluations of $f(x_r,y_r)$. A method that requires R functional evaluations is known as the R-stage Runge-Kutta method.

Two-stage Runge-Kutta method

1. Modified Euler method:

$$y_{n+1} - y_n = hf\left(x_n + \frac{1}{2}h, y_n + \frac{1}{2}hf(x_n, y_n)\right)$$

Interval of absolute stability: (–2,0)

2. Improved Euler method:

$$y_{n+1} - y_n = \frac{1}{2}h[f(x_n y_n) + f(x_n + h, y_n + hf(x_n, y_n))]$$

Interval of absolute stability: (–2,0)

Three-stage Runge-Kutta method

1. Heun's third-order formula:

$$y_{n+1} - y_n = \frac{h}{4}(k_1 + 3k_3) \tag{2.110}$$

$$k_1 = f(x_n, y_n) \tag{2.111}$$

$$k_2 = f\left(x_n + \frac{1}{3}h, y_n + \frac{1}{3}hk_1\right) \tag{2.112}$$

$$k_3 = f\left(x_n + \frac{2}{3}h, y_n + \frac{2}{3}hk_2\right) \tag{2.113}$$

Interval of absolute stability: (–2.51,0)

2. Kutta's third-order rule

$$y_{n+1} - y_n = \frac{h}{6}(k_1 + 4k_2 + k_3) \tag{2.114}$$

$$k_1 = f(x_n, y_n) \tag{2.115}$$

$$k_2 = f\left(x_n + \frac{1}{2}h, y_n + \frac{1}{2}hk_1\right) \tag{2.116}$$

$$k_3 = f(x_n + h, y_n - hk_1 + 2hk_2) \tag{2.117}$$

Interval of absolute stability: (–2.51,0)

Four-stage Fourth-order Runge-Kutta method
1.

$$y_{n+1} - y_n = \frac{h}{6}(k_1 + 2k_2 + 2k_3 + k_4) \tag{2.118}$$

$$k_1 = f(x_n, y_n) \tag{2.119}$$

$$k_2 = f\left(x_n + \frac{1}{2}h, y_n + \frac{1}{2}hk_1\right) \tag{2.120}$$

$$k_3 = f\left(x_n + \frac{1}{2}h, y_n + \frac{1}{2}hk_2\right) \tag{2.121}$$

$$k_4 = f(x_n + h, y_n + hk_3) \tag{2.122}$$

Interval of absolute stability: (–2.78,0)

2.

$$y_{n+1} - y_n = \frac{h}{8}(k_1 + 3k_2 + 3k_3 + k_4) \tag{2.123}$$

$$k_1 = f(x_n, y_n) \tag{2.124}$$

$$k_2 = f\left(x_n + \frac{1}{3}h, y_n + \frac{1}{3}hk_1\right) \tag{2.125}$$

$$k_3 = f\left(x_n + \frac{2}{3}h, y_n - \frac{1}{3}hk_1 + hk_2\right) \tag{2.126}$$

$$k_4 = f(x_n + h, y_n + hk_1 - hk_2 + hk_3) \tag{2.127}$$

Interval of absolute stability: (–2.78,0)

Fifth-order six-stage Runge-Kutta method

$$y_{n+1} - y_n = \frac{h}{90}(7k_1 + 32k_3 + 12k_4 + 32k_5 + 7k_6) \tag{2.128}$$

$$k_1 = f(x_n, y_n) \tag{2.129}$$

$$k_2 = f\left(x_n + \frac{1}{2}h, y_n + \frac{1}{2}hk_1\right) \tag{2.130}$$

$$k_3 = f\left(x_n + \frac{1}{4}h, y_n + \frac{1}{16}h(3k_1 + k_2)\right) \tag{2.131}$$

$$k_4 = f\left(x_n + \frac{1}{2}h, y_n + \frac{1}{2}hk_3\right) \tag{2.132}$$

$$k_5 = f\left(x_n + \frac{3}{4}h, y_n + \frac{3}{16}h(-k_2 + 2k_3 + 3k_4)\right) \tag{2.133}$$

$$k_6 = f\left(x_n + hy_n + \frac{1}{7}h(k_1 + 4k_2 + 6k_3 - 12k_4 + 8k_5)\right) \tag{2.134}$$

Interval of absolute stability: (–5.7,0)

2.8.3.1.2 Adams-Bashforth Family of Methods

For an in-depth discussion of the Adams-Bashforth family of methods, see Johnson and Riess (1982).

One-step Adams-Bashforth or Euler's Rule

$$y_{n+1} - y_n = hf_n \tag{2.135}$$

Interval of absolute stability: (–2,0)

Two-step Adams-Bashforth

$$y_{n+2} - y_{n+1} = \frac{h}{2}(3f_{n+1} - f_n) \tag{2.136}$$

Interval of absolute stability: (–1,0)

Three-step Adams-Bashforth

$$y_{n+3} - y_{n+2} = \frac{h}{12}(23f_{n+2} - 16f_{n+1} + 5f_n) \tag{2.137}$$

Interval of absolute stability: (–6/11,0)

Four-step Adams-Bashforth

$$y_{n+4} - y_{n+3} = \frac{h}{24}(55f_{n+3} - 59f_{n+2} + 37f_{n+1} - 9f_n) \tag{2.138}$$

Interval of absolute stability: (–3/10,0)

2.8.3.2 Implicit Methods

2.8.3.2.1 Trapezoidal, Simpson, and Runge-Kutta

Trapezoidal rule

$$y_{n+1} - y_n = \frac{h}{2}(f_{n+1} + f_n) \tag{2.139}$$

Interval of absolute stability: (–∞,0)

Simpson's rule

$$y_{n+2} - y_n = \frac{h}{3}(f_{n+2} + 4f_{n+1} + f_n) \tag{2.140}$$

Interval of relative stability: (0,∞)

Fourth-order two-stage implicit Runge-Kutta method

$$y_{n+1} - y_n = \frac{h}{2}(k_1 + k_2) \tag{2.141}$$

$$k_1 = f\left(x_n + \left(\frac{1}{2} + \frac{\sqrt{3}}{6}\right)h, y_n + \frac{1}{4}hk_1 + \left(\frac{1}{4} + \frac{\sqrt{3}}{6}\right)hk_2\right) \tag{2.142}$$

$$k_2 = f\left(x_n + \left(\frac{1}{2} - \frac{\sqrt{3}}{6}\right)h, y_n + \left(\frac{1}{4} - \frac{\sqrt{3}}{6}\right)hk_1 + \frac{1}{4}hk_2\right) \tag{2.143}$$

Interval of absolute stability: $(-\infty,0)$.

2.8.3.2.2 Adams-Moulton Family of Methods

One-step Adams-Moulton, backward Euler's rule

$$y_{n+1} - y_n = hf_{n+1} \tag{2.144}$$

Interval of absolute stability: $(-\infty,0)$

Two-step Adams-Moulton, trapezoidal rule

$$y_{n+2} - y_{n+1} = \frac{h}{2}(f_{n+2} + f_{n+1}) \tag{2.145}$$

Interval of absolute stability: $(-\infty,0)$

Three-step Adams-Moulton

$$y_{n+3} - y_{n+2} = \frac{h}{12}(5f_{n+2} + 8f_{n+1} - f_{n+1}) \tag{2.146}$$

Interval of absolute stability: $(-6,0)$

Four-step Adams-Moulton

$$y_{n+4} - y_{n+3} = \frac{h}{24}(9f_{n+4} + 19f_{n+3} - 5f_{n+2} + f_{n+1}) \tag{2.147}$$

Interval of absolute stability: $(-3,0)$

Software: The method chosen of course depends on the nature of the equation. The analysis presented earlier may be of great help in selecting the right kind of step size balancing the stability and convergence.

2.9 ORDINARY DIFFERENTIAL EQUATIONS

In this section, formulae for the solution of selected differential equations are presented. The advantage of having the solution expressed in terms of the formula is that the solution is known without having to know the values of the parameters. Sometimes, the solution is given as an implicit nonlinear algebraic equation. In such cases, the advantage of analytical formulae over numerical computation diminishes.

2.9.1 Linear First-Order Differential Equation

A linear differential equation is an equation in which the unknown function appears in linear form, i.e., with the power of 1. The general linear first-order differential equation is

$$\frac{dy}{dx} + p(x)y(x) = q(x)$$

The general solution to this differential equation subjected to the condition

$$y(0) = y_0$$

is given by

$$y(x) = y_0 \exp\left[-\int_0^x p(t)dt\right] + \int_0^x q(t)\exp\left[\int_x^t p(s)ds\right]dt \tag{2.148}$$

2.9.2 Nonlinear First-Order Differential Equation

2.9.2.1 Autonomous Nonlinear Equation

An autonomous equation is an equation in which the independent variable does not appear explicitly. The general form is

$$\frac{dy}{dx} = F(y), \quad y(0) = y_0$$

The general solution is given by the implicit function

$$\int_{y_0}^{y} \frac{dy}{F(y)} = x$$

2.9.2.2 Implicit Equation

An implicit differential equation is an equation in which the dependent variable is expressed as a function of its derivative:

$$y = f\left(\frac{dy}{dx}\right) \tag{2.149}$$

$$\text{Let } p = \frac{dy}{dx} \quad \text{thus} \quad dy = pdx$$

From Equation (2.149),

$$dy = f'(p)dp = pdx$$

The solution is given by

$$y = f(p), \;\; x = \int \frac{f'(p)dp}{p} + c \tag{2.150}$$

$$x = f\left(\frac{dy}{dx}\right)$$

$$\text{Let } p = \frac{dy}{dx} \quad \text{thus} \quad dy = pdx$$

From Equation (2.150),

$$dx = f'(p)dp$$

$$dy = pdx = pf'(p)dp$$

The solution is given by

$$y = \int pf'(p)dp + c, \;\; x = f(p)$$

2.9.2.3 Lagrange Equation

$$y = xf\left(\frac{dy}{dx}\right) + g\left(\frac{dy}{dx}\right)$$

$$\text{Let } p = \frac{dy}{dx} \quad \text{thus} \quad dy = pdx$$

$$pdx = f(p)dx + xf'(p)dp + g'(p)dp$$

Dividing throughout by dp gives

$$\frac{dx}{dp}[p - f(p)] = xf'(p) + g'(p)$$

that can be solved to obtain the solution $x(p)$, which in conjunction with the following equation forms the complete solution.

$$y = xf(p) + g(p) = \int^{p} \frac{[f'(p) + g'(p)]dp}{p - f(p)}$$

2.9.2.4 Separable Equation

$$\frac{dy}{dx} = f(x)g(y)$$

The solution to the equation with $y(0) = y_0$ is given by

$$\int_{y_0}^{y} \frac{dy}{g(y)} = \int_0^x f(x)dx$$

2.9.2.5 Bernoulli Equation

$$\frac{dy}{dx} + P(x)y = Q(x)y^n, \ \ y(0) = y_0$$

is transformed into a linear equation by the substitution

$$u(x) = y(x)^{1-n}$$

to get the equation for $u(x)$ as

$$\frac{1}{(1-n)}\frac{du}{dx} + P(x)u = Q(x), \ \ y(0) = y_0$$

The solution is given by

$$y(x) = \left\{ y_0^{1-n} \exp\left[(n-1)\int_0^x P(t)dt\right] + (1-n)\int_0^x \exp\left[(1-n)\int_x^t P(s)ds\right]Q(t)dt \right\}^{1/1-n}$$

Example 2.6

Consider the following isothermal parallel reactions in a constant-volume batch reactor with the reaction order of 1 for the first reaction and order n for the second reaction:

$$A \xrightarrow{k_1} B$$

$$nA \xrightarrow{k_n} C$$

The mass balance for the species A is given by

$$\frac{dA}{dt} = -k_1 A - nk_n A^n, \;\; A(0) = A_0$$

The solution is given by

$$A(t) = \left[\left(A_0^{1-n} + \frac{nk_n}{k_1}\right)e^{(n-1)k_1 t} - \frac{nk_n}{k_1}\right]^{1/(1-n)}, \;\; n > 1$$

2.9.2.6 Exact Differential Equations

$$N(x,y)\frac{dy}{dx} + M(x,y) = 0, \quad y(0) = y_0$$

This is often written in the form

$$M(x,y)dx + N(x,y)dy = 0$$

The equation is said to be exact if

$$\frac{\partial M}{\partial y} = \frac{\partial N}{\partial x}$$

Then the solution is given by the implicit function, $\psi(x,y)$, where

$$\psi(x,y) = 0\int_0^x M(t,y)dt + \int_{y_0}^{y}\left[N(x,s) - \int_0^x \frac{\partial M(t,s)}{\partial s}dt\right]ds$$

2.9.2.7 Homogeneous Equations

A nonlinear differential equation

$$\frac{dy}{dx} = f(x,y)$$

is said to be homogeneous of degree 0 if

$$f(tx,ty) = f(x,y) = tF\left(\frac{y}{x}\right)$$

The transformation $y = xv$ converts the equation to

$$x\frac{dv}{dx} = F(v) - v$$

that then can be solved by the solution method for a separable equation.

2.9.2.8 Ricatti Equations

$$\frac{dy}{dx} = P(x)y^2 + Q(x)y + R(x), \quad y(0) = y_0 \tag{2.151}$$

Ricatti equations can be solved if P, Q, and R are constant. The solution is then

$$x = \int_{y_0}^{y} \frac{dz}{Pz^2 + Qz + R}$$

In general, if a particular solution $y_1(x)$ to Equation (2.151) is known, then letting $y(x) = z(x) + y_1(x)$ transforms Equation (2.151) to the Bernoulli equation:

$$\frac{dz}{dx} = P(x)z^2 + (2P(x)y_1 + Q(x))z$$

For the dynamics of a CSTR of volume V fed with the reactant concentration, C_f, with an nth-order chemical reaction,

$$\frac{dC}{dt} = \frac{F}{V}(C_f - C) - kC^n$$

$$C(0) = C_0$$

The solution is given by

$$t = \int_{C_0}^{C} \frac{dC}{F(C_f - C)/V - kC^n} \tag{2.152}$$

For $n = 2$, the integral in Equation (2.152) can be evaluated to give

$$-\omega t = \ln\left[\frac{(C - C_+)(C_0 - C_-)}{(C - C_-)(C_0 - C_+)}\right]$$

that can be solved for C as

$$C = \frac{C_+(C_0 - C_-) - C_-(C_0 - C_+)e^{-\omega t}}{(C_0 - C_-) - (C_0 - C_+)e^{-\omega t}}$$

where

$$C_\pm = \frac{F}{2kV}\left(1 \pm \sqrt{1 + 4C_f kV/F}\right) \quad \text{and} \quad \omega = \frac{F}{V}\sqrt{1 + 4C_f kV/F}$$

2.9.3 Second-Order Differential Equations

2.9.3.1 Homogeneous Linear Equations with Constant Coefficients

The mass balance for a first-order reaction in a tubular reactor with a flow velocity of v and the concentration of reactant in feed, C_f, undergoing a reaction with the rate constant of k is governed by the following second-order linear equation with constant coefficients:

$$D\frac{d^2C}{dx^2} - v\frac{dC}{dx} - kC = 0 \tag{2.153}$$

subjected to boundary conditions:

$$-D\frac{dC}{dx} = v(C_f - C), \quad x = 0$$

$$\frac{dC}{dx} = 0, \quad x = L$$

where L is the reactor length and D is the diffusion coefficient. The solutions are determined by the roots of the characteristic equation,

$$D\lambda^2 = v\lambda - k = 0$$

that is given by

$$\lambda_{1,2} = \frac{v \pm \sqrt{v^2 + 4Dk}}{2D}$$

$$C(x) = A\exp(\lambda_1 x) + B\exp(\lambda_2 x)$$

Equivalently,

$$C(x) = \exp\left(\frac{v}{2D}x\right)[A\cosh(\gamma x) + B\sinh(\gamma x)] \tag{2.154}$$

where

$$\gamma = \frac{\sqrt{v^2 + 4Dk}}{2D}$$

$$A = \frac{vC_f(v\sinh(\gamma L) + 2D\gamma\cosh(\gamma L))}{(v^2 + 2Dk)\sinh(\gamma L) + 2Dv\gamma\cosh(\gamma L)}$$

$$B = -\frac{vC_f(v\cosh(\gamma L) + 2D\gamma\sinh(\gamma L))}{(v^2 + 2Dk)\sinh(\gamma L) + 2Dv\gamma\cosh(\gamma L)}$$

2.9.3.2 Inhomogeneous Linear Differential Equations with Constant Coefficients

Consider an inhomogeneous linear differential equation with constant coefficients given by

$$D\frac{d^2C}{dx^2} - v\frac{dC}{dx} - kC = S(x) \tag{2.155}$$

The solution of Equation (2.155) is given by

$$C(x) = Ay_1(x) + By_2(x) + C_p(x)$$

where $C_p(x)$ is obtained by the method of variation of parameters, as follows. Let

$$C_p(x) = \alpha(x)y_1(x) + \beta(x)y_2(x)$$

where $y_1(x)$ and $y_2(x)$ are the two linearly independent solutions given in the previous section as

$$y_1(x) = \exp\left(\frac{v}{2D}x\right)\cosh(\gamma x), \quad y_2(x) = \exp\left(\frac{v}{2D}x\right)\sinh(\gamma x)$$

where

$$\gamma = \frac{\sqrt{v^2 + 4Dk}}{2D}$$

$$C_p'(x) = \alpha'(x)y_1(x) + \beta'(x)y_2(x) + \alpha(x)y_1'(x) + \beta(x)y_2'(x)$$

For $C'(x)$ to assume the same functional form as if α and β were constants, it is required that

$$\alpha'(x)y_1(x) + \beta'(x)y_2(x) = 0$$

The second derivative is then

$$C_p''(x) = \alpha'(x)y_1'(x) + \alpha(x)y_1''(x) + \beta'(x)y_2'(x) + \beta(x)y_2''(x)$$

Substituting $C_p''(x)$ and $C_p'(x)$ into the nonhomogeneous equation, one obtains a system of first-order differential equations for $\alpha(x)$ and $\beta(x)$:

$$\alpha'(x)y_1(x) + \beta'(x)y_2(x) = 0$$

$$\alpha'(x)y_1'(x) + \beta'(x)y_2'(x) = S(x)$$

The solution is given by

$$\alpha(x) = -\int^{x} \frac{S(\xi)}{y_1(\xi)y_2'(\xi) - y_1'(\xi)y_2(\xi)} y_2(\xi)d\xi$$

$$\beta(x) = \int^{x} \frac{S(\xi)}{y_1(\xi)y_2'(\xi) - y_1'(\xi)y_2(\xi)} y_1(\xi)d\xi$$

Substituting $\alpha(x)$ and $\beta(x)$ in $C_p(x)$ gives the particular solution

$$C_p(x) = \int^{x} \frac{y_1(t)y_2(x) - y_1(x)y_2(t)}{y_1(t)y_2'(t) - y_1'(t)y_2(t)} S(t)dt$$

and the general solution

$$C(x) = Ay_1 + By_2 + \int^{x} \frac{y_1(t)y_2(x) - y_1(x)y_2(t)}{y_1(t)y_2'(t) - y_1'(t)y_2(t)} S(t)dt$$

where A and B are constants that can be determined on the specification of boundary conditions.

2.9.3.3 Green's Function

The method of Green's function expresses the solution of the inhomogeneous boundary-value problem as the integral representation of the inhomogeneous function (Friedman, 1956; Stakgold, 1979). Given the boundary-value problem,

$$\begin{aligned} &a_2 \frac{d^2y}{dx^2} + a_1 \frac{dy}{dx} + a_0 y = g(x) \\ &\alpha_1 \frac{dy}{dx} + \beta_1 y = 0, \quad x = 0 \\ &\alpha_2 \frac{dy}{dx} + \beta_2 y = 0, \quad x = 1 \end{aligned} \tag{2.156}$$

The above boundary-value problem is transformed to the following self-adjoint forms:

$$\begin{aligned} &\frac{d}{dx}\left(p(x)\frac{dy}{dx}\right) + q(x)y = f(x) \\ &B_1(y) = \alpha_1 \frac{dy}{dx} + \beta_1 y = 0, \quad x = 0 \\ &B_2(y) = \alpha_2 \frac{dy}{dx} + \beta_2 y = 0, \quad x = 1 \\ &p(x) = \exp\left(\int^{x} \frac{a_1}{a_2} dx\right), \quad q(x) = \frac{a_0(x)p(x)}{a_2(x)}, \quad f(x) = \frac{p(x)g(x)}{a_2(x)} \end{aligned} \tag{2.157}$$

Green's function for Equation (2.157) is given by

$$G(x,\xi)=\begin{cases}\dfrac{v_1(x)v_2(\xi)}{p(\xi)W(v_1(\xi),v_2(\xi))} & x\le\xi\\ \dfrac{v_1(\xi)v_2(x)}{p(\xi)W(v_1(\xi),v_2(\xi))} & x>\xi\end{cases}$$

where $v_i(x)$ (i = 1,2) are the two linearly independent solutions of the homogeneous equation such that $B_i(v_i) = 0$, and $W(u,v)$ is the Wronskian of u and v:

$$W(u,v)=\begin{vmatrix}u & v\\ u' & v'\end{vmatrix}$$

that is nonzero, because u and v are linearly independent solutions.

The $pW(u,v)$ is constant in the interval [0,1] for any pair of functions u and v satisfying the homogeneous version of the differential equation in (2.156) and the homogeneous boundary conditions.

The solution of Equation (2.157) is given by

$$y(x)=\int_0^1 G(x,\xi)g(\xi)d\xi$$

Equation (2.156), with the following nonhomogeneous boundary conditions,

$$\alpha_1\frac{dy}{dx}+\beta_1 y=\gamma_1,\quad x=0$$

$$\alpha_2\frac{dy}{dx}+\beta_2 y=\gamma_2,\quad x=1$$

is given by

$$y(x)=\frac{\gamma_2 p(1)[\alpha_2 v_2(1)-\beta_2 v_2'(1)]}{p(x)W(v_1(x),v_2(x))}v_1(x)-\frac{\gamma_1 p(0)[\alpha_1 v_1(0)-\beta_1 v_1'(0)]}{p(x)W(v_1(x),v_2(x))}v_2(x)+\int_0^1 G(x,\xi)g(\xi)d\xi$$

Example 2.7

The steady-state mass balance in a tubular reactor with a source term (reactant fed along the length of the reactor) is governed by the following boundary-value problem:

$$D\frac{d^2C}{dx^2}-v\frac{dC}{dx}-ky=-S(x)$$

$$D\frac{dC}{dx}-vC=-vC_f,\quad x=0$$

$$\frac{dC}{dx}=0,\quad x=L$$

The solution is given by

$$C(x)=C_1(x)+\int_0^1 \exp\left(-\frac{v}{D}x\right)G(x,\xi)S(\xi)d\xi$$

where $C_1(x)$ is the solution of the homogeneous equation and $C_0 \neq 0$ is given by Equation (2.154), and the Green's function $G(x,\xi)$ for $C_0 = 0$ is given by

$$G(x,\xi)=\begin{cases} -\dfrac{4D^2qv_1(x)v_2(\xi)}{4Dqv\cosh(qL)+(4D^2q^2+v^2)\sinh(q)} & x<\xi \\ -\dfrac{4D^2qv_1(\xi)v_2(x)}{4Dqv\cosh(qL)+(4D^2q^2+v^2)\sinh(q)} & x\geq\xi \end{cases} \tag{2.158}$$

where the two linearly independent solutions v_1 and v_2 satisfying $B_i(v_i)$ are

$$v_1(x)=\exp\left(\frac{v}{2D}x\right)\left[\cosh(qx)+\frac{vL}{2Dq}\sinh(qx)\right]$$

$$v_2(x)=\exp\left(\frac{v}{2D}x\right)\left[\cosh(q(x-L))-\frac{vL}{2Dq}\sinh(q(x-L))\right]$$

2.9.3.4 Green's Function by Eigenfunction (Mercer's) Expansions

Consider the Green's function defined by the following differential equations:

$$\begin{aligned} &\frac{d}{dx}\left(p(x)\frac{dG}{dx}\right)+q(x)G-\lambda r(x)G=\delta(x-\xi) \\ &\alpha_1\frac{dG(a,\xi;\lambda)}{dx}+\beta_1 G(a,\xi;\lambda)=0, \quad x=a \\ &\alpha_2\frac{dG(b,\xi;\lambda)}{dx}+\beta_2 G(b,\xi;\lambda)=0, \quad x=b \end{aligned} \tag{2.159}$$

where $\delta(x-\xi)$ is the dirac delta function (see Appendix 2.B). Let $y_i(x)$ be the normalized eigenfunctions corresponding to the eigenvalues λ_i of the operator, then we have, $Ly_i = \lambda_i y$ where

$$L\equiv-\frac{1}{r(x)}\left[\frac{d}{dx}\left(p(x)\frac{d}{dx}\right)+r(x)q(x)\right] \tag{2.160}$$

Since L is self-adjoint, the eigenfunctions y_i and y_j, corresponding to different eigenvalues λ_i and λ_j, respectively, are orthogonal, i.e.,

$$\int_a^b y_i(x)y_j(x)r(x)dx=\delta_{i,j}=\begin{cases}1 & \text{if } i=j \\ 0 & \text{if } i\neq j\end{cases}$$

Let

$$G(x;\xi;\lambda)=\sum_i c_i(\xi;\lambda)y_i(x) \tag{2.161}$$

where

$$c_i=\int_a^b r(x)y_i(x)G(x,\xi;\lambda)dx$$

Multiplying Equation (2.159) by $y_i(x)$ and integrating over (a,b) gives

$$\int_a^b\left[\frac{d}{dx}\left(p(x)\frac{dG}{dx}\right)+q(x)G-\lambda r(x)G\right]y_i dx=\int_a^b\delta(x-\xi)y_i dx$$

$$=\int_a^b\left[\underbrace{\frac{d}{dx}\left(p(x)\frac{dy_i}{dx}\right)+q(x)y_i}_{\lambda_i r(x)y_i(x)}\right]Gdx-\int_a^b\lambda r(x)y_iGdx=\int_a^b\delta(x-\xi)y_i(x)dx$$

$$\lambda_i\int_a^b r(x)y_i(x)Gdx-\lambda\int_a^b r(x)y_i(x)Gdx=y_i(\xi)$$

$$c_i(\lambda_i-\lambda)=y_i(\xi)$$

$$G(x,\xi;\lambda)=\sum_i\frac{y_i(x)y_i(\xi)}{\lambda_i-\lambda}$$

2.9.4 Linear Higher-Order Differential Equations

2.9.4.1 Homogeneous Equation

$$\sum_{i=1}^n a_i\frac{d^iy}{dt^i}=0$$

The general solution is given by

$$\sum_{i=1}^n a_i\lambda^i=0$$

where λ_i are the roots of the polynomial. Now (a) if the roots of the polynomial are distinct, then the solution is given by

$$y(x)=\sum_{i=1}^n c_i\exp(\lambda_i x)$$

or (b) if λ_i is a root with multiplicity $k_i(\Sigma_j^m k_j=n)$, then the solution is given by

$$y(x)=\sum_{i=1}^{m}\left(\sum_{k_j=0}^{k_i-1}c_{i,k_j}t^{k_j}\right)\exp(\lambda_i x)$$

2.9.4.2 Inhomogeneous Equation

$$\sum_{i=1}^{n}a_i\frac{d^iy}{dt^i}=f(t)$$

Let $y_i = \exp(\lambda_i x)$, $i = 1,2,\ldots,n$ be the n solutions of the homogeneous equation, i.e., the n solutions for $f(t) = 0$. Let us define the vectors

$$\mathbf{Y}_i=\begin{bmatrix} y_i \\ \dfrac{dy_i}{dx} \\ \cdots \\ \dfrac{d^{n-1}y_i}{dx^{n-1}} \end{bmatrix} \qquad \boldsymbol{\delta}_n=\begin{bmatrix} 0 \\ 0 \\ \vdots \\ 1 \end{bmatrix}$$

The Wronskian of these solutions is defined as

$$W(\mathbf{Y}_1,\mathbf{Y}_2,\ldots,\mathbf{Y}_n)=\begin{vmatrix} y_1 & y_2 & \cdots & y_n \\ \dfrac{dy_1}{dx} & \dfrac{dy_2}{dx} & \cdots & \dfrac{dy_n}{dx} \\ \dfrac{d^2y_1}{dx} & \vdots & \cdots & \dfrac{d^2y_n}{dx} \\ \vdots & \vdots & \vdots & \vdots \\ \dfrac{d^{n-1}y_1}{dx} & \dfrac{d^{n-1}y_2}{dx} & \cdots & \dfrac{d^{n-1}y_n}{dx} \end{vmatrix}$$

and let

$$W_1=W(\boldsymbol{\delta}_n,\mathbf{Y}_2,\ldots,\mathbf{Y}_n)\cdots W_n=W(\mathbf{Y}_1,\mathbf{Y}_2,\ldots,\boldsymbol{\delta}_n)\quad \text{and}\quad \boldsymbol{\delta}_n=[0\quad 0\quad \cdots\quad 0\quad 1]^T$$

$$y(x)=y_h(x)+\sum_{i=1}^{n}y_i(x)\int_0^x\frac{W_i}{W(\mathbf{Y}_1,\mathbf{Y}_2,\ldots,\mathbf{Y}_n)}f(t)dt$$

where $y_h(x)$ is the solution of the homogeneous equation.

2.9.4.3 Application of Higher-Order Equations

Consider the sequence of reactions following the first-order kinetics

$$A \xrightarrow{k_1} B \xrightarrow{k_2} C$$

taking place in a tubular reactor. The mass balances for A and B are governed by the following system of boundary-value problems:

$$D_A \frac{d^2C_A}{dx^2} - v_A \frac{dC_A}{dx} - k_1 C_A = 0 \tag{2.162}$$

$$x = 0, \quad v_A(C_{A0} - C_A) = -D_A \frac{dC_A}{dx}; \quad x = L, \quad \frac{dC_A}{dx} = 0 \tag{2.163}$$

$$D_B \frac{d^2C_B}{dx^2} - v_B \frac{dC_B}{dx} + k_1 C_A - k_2 C_B = 0 \tag{2.164}$$

$$x = 0, \quad v_B C_B = D_B \frac{dC_B}{dx}; \quad x = L, \frac{dC_B}{dx} = 0 \tag{2.165}$$

where v_A and v_B are the convective velocities of species A and B, respectively, while D_A and D_B indicate the diffusivities of species A and B, respectively. A single fourth-order differential equation can be obtained by eliminating C_A from Equation (2.164), as

$$\begin{aligned} &D_A D_B \frac{d^4C_B}{dx^4} - (D_A v_B + D_B v_A)\frac{d^3C_B}{dx^3} \cdots \\ &- (D_A k_2 - v_A v_B + D_B k_1)\frac{d^2C_B}{dx^2} + (v_A k_2 + v_B k_1)\frac{dC_B}{dx} + k_1 k_2 C_B = 0 \end{aligned} \tag{2.166}$$

The boundary conditions are derived by eliminating C_A from Equation (2.164),

$$\begin{aligned} x = 0, \quad &- D_A D_B \frac{d^3C_B}{dx^3} + (D_A v_B + D_B v_A)\frac{d^2C_B}{dx^2} \cdots \\ &+ (D_A k_2 - v_A v_B)\frac{dC_B}{dx} - v_A k_2 C_B - k_1 v_A C_{A0} = 0 \end{aligned} \tag{2.167}$$

$$x = L, \quad D_B \frac{d^3C_B}{dx^3} - v_B \frac{d^2C_B}{dx^2} = 0 \tag{2.168}$$

Equation (2.166), along with the two original and the two new boundary conditions given by Equation (2.167) and Equation (2.168), form a boundary-value problem for C_B.

Alternatively, substituting the solution of Equation (2.162), which is given by Equation (2.154), into Equation (2.164) gives an equation for C_B that is solved by the method of Green's function:

$$C_B(x) = k_2 \int_0^L C_A(\xi) G(x, \xi) d\xi$$

where the Green's function is given by Equation (2.158).

2.9.4.4 Finite Element Method

Various formulations of finite element methods have been proposed. For an exhaustive account on finite element methods, the reader is referred to Chen (2005), Donea (2003), Reddy (2005), etc. We present here one of the popular formulations known as the weak formulation of the governing differential equation that, instead of requiring the solution to be twice continuously differentiable, requires that the derivative of the solution be square integrable. We illustrate the weak formulation of the boundary-value problem, Equation (2.157).

To derive the weak formulation, multiplying Equation (2.157) by a test function, $\phi(x)$ (any member of a family of suitably smooth functions), and integrating by parts over an arbitrary element (x_1,x_2) we get

$$-\int_{x_1}^{x_2} a\frac{dy}{dx}\frac{d\phi}{dx}dx+\int_{x_1}^{x_2} qy\phi dx-\int_{x_1}^{x_2} f\phi dx\cdots$$

$$+\frac{a(x_2)\phi(x_2)}{\alpha_2}[-\beta_2 y(x_2)+\gamma_2]-\frac{a(x_1)\phi(x_1)}{\alpha_1}[-\beta_1 y(x_1)+\gamma_1]$$

Let the approximation solution on the local element $y^{(e)}$ be

$$y^{(e)}(x)=\sum_{j=1}^{n} y_j^{(e)}\psi_j^{(e)}(x)$$

where $y_j^{(e)}$ are the parameters to be determined, and $\psi_j^{(e)}(x)$ are the approximation functions given by

$$\psi_1^{(e)}(x)=\frac{x_{e+1}-x}{x_{e+1}-x_e}\qquad \psi_2^{(e)}(x)=\frac{x-x_e}{x_{e+1}-x_e}\qquad x_e\le x\le x_{e+1}$$

The functions $\psi_j^{(e)}(x)$ are endowed with the following properties:

$$1.\ \psi_i^{(e)}(x_j)=\begin{cases}0 & \text{if } i\neq j\\ 1 & \text{if } i=j\end{cases}\qquad x_1=x_e\quad x_2=x_{e+1} \tag{2.169}$$

$$2.\ \sum_{i=1}^{2}\psi_i^{(e)}(x)=1 \tag{2.170}$$

Selecting $\phi = \psi_i$ and substituting the approximate solution into the weak formulation, one obtains the local Galerkin finite element equation,

$$-\sum_{j=1}^{n}\left[\int_{x_1}^{x_2}\left(a\frac{d\psi_i}{dx}\frac{d\psi_j}{dx}+q\psi_i\psi_j\right)dx-\frac{a(x_2)\beta_2}{\alpha_2}\psi_i(x_2)\psi_j(x_2)+\frac{a(x_1)\beta_1}{\alpha_1}\psi_i(x_1)\psi_j(x_1)\right]y_j^{(e)}\cdots$$

$$-\int_{x_1}^{x_2} f\psi_i dx+\frac{a(x_2)\psi_i(x_2)\gamma_2}{\alpha_2}-\frac{a(x_1)\psi_i(x_1)\gamma_1}{\alpha_1}$$

The above equation may be written in matrix form with the following matrix elements:

$$K_{11}^{(e)} = \int_{x_1}^{x_2} \left(a \frac{d\psi_1}{dx} \frac{d\psi_1}{dx} + q\psi_1\psi_1 \right) dx + \frac{a(x_1)\beta_1}{\alpha_1} \tag{2.171}$$

$$K_{12}^{(e)} = K_{21}^{(e)} = \int_{x_1}^{x_2} \left(a \frac{d\psi_1}{dx} \frac{d\psi_2}{dx} + q\psi_1\psi_2 \right) dx \tag{2.172}$$

$$K_{22}^{(e)} = \int_{x_1}^{x_2} \left(a \frac{d\psi_2}{dx} \frac{d\psi_2}{dx} + q\psi_1\psi_1 \right) dx - \frac{a(x_2)\beta_1}{\alpha_2} \tag{2.173}$$

$$F_1^{(e)} = -\int_{x_1}^{x_2} f\psi_1 dx - \frac{a(x_1)\gamma_1}{\alpha_1} \tag{2.174}$$

$$F_2^{(e)} = -\int_{x_1}^{x_2} f\psi_2 dx + \frac{a(x_2)\gamma_2}{\alpha_2} \tag{2.175}$$

2.10 PARTIAL DIFFERENTIAL EQUATIONS

A partial differential equation in a function z(x,y) of two independent variables x and y may be represented in general by the implicit equation

$$F(x, y, z, z_x, z_y, \ldots) = 0$$

where

$$z_x \equiv \frac{\partial z}{\partial x} \text{ and } z_y \equiv \frac{\partial z}{\partial y}$$

are partial derivatives. If only first derivatives are involved, the equation is referred to as a first order partial differential equation. If higher derivatives are involved, one has higher order partial differential equations. If the function F is linear in the dependent variable z and its derivatives, it is referred to as a linear partial differential equation. If it is nonlinear with respect to z, we have a *quasilinear* partial differential equation.

2.10.1 First-Order Partial Differential Equations

We consider a first-order partial differential equation in a function z of two variables x and y. The quasilinear partial differential equation is given by

$$a(x, y, z)\frac{\partial z(x, y)}{\partial x} + b(x, y, z)\frac{\partial z(x, y)}{\partial y} = c(x, y, z) \tag{2.176}$$

that must be solved subject to the specification of z on some initial curve represented parametrically by $x = f(s)$, $y = g(s)$, and $z = h(s)$. The method of characteristics reduces the partial differential

equation to a system of ordinary differential equations and proceeds as follows. We define a characteristic direction on the plane $x - y$ by the differential equations

$$\frac{\partial x}{\partial t} = a(x,y,z), \quad \frac{\partial y}{\partial t} = b(x,y,z), \quad \frac{\partial z}{\partial t} = c(x,y,z) \tag{2.177}$$

the third of which follows from substituting the first two into the partial differential Equation (2.176). The ordinary differential equations are solved subject to the initial conditions $x(0,s) = f(s)$, $y(0,s) = g(s)$, $z(0,s) = h(s)$. The ordinary differential Equations (2.177) are solved by the methods used for ordinary differential equations to obtain the solution $x(t,s)$, $y(t,s)$, $z(t,s)$. The entire solution surface is generated by varying the parameter s over the range of the initial curve. If it is desired to get the solution in the form $z = Z(x,y)$, then we must invert (t,s) to obtain x,y. We consider the following example, from Rhee et al. (1986).

Example 2.8

The dynamics of a plug-flow reactor with a fluid velocity, v, and the first-order reaction kinetics is governed by

$$\frac{\partial c}{\partial t} + v\frac{\partial c}{\partial x} = -kc$$

$$c(x,0) = f(x), \quad c(0,t) = g(t)$$

The characteristic equations are

$$\frac{dt}{dx} = 1$$

$$\frac{dx}{ds} = v$$

$$\frac{dc}{ds} = -kc$$

Figure 2.1 shows the space-time domain divided by the line $x = vt$ into two regions, $x > vt$ and $x < vt$. For the characteristic lines in the region $x > vt$, the characteristics intersect the x-axis on which the initial condition is specified. The initial condition is parameterized by ξ:

$$t = 0, \quad x = \xi, \quad c = f(\xi) \quad \text{for } s = 0$$

In the region $x < vt$, feed condition is used:

$$x = 0, \quad t = \eta, \quad c = g(\eta) \quad \text{for } s = 0$$

For $x > vt$, the characteristic line emanating from the condition $t = 0$, $x = \xi$ is $f(\xi)$, and integration from $t = 0$ to $t = s$ gives

$$t = s, \quad x = vs + \xi, \quad c(s,\xi) = f(\xi)\exp(-ks)$$

Eliminating s and ξ from the initial and boundary conditions,

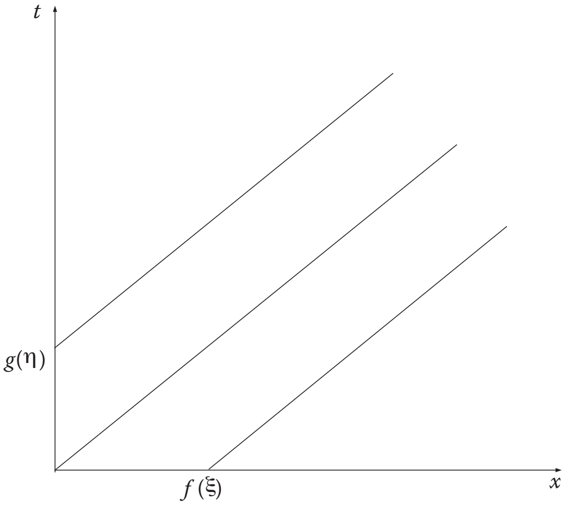


FIGURE 2.1 Characteristic plane for integration of plug-flow reactor.

$$c(x,t) = f(x - vt)\exp(-kt), \quad \text{for } x > vt$$

For $x < vt$, the characteristic line evolving from the condition $x = 0$, $t = \eta$ is represented by $g(\eta)$. Thus,

$$t = s + \eta, \quad x = vs, \quad c(s,\eta) = g(\eta)\exp(-ks)$$

Eliminating s and η in terms of x and t gives

$$c(x,t) = g\left(t - \frac{x}{v}\right)\exp\left(-\frac{kx}{v}\right) \quad \text{for } x < vt$$

The above can be generalized for n variables, as below (John, 1986). Given a first-order partial differential equation in n variables,

$$\sum_{i=1}^{n} a_i(x_1, x_2, \ldots, x_n, z) z_{x_i} = c(x_1, x_2, \ldots, x_n, z)$$

The characteristic curves in $x_1, x_2, \ldots, x_n, z$ are given by

$$\frac{dx_i}{dt} = a_i(x_1, x_2, \cdots, x_n, z) \quad \text{for } i = 1, \cdots, n$$

$$\frac{dz}{dt} = c(x_1, x_2, \cdots, x_n, z)$$

x_i and z satisfy the *initial conditions* in $n - 1$ dimensions given parametrically,

$$x_i = f_i(s_1, \ldots, s_{n-1}, t), \quad \text{for } i = 1, \ldots, n$$

$$z = h(s_1, \ldots, s_{n-1})$$

The solution of the characteristic equations is parametrically represented by

$$x_i = f_i(s_1,\cdots,s_{n-1},t), \quad \text{for } i = 1,\cdots,n$$

$$z = Z(s_1,\cdots,s_{n-1},t)$$

These equations form a parametric representation for the integral surface $z = z(x_1,\ldots,x_n)$, provided that the parametric variables in the initial conditions can be inverted to obtain $(s_1,\ldots,s_{n-1},t)$ as functions of $(x_1,\ldots,x_n)$. This is the case when the Jacobian

$$J = \begin{vmatrix} \dfrac{\partial f_1}{\partial s_1} & \cdots & \dfrac{\partial f_n}{\partial s_1} \\ \vdots & \cdots & \vdots \\ \dfrac{\partial f_1}{\partial s_{n-1}} & \cdots & \dfrac{\partial f_n}{\partial s_{n-1}} \\ a_1 & \cdots & a_n \end{vmatrix}$$

does not vanish.

2.10.2 Classification of Second-Order Equations

Second-order equations are classified into different types, depending on the coefficients of the second-order derivatives. The auxiliary conditions to determine a unique solution depend on the type of equation. Auxiliary conditions specified incorrectly with the type of equation lead to an ill-posed problem that may not reflect physical reality.

The general second-order partial differential equation in n-variables is written as

$$\sum_{i=1}^{n}\sum_{k=1}^{n} a_{ik}(x_1,x_2,\ldots x_n)\frac{\partial^2\Phi}{\partial x_i \partial x_k} + B\frac{\partial^2\Phi}{\partial t^2} + C\left(x_1,\ldots,x_n;\Phi;\frac{\partial\Phi}{\partial x_1},\ldots,\frac{\partial\Phi}{\partial x_n}\right) = 0 \tag{2.178}$$

The equation is elliptic if and only if $B = 0$ and is hyperbolic if and only if $B < 0$. If $B = 0$ and the matrix $[a_{ik}]$ is nonnegative definite, the equation is parabolic.

For hyperbolic and parabolic equations, the conditions on $(x_1,x_2,\ldots,x_n)$ are prescribed on the boundary of the region, and the conditions on t must be prescribed at $t = 0$. These equations are often referred to as evolution equations. These equations describe the time evolution of a process from a given initial configuration.

As a consequence of the evolutionary nature of the hyperbolic and parabolic equations, boundary conditions are specified on the boundary of the spatial variables, and initial conditions are specified on the time variable, t.

Elliptic equations describe steady-state or equilibrium processes. For such equations, all auxiliary conditions must be prescribed on the boundary of the region of interest. Initial conditions given to elliptic equations lead to ill-posed problems. Solutions to these ill-posed problems exhibit sensitivity to the initial data. Small changes to the initial data cause large changes in the solution.

There are three kinds of boundary conditions for elliptic equations. If the values of the unknown function are prescribed on the boundary, then the problem is called the Dirichlet problem. If the derivatives of the unknown function are prescribed on the boundary, then it is called the Neumann problem. If a linear combination of the function values and the derivatives is specified, then it is called the Robin problem.

The methods for solving a second-order partial differential equation are separation of variables, similarity variable, Laplace transform, Fourier transform, and Hankel transform. Each of the

methods is applicable to all three types of equations. However, the geometry and boundary conditions largely determine the proper application of the method of solution.

The solutions for one-dimensional parabolic and hyperbolic problems and two-dimensional elliptic problems are presented in this section. The technique for solving one-dimensional problems can be applied to solve higher-dimensional problems. An elaborate account of the physics and mathematics of the partial differential equation can be found in textbooks and monographs on partial differential equations (see, for example, Evans, 1998; and Guenther and Lee, 1996).

2.10.3 Parabolic Equations

A prototype of the parabolic equation is the diffusion equation. Diffusion equations are commonly encountered in chemical engineering processes. In the following subsections, the methods of solving one-dimensional diffusion equations are presented. These methods can be easily extended to higher-dimensional problems.

2.10.3.1 Separation of Variables

Consider a one-dimensional diffusion equation of the following form:

$$\mathcal{L}u = \left(\frac{\partial}{\partial t} - \frac{\partial^2}{\partial x^2}\right) u = 0 \quad 0 < x < 1$$

$$u(x,0) = u_0(x), \quad u(0,t) = u(1,t) = 0$$

The method of separation of variables is applicable for linear homogeneous equations, i.e., $\mathcal{L}(u + v) = \mathcal{L}u + \mathcal{L}v$, $\mathcal{L}(\alpha u) = \alpha\mathcal{L}u$, in a finite domain. The method of separation of variables assumes that

$$u(x,t) = U(x)T(t)$$

Substituting into the equation gives

$$\frac{T'(t)}{T(t)} = \frac{X''(x)}{X(x)}$$

$$T(0) = u_0(x), \quad X(0) = X(1) = 0$$

that shows that the ratios of the unknown functions must be constant:

$$\frac{T'}{T} = -\lambda^2 = \frac{X''}{X}$$

Thus,

$$X(x) = A\sin(\lambda x) + B\cos(\lambda x)$$

$$X(0) = 0 \Rightarrow B = 0, \quad X(1) = 0 \Rightarrow \lambda = n\pi$$

Because the equation is linear, the principle of superposition applies, i.e., the sum of linearly independent solutions is also a solution. Thus a general solution is

$$u(x,t) = \sum_{n=1}^{\infty} A_n \sin(n\pi x)\exp(-n^2\pi^2 t)$$

The expression for the coefficient A_n can be obtained as follows. The initial condition gives

$$u(x,0) = u_0(x) = \sum_{n=1}^{\infty} A_n \sin(n\pi x)$$

Multiplying the above equation by $\sin(m\pi x)$ and integrating over (0,1) gives

$$A_n = 2\int_0^1 u_0(x)\sin(n\pi x)dx$$

The answer is obtained by making use of the orthogonal property,

$$2\int_0^1 \sin(n\pi x)\sin(m\pi x)dx = \delta_{m,n}, \quad \text{where } \delta_{m,n} \text{ is the Kronecker delta}$$

The method of separation of variables is applicable for higher-order and higher-dimensional equations, but it requires that the equation and boundary conditions be homogeneous in a finite domain.

2.10.3.2 Inhomogeneous Equation, Duhamel's Principle

Duhamel's principle helps to represent solutions to inhomogeneous initial boundary-value problems in terms of the solutions to homogeneous problems. The solution of the inhomogeneous equation,

$$\frac{\partial u}{\partial t} = \frac{\partial u^2}{\partial x^2} + h(x,t) \tag{2.179}$$

subjected to boundary conditions

$$u(0,t) = u(1,t) = u(x,0) = 0$$

is given by

$$u(x,t) = \int_0^t v(x,t-\tau;\tau)d\tau \tag{2.180}$$

where $v(x,t;\tau)$ is the solution of the following homogeneous equation:

$$\frac{\partial v}{\partial t} = \frac{\partial^2 v}{\partial x^2}$$

$$v(0,t;\tau) = v(1,t;\tau) = 0$$

$$v(x,0;\tau) = h(x,\tau)$$

the solution of which clearly follows:

$$v(x,t,\tau)=2\sum_{n=1}^{\infty}\sin(n\pi x)\int_0^1 h(x',\tau)\sin(n\pi x')dx' e^{-n^2\pi^2 t}$$

Duhamel's principle can be confirmed from the fact that it yields the nonhomogeneous equation starting from the solution itself, as follows:

$$\frac{\partial u}{\partial t}=v(x,0,t)+\int_0^t \frac{\partial u}{\partial t}(x,t-\tau,\tau)d\tau$$

$$\frac{\partial u}{\partial t}=h(x,t)+\int_0^t \frac{\partial u}{\partial t}(x,t-\tau,\tau)d\tau$$

$$\frac{\partial^2 u}{\partial x^2}=\int_0^t \frac{\partial^2 u}{\partial x^2}(x,t-\tau,\tau)d\tau=\int_0^t \frac{\partial u}{\partial t}(x,t-\tau,\tau)d\tau$$

$$\frac{\partial^2 u}{\partial x^2}=\frac{\partial u}{\partial t}-h(x,t)$$

that is the nonhomogeneous equation.

Use of Equation (2.180) gives

$$u(x,t)=\int_0^t 2\sum_{n=1}^{\infty}\sin(n\pi x)\int_0^1 h(x',\tau)\sin(n\pi x')e^{-n^2\pi^2(t-\tau)}dx'd\tau$$

Thus the solution of the inhomogeneous equation

$$\frac{\partial u}{\partial t}=\frac{\partial^2 u}{\partial x^2}+h(x,t)$$

$$u(0,t)=u(1,t)=0$$

$$u(x,0)=u_0(x)$$

is obtained by the superposition principle (i.e., a linear combination of solutions to the linear system is also a solution to the same linear system):

$$u(x,t)=\sum_{n=1}^{\infty}A_n\sin(n\pi x)\exp(-n^2\pi^2 t)+\int_0^t\sum_{n=1}^{\infty}B_n(\tau)\sin(n\pi x)\exp[-n^2\pi^2(t-\tau)]d\tau$$

where

$$A_n=2\int_0^1 u_0(x)\sin(n\pi x)dx$$

$$B_n(\tau)=2\int_0^1 h(x,\tau)\sin(n\pi x)dx$$

2.10.3.3 Inhomogeneous Boundary Conditions

Generally, the initial boundary-value problem given by

$$\frac{\partial u}{\partial t}=\frac{\partial^2 u}{\partial x^2}$$

$$u(x,0)=u_0(x),\quad u(0,t)=a(t),\quad u(1,t)=b(t)$$

is solved by letting $u(x,t) = v(x,t) + w(x,t)$ such that v(0,t) = $v(1,t) = 0$. Thus, $w(0,t) = a(t)$, $w(1,t) = b(t)$. The simplest function $w(x,t)$ that satisfies the boundary conditions is

$$w(x,t)=[b(t)-a(t)]x+a(t)$$

Substitution for $u(x,t)$ into the equation gives

$$\frac{\partial v}{\partial t}=\frac{\partial^2 v}{\partial x^2}+[a'(t)-b'(t)]x-a'(t)$$

$$v(0,t)=v(1,t)=0$$

$$v(x,0)=u_0(x)+[a(0)-b(0)]x-a(0)$$

The solution of the transformed equation can then be easily obtained using Duhamel's principle with $h(x,t) = [a'(t) - b'(t)]x - a'(t)$.

The methods presented here can be neatly integrated into the subject of linear operators (Ramkrishna and Amundson, 1985), extending considerably the variety of problems that can be solved. For the solution using the method of Fourier transforms, the reader is referred to Varma and Morbidelli (1997).

2.10.3.4 Similarity Solutions

The equation suggests a similarity solution when there is no characteristic length scale, i.e., the domain is either a semi-infinite or infinite region. Consider the diffusion equation in a positive real line:

$$\frac{\partial u}{\partial t}=\frac{\partial^2 u}{\partial x^2},\quad 0<x<\infty$$

$$u(x,0)=0,\quad u(0,t)=u_0(t)$$

Let the transformed variable be $\eta = y/(2\sqrt{t})$ and hence $u(x,t)=\Theta(t)F(\eta)$. Such a scaling behavior is typical of diffusion processes:

$$\frac{\partial u}{\partial x}=\frac{\partial u}{\partial \eta}\frac{\partial \eta}{\partial x}=\Theta F'(\eta)\frac{1}{2\sqrt{t}};\quad \frac{\partial^2 u}{\partial x^2}=\Theta F''(\eta)\frac{1}{4t}$$

and

$$\frac{\partial u}{\partial t} = \Theta' F + \Theta F' \frac{\partial \eta}{\partial t} = \Theta' F + \Theta F' \left(-\frac{\eta}{2t} \right)$$

Substituting the transformed variables into the diffusion equation yields

$$\Theta(F'' + 2\eta F') = 4t\Theta' F$$

If $\Theta(t) = ct^n$, then the equation becomes

$$F'' + 2\eta F' - 4nF = 0, \quad F(0) = 1, \quad F(\infty) = 0$$

that is a linear second-order ordinary differential equation. The solution $F_n(\theta)$, depending on the exponent n, is given by

$$F_n(\theta) = \frac{2}{\sqrt{\pi}} \int_\theta^\infty \left(1 - \frac{\theta^2}{s^2} \right)^n \exp(-s^2) ds$$

For each $n = 1,2,\ldots$, $F_n(\eta)$ also satisfies the original diffusion equation. By the superposition principle for linear equations,

$$u(x,t) = \sum_{n=0}^{\infty} a_n t^n F_n\left(\frac{x}{2\sqrt{t}} \right)$$

is a solution. Applying the remaining condition at $x = 0$,

$$u(0,t) = u_0(t) = \sum_{n=0}^{\infty} a_n t^n$$

Assuming that $u_0(t)$ is analytic, a_n can be evaluated using power series expansion.

2.10.3.5 Inhomogeneous Equation in Infinite Domain

Consider the temperature distribution in an infinite rod governed with the heat source described by the equation

$$\frac{\partial u}{\partial t} = \frac{\partial^2 u}{\partial x^2} + h(x,t), \quad -\infty < x < \infty$$

$$u(x,0) = u_0(x)$$

The problem is solved by superimposing the solutions

$$u = v_1 + v_2$$

where $v_1(x,t)$ is the solution of

$$\frac{\partial v_1}{\partial t} = \frac{\partial^2 v_1}{\partial x^2}, \quad -\infty < x < \infty$$

$$v_1(x,0) = u_0(x)$$

and $v_2(x,t)$ satisfies

$$\frac{\partial v_2}{\partial t} = \frac{\partial^2 v_2}{\partial x^2} + h(x,t), \quad -\infty < x < \infty$$

$$v_2(x,0) = 0$$

For the inhomogeneous equation,

$$\frac{\partial v}{\partial t} = \frac{\partial^2 v}{\partial x^2} + h(x,t), \quad 0 < x < \infty$$

$$v(0,t) = a(t)$$

$$v(x,0) = u_0(x)$$

the solution is given with the use of Duhamel's principle (Section 2.10.3.2):

$$v(x,t) = u_h(x,t) + \int_0^t \int_0^\infty [k(x-s,t-\tau) - k(x+s,t-\tau)]h(s,\tau)dsd\tau$$

where $u_h(x,t)$ is the solution of the homogeneous equation, and $k(x,t)$ is the fundamental solution.

2.10.4 Hyperbolic Equations

A prototype of a hyperbolic equation is the wave equation. The wave equation governs many physical phenomena such as the propagation of sound waves, water waves, vibration of a membrane in a two-dimensional setting, and vibration of a string in a one-dimensional setting.

2.10.4.1 d'Alembert's Solution

The one-dimensional wave equation in an infinite domain can be solved by a change of independent variables to reduce the wave equation that can be integrated to produce d'Alembert's solution. Consider a one-dimensional wave equation,

$$\frac{\partial^2 u}{\partial t^2} = \frac{\partial^2 u}{\partial x^2}, \quad -\infty < x < \infty$$

$$u(x,0) = f(x) \tag{2.181}$$

$$\frac{\partial u(x,0)}{\partial t} = g(x)$$

Let $\xi = x - t$ and $\eta = x + t$. Then the equation is transformed to

$$\frac{\partial^2 u}{\partial \xi \partial \eta} = 0$$

The general solution is given by

$$u(x,t) = F(x-t) + G(x+t)$$

Applying the initial conditions,

$$F(x) + T(x) = f(x)$$

$$-F'(x) + G'(x) = g(x)$$

Solving the above system for F and G gives

$$F(x-t) = \frac{1}{2} f(x-t) - \frac{1}{2}\int_0^{x-t} g(s)ds$$

$$G(x+t) = \frac{1}{2} f(x+t) + \frac{1}{2}\int_0^{x+t} g(s)ds$$

Therefore

$$u(x,t) = \frac{1}{2}[f(x-t) + f(x+t)] + \frac{1}{2}\int_{x-t}^{x+t} g(s)ds$$

For an inhomogeneous linear equation,

$$\frac{\partial^2 u}{\partial t^2} = \frac{\partial^2 u}{\partial x^2} + h$$

$$u(x,0) = f(x)$$

$$\frac{\partial u(x,0)}{\partial t} = g(x)$$

The solution is obtained by defining

$$u(x,t) = v(x,t) + w(x,t)$$

where $v(x,t)$ is the solution of Equation (2.181) and $w(x,t)$ satisfies

$$\frac{\partial^2 w}{\partial t^2} = \frac{\partial^2 w}{\partial x^2}, \quad -\infty < x < \infty$$

$$w(x,0) = 0$$

$$\frac{\partial w(x,0)}{\partial t} = 0$$

Defining $\xi = x - t$ and $\eta = x + t$ transforms the above equation to

$$\frac{\partial^2 u}{\partial\xi\partial\eta} = -\frac{1}{4}h\left(\frac{1}{2}(\xi+\eta), -\frac{1}{2}(\xi-\eta)\right)$$

$$w(s,s) = \frac{\partial w(s,s)}{\partial\xi} = \frac{\partial w(s,s)}{\partial\eta} = 0$$

the solution of which is

$$w(x,t) = \frac{1}{2}\int_0^t \int_{x-t}^{x+t} h(y,z)dydz$$

Therefore, the solution of the inhomogeneous wave equation is given by

$$u(x,t) = \frac{1}{2}[f(x-t)+f(x+t)] + \frac{1}{2}\int_{x-t}^{x+t} g(s)ds + \frac{1}{2}\int_0^t \int_{x-t+\tau}^{x+t+\tau} h(y,z)dydz$$

2.10.4.2 Separation of Variables

Consider a one-dimensional inhomogeneous equation

$$\frac{\partial^2 u}{\partial t^2} = \frac{\partial^2 u}{\partial x^2} + h$$

subjected to the boundary conditions

$$u(0,t) = a(t)$$

$$u(1,t) = b(t)$$

$$u(x,0) = f(x)$$

$$\frac{\partial u(x,0)}{\partial t} = g(x)$$

Let $u(x,t) = v(x,t) + x[b(t) - a(t)] + a(t)$, where $v(x,t)$ satisfies

$$\frac{\partial^2 v}{\partial t^2} = \frac{\partial^2 v}{\partial x^2} + h - x[b''(t) - a''(t)] - a''(t)$$

$$v(0,t) = v(1,t) = 0$$

$$v(x,0) = f(x) - x[b(0) - a(0)] - a(0)$$

$$\frac{\partial v(x,0)}{\partial t} = g(x) - x[b'(0) - a'(0)] - a'(0)$$

The problem for $v(x,t)$ is solved by defining

$$v(x,t) = v_1(x,t) + v_2(x,t)$$

where $v_1(x,t)$ is the solution of

$$\frac{\partial^2 v_1}{\partial t^2} = \frac{\partial^2 v_1}{\partial x^2}$$

$$v_1(0,t) = v_1(1,t) = 0$$

$$v_1(x,0) = f(x) - x[b(0) - a(0)] - a(0)$$

$$\frac{\partial v_1(x,0)}{\partial t} = g(x) - x[b'(0) - a'(0)] - a'(0)$$

that is solved by letting $v_1(x,t) = X(x)T(t)$. The equation becomes

$$X'' = -\lambda^2 X$$

$$X(0) = X(1) = 0$$

$$X(x) = C_1 \sin(\lambda x) + C_2 \cos(\lambda x)$$

$$X(0) = 0 = C_2$$

$$X(1) = 0 \Rightarrow \lambda = n\pi$$

$$T'' = -\lambda^2 T$$

$$T_n(t) = A_n \sin(n\pi t) + B_n \cos(n\pi t)$$

The general solution is

$$v_1(x,t) = \sum_{n=1}^{\infty} [A_n \sin(n\pi t) + B_n \cos(n\pi t)] \sin(n\pi x)$$

where

$$B_n = 2\int_0^1 \{f(x) - x[b(0) - a(0)] - a(0)] \sin(n\pi x) dx$$

$$A_n = \frac{2}{n\pi}\int_0^1 \{g(x) - x[b'(0) - a'(0)] - a'(0)\} \sin(n\pi x) dx$$

and $v_2(x,t)$ is the solution of

$$\frac{\partial^2 v_2}{\partial t^2} = \frac{\partial^2 v_2}{\partial x^2} + h - x[b''(t) - a''(t)] - a''(t)$$

$$v_2(0,t) = v_2(1,t) = v_2(x,0) = 0$$

$$\frac{\partial v_2(x,0)}{\partial t} = 0$$

which is solved by Duhamel's principle (Section 2.10.3.2), which states that the solution of the inhomogeneous equation is given by

$$v_2(x,t) = \int_0^t w(x, t-\tau, \tau) d\tau$$

where $w(x,t)$ satisfies

$$\frac{\partial^2 w}{\partial t^2} = \frac{\partial^2 w}{\partial x^2}$$

$$w(0,t,\tau) = w(1,t,\tau) = w(x,0,\tau) = 0$$

$$\frac{\partial w(x,0,\tau)}{\partial t} = h(x,\tau) - x[b''(\tau) - a''(\tau)] - a''(\tau)$$

The solution is given by

$$w(x,t,\tau) = \sum_1^{\infty} C_n(\tau) \sin(n\pi t) \sin(n\pi x)$$

where

$$C_n(\tau) = \frac{2}{n\pi} \int_0^1 \{h(x,\tau) - x[b''(\tau) - a''(\tau)] - a''(\tau)\} \sin(n\pi x) dx$$

Thus the solution of the inhomogeneous equation is given by

$$u(x,t) = x[b(t) - a(t)] + a(t) + \sum_{n=1}^{\infty} [A_n \sin(n\pi t) + B_n \cos(n\pi t)] \sin(n\pi x) +$$

$$\int_0^t \sum_{n=1}^{\infty} C_n(\tau) \sin(n\pi(t-\tau)) \sin(n\pi x) d\tau$$

2.10.5 Elliptic Equations

A prototype of the elliptic equation is the Laplace equation. The Laplace equation describes the steady-state distribution of energy or matter inside the domain given the distribution on the boundary. The dynamics of a given process may or may not come to a steady state. If the dynamics does not lead to an equilibrium, then the solution does not exist. Consider the steady-state temperature distribution in a unit cube governed by the following Poisson's equation:

$$\nabla^2 u = f(x,y,z), \quad (x,y,z) \in \mathcal{D}$$

where $\mathcal{D}$ is the domain of the region. The general boundary condition is written as

$$-\alpha\frac{\partial u}{\partial n}+Bu=\gamma(x,y,z)\in\beta$$

When $\alpha = 0$, the boundary condition is called the Dirichlet boundary condition; when $\beta = 0$, it is called the Neumann boundary condition. Otherwise, it is known as the Robin boundary condition. When $\gamma \neq 0$, the boundary condition is homogeneous. Otherwise, it is inhomogeneous. When $\alpha = 0$ and $\beta \neq 0$, u on the boundary is known and is described by γ. When $\alpha \neq 0$ and $\beta = 0$, the derivative is described on the boundary, and u on the boundary is the unknown that must be solved. When both $\alpha \neq 0$ and $\beta \neq 0$, both the u and its derivative are unknown.

The elliptic equation describes a steady-state or an equilibrium process within the region. Physically, steady state is not attained unless the net rate of generation is balanced with the net flux into the region. The physics is manifested in the existence of the solution. Thus, the elliptic equation does not admit a solution unless the condition for the existence of a steady state is satisfied.

For $\beta = 0$, the condition for the existence of a solution of the Poisson equation is

$$\int_{\mathcal{B}}\gamma dS=\int_{\mathcal{D}}f(x,y,z)dxdydz$$

The physical interpretation of the above condition is that, at steady state, the generation must be balanced by the efflux.

2.10.5.1 Poisson Integral Formula

Consider the Laplace equation

$$\nabla^2 u=\frac{1}{r}\frac{\partial}{\partial r}\left(r\frac{\partial u}{\partial r}\right)+\frac{1}{r^2}\frac{\partial^2 u}{\partial\theta^2}=0,\quad 0\le r<1,\quad 0\le\theta\le 2\pi$$

$$u(1,\theta)=f(\theta)$$

Assume that $u(r,\theta) = R(r)\Theta(\theta)$. Substituting into the equation and rearranging, we get

$$\frac{r^2R''+rR'}{R}=-\frac{\Theta''}{\Theta}=\lambda^2$$

The solution is given by

$$\Theta(\theta)=A\cos(\lambda\theta)+B\sin(\lambda\theta)$$

To determine the value of λ, the condition of periodicity is imposed:

$$\Theta(\theta+2\pi)=\Theta(\theta)$$

Thus $\lambda = n$, $n = 0,2,4,\ldots$. The solution for R is

$$R(r)=Cr^n+Dr^{-n}$$

To ensure that the solution is finite at $r = 0$, $D = 0$. Thus, by the superposition principle, the general solution is given by

$$u(r,\theta) = \frac{a_0}{2} + \sum_{n=1}^{\infty} r^n (a_n \cos(n\theta) + b_n \sin(n\theta))$$

where

$$a_n = \frac{1}{\pi}\int_0^{2\pi} f(\theta)\cos(n\theta)d\theta, \quad b_n = \frac{1}{\pi}\int_0^{2\pi} f(\theta)\sin(n\theta)d\theta$$

Substituting a_n and b_n into the solution, we get

$$u(r,\theta) = \frac{1}{\pi}\int_0^{2\pi}\left\{\frac{1}{2} + \sum_{n=1}^{\infty} r^n[\cos(n\theta)\cos(n\phi) + \sin(n\theta)\sin(n\phi)]\right\} f(\phi)d\phi$$

$$= \frac{1}{\pi}\int_0^{2\pi}\left\{\frac{1}{2} + \sum_{n=1}^{\infty} r^n \cos[n(\phi-\theta)]\right\} f(\phi)d\phi$$

$$= \frac{1-r^2}{2\pi}\int_0^{2\pi}\frac{f(\phi)d\phi}{1-2r\cos(\phi-\theta)+r^2}$$

that is obtained by summing the series in the braces.

The solution of the Laplace equation in a unit sphere with $f(\theta,\phi)$ prescribed on the surface of the sphere is given by

$$u(r,\theta,\phi) = \frac{1}{4\pi}\int_0^{2\pi}\int_0^{\pi}\frac{(1-r^2)f(\theta',\phi')}{(1-2r\cos\Theta+r^2)^{3/2}}\sin\phi' d\phi' d\theta'$$

where

$$\cos\Theta = \cos\phi\cos\phi' + \sin\phi\sin\phi'\cos(\theta-\theta')$$

2.10.5.2 Green's Function

The solution of the Poisson equation

$$\nabla^2 u = h, \quad 0 \le r \le 1, \quad 0 \le \theta \le 2\pi$$

$$u(1,\theta) = 0$$

is given by

$$u(r,\theta) = \int_0^1\int_0^{2\pi} G(r,\theta;\rho,\phi)h(\rho,\phi)\rho d\rho d\phi$$

where the Green's function is given by

$$G(r,\theta;\rho,\phi)=\frac{1}{4\pi}\log[1+r^2\rho^2-2r\rho\cos(\theta-\phi)]-\frac{1}{4\pi}\log[r^2+\rho^2-2r\rho\cos(\theta-\phi)]$$

Generally, the equation

$$\nabla^2 u=h,\quad 0\le r<1,\quad 0\le\theta\le 2\pi$$

$$u(1,\theta)=f(\theta)$$

is solved by letting $u = v + w$, where $v(r,\theta)$ is solved by the Poisson integral formula and $w(r,\theta)$ is solved by the Green's function.

The Fourier transform can be used to solve the Dirichlet problem in the infinite domain, and the Fourier sine transform can be used in the semi-infinite domain. The Fourier cosine transform is appropriate for the Neumann problem in the semi-infinite domain.

2.10.6 Computational Fluid Mechanics

The governing equations of fluid flows are seldom analytically solved. Often, the analytical solutions involve restricted assumptions and approximations. Hence, many engineering problems involving fluid flows must be solved numerically.

***Software**: In view of the rigor involved in numerical solution, many commercial software packages have been developed that serve the purpose of computational fluid dynamics (CFD). Appendix 2.A gives a listing of sources for various commercial as well as free CFD codes. These CFD codes may be broadly categorized into either finite volume method based or finite element method based. For a detailed account of computational methods, see the books by Patankar (1980), Ferziger and Peric (2002), Ranade (2002), Chen (2005), Reddy (2005), and so forth.*

2.11 INTEGRAL EQUATIONS

Mathematical models of physical processes yield differential equations when changes brought about in the system arise from purely local effects. Thus diffusion, convection, etc., contribute to local changes alone. However, there are many processes in which changes are brought about by cumulative contributions from afar. Examples are radiative heat transport; transport of mass, momentum, and energy between particles and the continuous phase in a dispersed phase system; and so on. Integral equations arise from the modeling of such systems. The methods for solving integral equations are presented in the following subsections with illustrative examples.

There are two classes of integral equations, Fredholm and Volterra. In the following subsections, the methods for solving each class of integral equations are presented.

2.11.1 Volterra Integral Equations

Volterra integral equations are of the following forms:

$$\int_a^x K(x,y)u(y)dy=f(x) \qquad (2.182)$$

$$u(x)-\lambda\int_a^x K(x,y)u(y)dy = f(x) \tag{2.183}$$

$$p(x)u(x)-\lambda\int_a^x K(x,y)u(y)dy = f(x) \tag{2.184}$$

The first equation is known as a Volterra equation of the first kind, and the last two are of the second and the third kinds, respectively. An integral equation of the third kind can be transformed into an integral equation of the second kind if $p(x) \neq 0$.

Differentiating the integral equation of the first kind with respect to the independent variable x yields (under suitable continuity and differentiability conditions on various functions in the integral equation)

$$\frac{df}{dx} = \lambda\int_0^x \frac{\partial K(x,y)}{\partial x}u(y)dy + \lambda K(x,x)u(x) \tag{2.185}$$

If $K(x,x) \neq 0$, then the Volterra equation of the first kind can be converted to a Volterra equation of the second kind,

$$u(x)+\int_0^x H(x,t)u(t)dt = g(x)$$

where

$$g(x) \equiv \frac{1}{K(x,x)}\frac{df}{dx}, \quad H(x,t) \equiv \frac{1}{K(x,x)}\frac{\partial K(x,t)}{\partial x} \tag{2.186}$$

Volterra equations are classified as regular and singular integral equations. If $K(x,y) < \infty$, the equations are called regular; otherwise, they are defined as singular. If $f(x) = 0$, the equations are termed homogeneous.

Each type of equation is further categorized into linear and nonlinear equations based on whether or not the unknowns in the equations appear as a first power. The following is an example of a nonlinear Volterra equation:

$$u(x) = f(x)+\int_0^x K(x,y)F(u(y))dy \tag{2.187}$$

Other forms of nonlinear integral equations also arise in applications.

2.11.2 Methods of Solution for Volterra Equations

The monograph by Linz (1985) provides a good theoretical and practical treatment of Volterra integral equations. In what follows, we list the solutions in accordance with the kernel type.

2.11.2.1 Kernel Is Only a Function of Dependent Variable

For $K(x,y) = K(y)$,

$$u(x) = f(x) + \int_0^x K(y)u(y)dy \tag{2.188}$$

is equivalent to

$$\frac{du}{dx} = \frac{df}{dx} + K(x)u(x), \quad \text{with } u(0) = f(0) \tag{2.189}$$

Equation (2.189) is a first-order linear differential equation. The solution is given by

$$u(x) = f(0)\exp\left[\int_0^x K(y)dy\right] + \int_0^x \frac{df}{dt}\exp\left[\int_t^x K(y)dy\right]dt \tag{2.190}$$

2.11.2.2 Separable Kernels

For a separable kernel, $K(x,y) = P(x)Q(y)$,

$$u(x) = f(x) + P(x)\int_0^x Q(y)u(y)dy \tag{2.191}$$

The solution is given by

$$u(x) = f(x) + P(x)\int_0^x Q(y)f(y)\exp\left[\int_y^x P(s)Q(s)ds\right]dy \tag{2.192}$$

2.11.2.3 Degenerate (Finite Rank) Kernels

$$u(x) = f(x) + \sum_{i=1}^{n}\int_0^x P_i(x)Q_i(y)u(y)dy \tag{2.193}$$

The solution is

$$u(x) = f(x) + \sum_{i=1}^{n} P_i(x)\nu_i(x) \tag{2.194}$$

where $y_i(x)$ is the solution of

$$\frac{d\nu_i(x)}{dx} = Q_i(x)\left[f(x) + \sum_{j=1}^{n} P_j(x)\nu_j(x)\right], \quad \nu_i(x) = 0 \quad i = 1,2,3,\ldots,n \tag{2.195}$$

2.11.2.4 Difference Kernels

When the kernel $K(x,y)$ depends only on the difference $(x - y)$, it is termed a *difference kernel*:

$$u(x) = f(x) + \lambda \int_0^x K(x-y)u(y)dy \tag{2.196}$$

The equation is solved by Laplace transform with the help of the convolution theorem:

$$\bar{u}(s) = \frac{\bar{f}(s)}{1-\lambda\bar{K}(s)}, \quad \lambda\bar{K} \neq 1$$

where $\bar{u}(s)$, $\bar{f}(s)$, and $\bar{K}(s)$ are the Laplace transforms of $u(x)$, $f(x)$, and $K(x)$, respectively.

Inverting the transform,

$$u(x) = \mathcal{L}^{-1}\left\{\frac{\bar{f}(s)}{1-\lambda\bar{K}(s)}\right\}$$

The inversion of the right hand side above would of course depend on the specific form of K(s). The method of resolvent kernels in the section below can also be applied here.

$$u(x) = f(x) + \lambda \int_0^x K(x,y)u(y)dy$$

2.11.2.5 Method of Resolvent Kernels

$$u(x) = f(x) + \lambda \int_0^x K(x,y)f(y)dy \tag{2.197}$$

The solution of a Volterra equation is given in terms of a resolvent kernel,

$$u(x) = f(x) + \lambda \int_0^x \Gamma(x,y;\lambda)f(y)dy \tag{2.198}$$

where the resolvent kernel is given in terms of the Neumann series as

$$\Gamma(x,y;\lambda) = \sum_{i=0}^{\infty} \lambda^i K_{i+1}(x,y) \tag{2.199}$$

$$K_1(x,y) = K(x,y) \tag{2.200}$$

$$K_2(x,y) = \int_y^x K(x,s)K(s,y)ds \tag{2.201}$$

$$\vdots \tag{2.202}$$

$$K_{i+1}(x,y) = \int_y^x K(x,s)K_i(s,y)ds \tag{2.203}$$

2.11.2.6 The Generalized Abel Integral Equation

$$f(x)=\int_0^x \frac{u(y)}{(x-y)^{\alpha}}dy, \quad 0<\alpha<1 \tag{2.204}$$

Following Tricomi (1957), the solution is given by

$$u(x)=\frac{\sin\alpha\pi}{\pi}\frac{d}{dx}\int_0^x \frac{f(y)}{(x-y)^{1-\alpha}}dy=\frac{\sin(\alpha\pi)}{\pi}\left[\frac{f(0)}{x^{1-\alpha}}+\int_0^x \frac{f'(y)}{(x-y)^{1-\alpha}}dy\right] \tag{2.205}$$

2.11.2.7 Numerical Solution of Volterra Integral Equations of the Second Kind

In this section, a simple method for the numerical solution of Volterra equations of the second kind is presented. An excellent treatment for the equation of the second kind can be found in Linz (1985).

Consider the following linear Volterra equation:

$$u(x)=f(x)+\int_a^x K(x,y)u(y)dy \tag{2.206}$$

The simplest numerical method to solve Equation (2.206) is to subdivide the interval (a,x) into n equal subintervals and evaluate the integral by summing the areas of the trapezoids in each of the subintervals. Let $\Delta x = (x - a)/n$, $n \geq 1$. Then

$$\int_a^x K(x,y)u(y)dy=\Delta x\left[\frac{1}{2}(K(x,a)u(a)+K(x,x)u(x))+\sum_{i=1}^{n-1}K(x,y_i)u(y_i)\right]$$

The solution $u(x)$ is then obtained at the discrete points $x_i = a + i\Delta x$. The integral Equation (2.206) is approximated by the following system of equations:

$$u(a)=f(a)$$

$$u(x_i)=f(x_i)+\Delta x\left[\frac{1}{2}(K(x_i,a)u(a)+K(x_i,x_n)u(x_n))+\sum_{j=1}^{i-1}K(x_i,y_j)u(y_j)\right] \tag{2.207}$$

$$i=1,2,\ldots,n, \quad y_j \leq x_i$$

In Equation (2.207), it is assumed that if the final index of the summation is less than the initial index, then the summation is zero. The system Equation (2.207) constitutes a system of $n + 1$ linear equations in $n + 1$ unknowns u_i, $i = 0,1,2,\ldots,n$, which can be easily solved by back substitution.

Nonlinear Volterra equations are solved by iterative methods. Two iterative methods are presented here. One is Newton's method, and the other is the method of successive substitution.

Consider the following nonlinear Volterra equation:

$$u(x)=f(x)+\int_a^x K(x,y,u(y))dy \quad (2.208)$$

Equation (2.209) is linearized by Newton's method to give

$$u_{k+1}(x)=f(x)+\int_a^x \left\{K(x,y,u_k(y))+\frac{\partial K}{\partial u}(x,y,u_k)u_{k+1}(y)-\frac{\partial K}{\partial u}(x,y,u_k(y))u_k(y)\right\}dy \quad (2.209)$$

Successive substitution is based on the following equation:

$$u_{k+1}(x)=f(x)+\int_a^x K(x,y,u_k(y))dy \quad (2.210)$$

The trapezoidal rule is used to convert Equation (2.210) to a set of algebraic equations.

Jerry (1985) discusses the solution to the nonlinear Volterra equations. The existence of linear equations is discussed in Section 2.7.1.

2.11.3 Fredholm Integral Equations

The equations of the form

$$\int_a^b K(x,y)u(y)dy=f(x) \quad (2.211)$$

$$u(x)-\lambda\int_a^b K(x,y)u(y)dy=f(x) \quad (2.212)$$

$$a(x)u(x)-\lambda\int_a^b K(x,y)u(y)dy=f(x) \quad (2.213)$$

are called the Fredholm integral equations of the first, second, and third kinds, respectively. Every boundary-value problem can be reduced to a Fredholm equation via the Green's function. Fredholm equations can be further classified into regular and singular integral equations. If the kernel of the equation is finite everywhere in the domain of the integration, the equation is regular. Otherwise, it is singular.

2.11.4 Methods of Solution for Fredholm Equations

We list here the solutions to Fredholm integral equations in accordance with the type of kernel.

2.11.4.1 Degenerate Kernels

The kernel $K(x,y)$ is said be a degenerate kernel if it can be expressed as $\Sigma_{i=1}^n a_i(x)b_i(y)$:

$$u(x)=f(x)+\lambda\sum_{i=1}^n\int_a^b a_i(x)b_i(y)u(y)dy \quad (2.214)$$

$$= f(x)+\lambda\sum_{i=1}^{n} a_i(x)\int_a^b b_i(y)u(y)dy \tag{2.215}$$

$$u(x) = f(x)+\lambda\sum_{i=1}^{n} c_i a_i(x) \tag{2.216}$$

where

$$c_k = \int_a^b b_k(y)u(y)dy \tag{2.217}$$

Substituting Equation (2.216) in Equation (2.217) gives a linear system of equation for c_k:

$$c_k = f_k + \lambda\sum_{i=1}^{n} a_{ki}c_i, \quad k = 1,2,\ldots,n$$

where

$$f_k = \int_a^b b_k(x)f(x)dx \tag{2.218}$$

$$a_{ki} = \int_a^b b_k(x)a_i(x)dx \tag{2.219}$$

If the determinant of the matrix $\mathbf{I} - \lambda\mathbf{A}$ is zero, then either the integral equation has no solution or it has infinitely many solution.

2.11.4.2 Method of Fredholm Resolvent Kernels

The solutions of

$$u(x) = f(x)+\lambda\int_a^b K(x,y)u(y)dy$$

is given by

$$u(x) = f(x)+\lambda\int_a^b \Gamma(x,y;\lambda)f(y)dy$$

where

$$\Gamma(x,y;\lambda) = \frac{D(x,y;\lambda)}{D(\lambda)}, \quad D(\lambda) \neq 0$$

The functions $\Gamma(x,y;\lambda)$, $D(x,y;\lambda)$, and $D(\lambda)$ are the Fredholm resolvents of the kernel, Fredholm minor, and Fredholm determinant, respectively. The $D(x,y;\lambda)$ is defined as

$$D(x,y;\lambda)=\sum_{n=0}^{\infty}\frac{(-\lambda)^n}{n!}B_n(x,y)$$

where

$$B_n(x,y)=C_nK(x,y)-n\int_a^b K(x,s)B_{n-1}(s,y)\,ds,\quad B_0(x,y)=K(x,y)$$

where

$$C_n=\int_a^b B_{n-1}(y,y)\,dy,\quad n=1,2,\ldots,\quad C_0=1$$

and

$$D(\lambda)=\sum_{n=0}^{\infty}\frac{(-\lambda)^n}{n!}C_n,\quad C_0=1$$

2.11.4.3 Method of Iterated Kernels

The solution of

$$u(x)=f(x)+\lambda\int_a^b K(x,y)u(y)\,dy$$

is given by

$$u(x)=f(x)+\lambda\int_a^b \Gamma(x,y;\lambda)f(y)\,dy$$

The iterated kernel $\Gamma(x,y;\lambda)$ is defined as

$$\Gamma(x,y;\lambda)=\sum_{i=1}^{\infty}\lambda^{i-1}K_i(x,y) \tag{2.220}$$

where

$$K_1(x,y)\equiv K(x,y),\quad K_i(x,y)=\int_a^b K(x,s)K_{i-1}(s,y)\,ds$$

The series defined in Equation (2.220) is convergent for $\max|\lambda B_n|<1$, where

$$B=\sqrt{\int_a^b\int_a^b K^2(x,y)dxdy}$$

2.11.4.4 Symmetric Kernels

If the kernel is symmetric, i.e., $K(x,y) = K(y,x)$, then the eigenvalues λ_i of the integral operator, defined by

$$u_i(x)=\int_a^b K(x,y)u(y)dy$$

are real, and the corresponding eigenvectors u_i are orthogonal, i.e.,

$$\int_a^b u_i(x)u_j(x)dx=0, \quad \text{for } i\neq j$$

For square-integrable kernels

$$\int_a^b\int_a^b K^2(x,y)dxdy<\infty$$

Following Jerry (1985), the solution of the nonhomogeneous Fredholm Equation (2.210) is given by

$$u(x)=f(x)+\lambda\sum_{i=1}^{\infty}\frac{a_i u_i(x)}{\lambda_i-\lambda}$$

where

$$a_i=\int_a^b f(x)u_i(x)dx$$

and

$$u_i(x)=\lambda_i\int_a^b K(x,y)u_i(y)dy$$

2.11.4.5 Numerical Solution of Nonhomogeneous Fredholm Equation of the Second Kind

In this subsection, a simple trapezoidal rule is used to derive a numerical scheme to solve Fredholm equations of the second kind. The use of a Gaussian quadrature to approximate the integral is discussed by Press et al. (1992).

Consider the following Fredholm equation:

$$u(x) = f(x) + \int_a^b K(x,y)u(y)dy \tag{2.221}$$

The equation is solved at discrete points $\{x_i\}$, and the integral is approximated by the trapezoidal rule to give the following system of equations:

$$u(x_i) = f(x_i) + \Delta x \left\{ \frac{1}{2}[K(x_i,a)u(a) + K(x_i,b)u(b)] + \sum_{j=1}^{n-1} K(x_i,y_j)u(y_j) \right\} \tag{2.222}$$

$$i = 0,1,\ldots n$$

where $x_0 = a$, $x_n = b$, $\Delta x = (b - a)/n$. Equation (2.223) represents a system of $n + 1$ equations in $n + 1$ unknowns $\{u_i\}_{i=0}^{n}$.

For the nonlinear equation,

$$u(x) = f(x) + \int_a^b K(x,y,u(y))dy \tag{2.223}$$

The simplest way to solve Equation (2.223) is by successive substitution:

$$u_{k+1}(x) = f(x) + \int_a^b K(x,y,u_k(y))dy \tag{2.224}$$

Equation (2.224) is solved by discretizing the integral using the trapezoidal rule and iterating the resulting system of algebraic equations until convergence criteria are met.

The second method of solution is by linearization using Newton's method to give

$$u_{k+1}(x) = f(x) + \int_a^b \left\{ K(x,y,u_k(y)) + \frac{\partial K}{\partial u}(x,y,u_k(y))u_{k+1}(y) - \frac{\partial K}{\partial u}(x,y,u_k(y))u_k(y) \right\} dy \tag{2.225}$$

The trapezoidal rule is used to discretize Equation (2.225) to form a system of linear equations that is solved iteratively for a given closer initial guess of $u_0(x)$.

2.11.4.6 Solution of Ill-Posed Fredholm Equations of the First Kind

It is seen in Section 2.2.6 that Fredholm equations of the first kind arise from inverse problem formulation, i.e., the determination of model parameters from experimental measurements. Inverse problems are generally ill posed. They lack the one or more of the three properties required for reliable model predictions:

1. Existence of solution
2. Uniqueness of solution
3. Stability with respect to small perturbations in model parameters

In this subsection, the ill-posed nature of Fredholm integral equations of the first kind is demonstrated with an example equation. A technique known as *regularization* to overcome these issues is presented. The essential idea for regularization is to approximate the integral equation of

the first kind with the integral equation of the second kind, which is a well-posed problem (see Wing, 1991).

To demonstrate the ill-posed nature, consider the following equation with degenerate kernel:

$$f(x) = \int_a^b \sum_{i=1}^n \alpha_i(x)\beta_i(y)u(y)dy$$
$$= \sum_{i=1}^n \alpha_i(x) \int_a^b \beta_i(y)u(y)dy = \sum_{i=1}^n c_i\alpha_i(x) \tag{2.226}$$

where

$$c_i = \int_a^b \beta_i(y)u(y)dy$$

For a given solution $u(x)$, $u_1(x) = u(x) + cg(x)$ is also a solution for arbitrary constant c, provided that $g(x)$ satisfies

$$\int_a^b \beta_i(x)g(x)dx = 0, \quad i = 1, 2, \cdots, n$$

To solve Equation (2.226), assume that

$$u(y) = \sum_{i=1}^n u_i\beta_i(y) \tag{2.227}$$

Substitution of Equation (2.227) in Equation (2.226) gives

$$\sum_{i=1}^n c_i\alpha_i(x) = \sum_{i=1}^n \alpha_i(x) \int_a^b \left\{ \sum_{j=1}^n u_i\beta_i(y)\beta_j(y)(y) \right\} dy$$
$$= \sum_{i=1}^n \alpha_i(x) \sum_{j=1}^n u_j \int_a^b \beta_i(y)\beta_j(y)dy \tag{2.228}$$
$$= \sum_{i=1}^n \alpha_i(x) \sum_{j=1}^n a_{ij}u_j$$

where

$$a_{ij} = \int_a^b \beta_i(y)\beta_j(y)dy$$

For linearly independent functions $\alpha_i(x)$, Equation (2.230) is a system of linear equations,

$$\mathbf{Au = c}$$

to be solved for u_i, which is used in the solution Equation (2.227).

2.11.4.7 Method of Regularization

This section presents a simplified treatment of the technique of Tikhonov regularization. The idea of regularization is to convert a original ill-posed problem (which means that the error in the solution is magnified by errors in the input data) into a well-posed problem for which the error in the solution is under control. More specifically, consider the solution of the following Fredholm integral equation of the first kind.

$$\int_a^b K(x,y)u(y)dy = f(x), \text{ i.e., } Au = f$$

where A is clearly a linear integral operator. By direct solution of the above equation we imply the minimization of the norm of the residual $Au\text{-}f$. This is ill-posed because small errors in f produce large errors in the solution u. To regularize this we ask to minimize

$$J(u) = \|Au - f\| + \alpha\|u\| \tag{2.229}$$

where $\alpha > 0$. This formulation is a well-posed problem because it prevents excessive detail in the solution. It is shown (Kress, 1989) that the minimizer u_α of Equation (2.231) is the unique solution of the equation

$$\alpha u + A^*Au = A^*f \tag{2.230}$$

where

$$A^*Au = \int_a^b K(y,x)K(x,y)u(y)dy$$

and

$$A^*f = \int_a^b K(y,x)f(y)dy$$

Thus, the ill-posed problem of a Fredholm equation of the first kind is approximated by the well-posed problem of the second kind.

The error of approximation is represented by the functional $J(u)$, which depends on the regularization parameter α. There are two components in this error. One component involves $\|Au - f\|$, which is due to the solution of the ill-posed problem, while the other component involves regularization $\alpha\|u\|$. The relative importance of each term in this functional is depicted in Figure 2.2. The strategy for choosing α is to minimize the functional $J(u)$. The criterion is called the L criterion in view of the shape of the function $J(u)$.

For the inverse problems of chemical engineering interest, the reader is referred to Ramkrishna and coworkers (Sathyagal et al. (1985), Muralidhar and Ramkrishna (1989), Wright and Ramkrishna (1992), etc.).

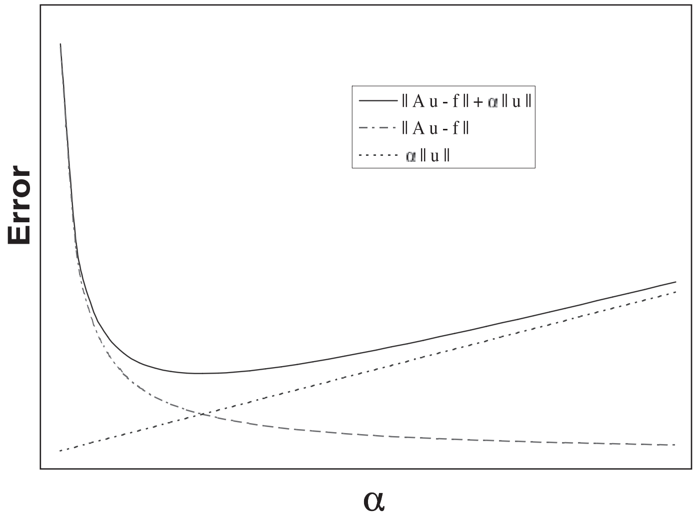

FIGURE 2.2 Total error of approximation as represented by the functional $J(u)$.

2.12 COMPLEX VARIABLES

Complex numbers owe their origin to the quest for the square root of a negative number. Thus the so-called imaginary number $i \equiv \sqrt{(-1)}$ is a fundamental element of complex numbers, written as $z = x + iy$, in which x is the *real* part and y is the *imaginary* part. Although real numbers quantify physical quantities, complex numbers provide very convenient representations of many physical phenomena. In quantum mechanics, the wave function is a complex function. Two-dimensional, incompressible, irrotational flows are represented by a complex flow potential, $w = \varphi + i\psi$, with φ, the velocity potential, as the real part, and ψ, the stream function, as the imaginary part.

2.12.1 Properties of Complex Numbers

A complex variable, $z = x + iy$, is alternatively represented as $z \equiv (x,y)$. Two complex numbers are equal if and only if their corresponding real and imaginary parts are equal. The addition, multiplication, and division of two complex numbers are given by

$$(x_1, y_1) \pm (x_2, y_2) = (x_1 \pm x_2, y_1 \pm y_2)$$

$$(x_1, y_1)(x_2, y_2) = (x_1 x_2 - y_1 y_2, y_1 y_2 + x_1 y_2)$$

and

$$\frac{(x_1, y_1)}{(x_2, y_2)} = \frac{(x_1 x_2 + y_1 y_2, x_2 y_1 - x_1 y_2)}{x_2^2 + y_2^2}, \quad \text{for } x_2^2 + y_2^2 \neq 0$$

The real number $\sqrt{x^2 + y^2}$ is called the modulus of a complex number, z. Unlike real numbers, complex numbers cannot be ordered (such as greater than or less than).

A special operation in a complex number system is

$$\bar{z} = x - iy = (x, -y)$$

The term $\bar{z}$ is said to be a complex conjugate of z. It follows that

$$z\bar{z} \equiv (x^2 + y^2, 0) = r^2 = (\text{Re}\, z)^2 + (\text{Im}\, z)^2$$

Complex numbers can also be represented in their polar form as

$$z \equiv (x, y) = re^{i\theta} = r(\cos\theta + i\sin\theta)$$

where

$$r = \sqrt{x^2 + y^2}, \quad \theta = \tan^{-1}\frac{y}{x}$$

The interpretation of r is the modulus (magnitude or the length) of the complex number, and θ (phase angle) is the argument of z, $\theta = \arg(z)$. Geometrically

$$z = re^{i\theta} = re^{i(\theta + 2n\pi)}$$

Thus $\arg(z)$ as a function should be restricted, such as

$$-\pi < \arg(z) < \pi$$

Such restriction defines the principal value of $\arg(z)$, which is denoted as $\text{Arg}(z)$:

$$\text{Arg}(z_1 z_2) = \text{Arg}(z_1) + \text{Arg}(z_2)$$

$$\text{Arg}\left(\frac{z_1}{z_2}\right) = \text{Arg}(z_1) + \text{Arg}(z_2)$$

The nth root of unity is defined as

$$z^n = 1 \Rightarrow z = \cos\left(\frac{2k\pi}{n}\right) + i\sin\left(\frac{2k\pi}{n}\right), \quad k = 1, 2, \cdots, n-1$$

2.12.2 Analytic Functions

A complex function $w = f(z)$ assigns a value of w in the complex plane to each value of z in the subset of the complex plane D. The set of complex numbers, D, is called the domain of definition of f. When the domain of definition is not specified, then it is understood that the function takes on all values of z for which f is defined. For example, the domain of $f(z) = 1/z$ is all of z such that $z \neq 0$.

Functions of a complex variable often encounter indefiniteness from being multivalued. To make a function single-valued, a function of a complex variable also includes its domain of definition.

Given a function of a complex variable $f(z)$, it is always possible to write

$$f(z) = f(x + iy) = u(x, y) + iv(x, y)$$

where $u(x,y)$ and $v(x,y)$ are real-valued functions or real variables (x,y). For example,

$$f(z)=\frac{1}{z}=\frac{1}{x+iy}=\frac{x-iy}{(x+iy)(x-iy)}=\frac{x}{x^2+y^2}-i\frac{y}{x^2+y^2}$$

Thus

$$u(x,y)=\frac{x}{x^2+y^2},\quad v(x,y)=\frac{-y}{x^2+y^2}$$

Given complex variables $z = (x,y)$, $z_0 = (x_0,y_0)$ and a function $w = f(z)$, the limit is defined as

$$\lim_{z\to z_0} f(z) = w_0 \Rightarrow \text{for a given } \varepsilon \text{ there exists a } \delta \text{ such that } |f(z)-w_0| < \varepsilon \text{ whenever } |z-z_0| < \delta$$

To be consistent, it is required that the limit of a function $f(z)$ as z tends to z_0 approaches in an arbitrary manner, not just in a particular direction. The limit is written as

$$\lim_{z\to z_0} f(z)=\lim_{(x,y)\to(x_0,y_0)} u(x,y)+i\lim_{(x,y)\to(x_0,y_0)} v(x,y)$$

A function is said to be continuous at z_0 if

$$\lim_{z\to z_0} f(z)=f(z_0)$$

For example, the function

$$f(z)=\begin{cases}\frac{1}{z}, & z\neq 0\\ 0 & z=0\end{cases}$$

is not continuous at $z_0 = 0$ because

$$\lim_{z\to 0}\neq f(0)$$

The derivative of a function $f(z)$ at z_0 is defined as

$$f'(z_0)=\lim_{z\to z_0}\frac{f(z)-f(z_0)}{z-z_0}$$

It follows that the rules of differentiation for real functions also hold for complex variables, i.e.,

The addition rule:

$$\frac{d}{dz}(f(z) \pm g(z)) = \frac{df}{dz} \pm \frac{dg}{dz}$$

The product rule:

$$\frac{d}{dz}(f(z)g(z)) = f(z)\frac{dg}{dz} + g(z)\frac{dy}{dz}$$

The quotient rule:

$$\frac{d}{dz}\frac{f(z)}{g(z)} = \frac{g(z)\frac{df}{dz} - f(z)\frac{dg}{dz}}{g^2(z)}$$

The derivative of a function of a complex variable $f(x + iy) = u(x,y) + iv(x,y)$ exists at $z_0 = (x_0,y_0)$ if and only if the following equations are satisfied:

$$\frac{\partial u}{\partial x} = \frac{\partial v}{\partial y} \quad \text{and} \quad \frac{\partial v}{\partial x} = -\frac{\partial u}{\partial y} \tag{2.231}$$

Equations (2.233) are known as Cauchy–Riemann equations. In polar coordinates, the $f(r_0e^{i\theta}) = u(r_0,\theta_0) + iv(r_0,\theta_0)$ is differentiable at (r_0,θ_0) if and only if

$$\frac{\partial u}{\partial r} = \frac{1}{r}\frac{\partial v}{\partial \theta} \quad \text{and} \quad \frac{\partial v}{\partial r} = -\frac{1}{r}\frac{\partial u}{\partial \theta} \tag{2.232}$$

It follows that the real and imaginary parts of a differentiable function are not independent, i.e., given $u(x,y)$, $v(x,y)$ can be constructed with an arbitrary constant. Given a differentiable function $f(z)$, the real and imaginary parts of f satisfy the Laplace equation:

$$\frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} = 0$$

$$\frac{\partial^2 v}{\partial x^2} + \frac{\partial^2 v}{\partial y^2} = 0$$

The $u(x,y)$ of a differentiable function $f(z)$ is also called a *harmonic function*, whereas $v(x,y)$ is called a conjugate harmonic function.

It also follows that if $f(z)$ is analytic, then the real and imaginary parts satisfy the Cauchy-Riemann equations, and it can be represented by a Taylor series in the neighborhood of z_0. A complex-valued function that is analytic in the whole complex plane is called an *entire function*. If a complex-valued function fails to be analytic at z_0 but is analytic at every other point in the neighborhood of z_0, then z_0 is said to be an isolated singular point of f. For example, 0 is an isolated singular point of $f(z) = 1/z$.

2.12.2.1 Elementary Functions

In accord with the definition of an entire function (analytic at all finite points of the complex plane), a polynomial

$$p(z) = \sum_{m=0}^{n} a_m x^m$$

is an entire function. The exponential, sine, and cosines are entire functions. They are represented by Taylor series expansion:

$$\sin(z) = \frac{e^{iz} - e^{-iz}}{2i} \quad \text{and} \quad \cos(z) = \frac{e^{iz} + e^{-iz}}{2}$$

Define

$$\sinh(z) = \frac{e^{z} - e^{-z}}{2}$$

$$\cosh(z) = \frac{e^{z} + e^{-z}}{2}$$

It follows that

$$\sin(iz) = i\sinh(z), \quad \sinh(iz) = i\sin(z) \quad \text{and}$$

$$\cosh(iz) = \cos(z), \quad \cos(iz) = \cosh(z)$$

$$\cosh^2(z) - \sinh^2(z) = 1$$

$$|\sin(z)|^2 = \sin^2 x + \sinh^2 y, \quad |\sinh(z)|^2 = \sinh^2 x + \sin^2 y \quad \text{and}$$

$$|\cos(z)|^2 = \cos^2 x + \cosh^2 y, \quad |\cosh(z)|^2 = \cosh^2 x + \cos^2 y$$

2.12.2.2 Multivalued Functions

Some of the functions that are useful in practical applications are not uniquely defined. Examples of such functions are nth roots of a complex variable for $n > 1$. For a specific example, consider the case when $n = 2$:

$$w = \sqrt{z} = re^{1/2(\theta + 2k\pi)i}$$

where k is an integer. With no restriction on k, $w = 1$ is the value corresponding to infinitely many values of k. Such behavior is not acceptable according to the definition of a function. To avoid this, restriction is placed on the values of k such that $k < n$. Geometrically, this restriction means that the radius vector from the origin to z is not allowed to circulate around the origin more than once. The semi-infinite ray extending from the origin is known as a branch cut. The origin is known as a branch point.

2.12.2.3 Logarithmic Functions

Given the entire function

$$z = re^{i\theta}$$

the function log z is

$$\log z = \log r + i\theta$$

where $r = |z|$ and $q = \arg(z)$. Because

$$re^{i\theta} = re^{i(\theta+2k\pi)}$$

$$\theta = \arg(z) = \arg(z) + 2k\pi$$

is not a single-valued function. The situation is similar to that in the previous section. Defining the principal value of the logarithmic function,

$$\text{Log } z = \text{Log } r + i\Theta, \quad (r > 0, -\pi < \Theta \leq \pi)$$

The mapping w = Log z is a single-valued and continuous function in its domain of definition, which is the set of all nonzero complex numbers; its range is the strip $-\pi < Im(w) \leq \Theta$. Thus the function Log z is analytic.

2.12.2.4 Cauchy Integral Formula

Consider a curve C parameterized by t, $z(t) = x(t) + iy(t)$, $a \leq t \leq b$ and a complex function $f(x + iy) = u(x,y) + iv(x,y)$. The contour integral of $f(z)$ along the curve z is

$$\int_C f(z)dz = \int_a^b (ux' - vy')dt + i\int_a^b (vx' + vy')dt$$

$$= \int_C udx - vdy + i\int_C vdx + udy$$

If $f(z)$ is analytic everywhere within and on a simple closed contour C, taken in the positive sense (i.e., traversing the curve, C, in counterclockwise direction), and if z_0 is any point interior to C, then

$$f(z_0) = \frac{1}{2\pi i}\int_C \frac{f(z)dz}{z - z_0} \tag{2.233}$$

A simple curve is a closed curve that does not intersect itself. Equation (2.235) is called the Cauchy integral formula. As a consequence of the Cauchy integral formula, we can write

$$\frac{d^n f(z_0)}{dz^n} = \frac{n!}{2\pi i}\int_C \frac{f(z)dz}{(z - z_0)^{n+1}}$$

2.12.2.5 Laurent Series

Let the function f be analytic throughout an annular domain $R_1 < |z - z_0| < R_2$, and let C denote any positive oriented simple closed contour around z_0 and lying in that domain. Then at each point z in the domain, $f(z)$ has the series representation

$$f(z) = \sum_{n=0}^{\infty} a_n (z - z_0)^n + \sum_{n=1}^{\infty} \frac{b_n}{(z - z_0)^n}$$

where

$$a_n = \frac{1}{2\pi i} \int_{C_1} \frac{f(s)ds}{(s - z_0)^{n+1}} \quad (n = 0, 1, 2, 3, \ldots)$$

$$b_n = \frac{1}{2\pi i} \int_{C_2} \frac{f(s)ds}{(s - z_0)^{-n+1}} \quad (n = 1, 2, 3, 4, \ldots)$$

is called the Laurent series.

The complex number that is the coefficient of $1/(z - z_0)$ (i.e., b_1 of the Laurent series) is known as the residue of f at the isolated singular point z_0. The principal part of f is the portion of the series involving negative exponents. If $b_n = 0$ for all $n > m$, then f is said to have a pole of order m. If $m = 1$, it is called a simple pole. If $m = \infty$, f is said to have an essential singularity. If $m = 0$, f is said to have a removable singularity.

2.12.3 Residue Theorem

Let $f(z)$ be analytic inside and on a simple closed contour C, except for a finite number of singular points, $z_1, z_2, \ldots, z_m$ inside C. Then

$$\int_{C_k} f(z)dz = 2\pi i \sum_{n=1}^{m} Res\ f(z); \quad \text{for } z = z_k \quad (k = 1, 2, 3, \ldots, n)$$

2.12.3.1 Calculus of Residues

If f has a pole of order m at z_0, then

$$\phi(z) = (z - z_0)^m f(z) = b_m + b_{m-1}(z - z_0) + b_{m-2}(z - z_0)^2 +$$

$$\cdots + b_1(z - z_0)^{m-1} + \sum_{n=0}^{\infty} a_n (z - z_0)^{n+m}$$

where $b_m \neq 0$; hence the point z_0 is a removable singular point of the function ϕ. It is seen that

$$b_m = \phi(z_0)$$

From the Taylor expansion of $\phi(z)$,

$$b_1 = \frac{1}{(m-1)!}\frac{d^{m-1}\phi(z_0)}{dz^{m-1}}$$

If $m = 1$, then

$$b_1 = \phi(z_0) = \lim_{z\to z_0}(z - z_0)f(z)$$

Consequently,

$$f(z) = \frac{\phi(z_0)}{(z-z_0)^m} + \frac{\phi'(z_0)}{(z-z_0)^{m-1}} + \cdots + \frac{\phi^{(m-1)}(z_0)}{(m-1)!}\frac{1}{z-z_0} + \sum_{n=m}^{\infty}\frac{\phi^{(n)}(z_0)}{n!}(z-z_0)^{n-m}$$

For example, if $q(z_0) = 0$, then

$$\phi(z) = \frac{p(z_0) + p'(z_0)(z-z_0) + \cdots}{q''(z_0)/2! + q'''(z-z_0)/3! + \cdots}$$

and

$$b_1 = \phi'(z_0) = 2\frac{p'(z_0)}{q''(z_0)} - \frac{2}{3}\frac{p(z_0)q'''(z_0)}{[q''(z_0)]^2}$$

2.12.3.2 Application of Complex Integration

One of the many applications of the theory of complex variables is the application of the residue theorem to evaluate definite real integrals. Another is to use conformal mapping to solve boundary-value problems involving harmonic functions. The residue theorem is also very useful in evaluating integrals resulting from solutions of differential equations by the method of integral transforms.

Evaluation of definite real integrals using the residue theorem requires proper specification of contours. For some problems, contours can be as simple as a semicircle in the upper half of the complex plane. Problems utilizing this contour are those with integration limits extending over the real line, i.e., $(-\infty,\infty)$, and the integrand being a rational function. We now illustrate the use of complex integration through an example (Fisher, 1999) as follows.

Example 2.9

Evaluate

$$\int_0^\infty \frac{\log x dx}{x^2 + b^2}$$

There are two simple poles, ib and $-ib$, on the imaginary axis. An appropriate contour for this integral is shown in Figure 2.3.

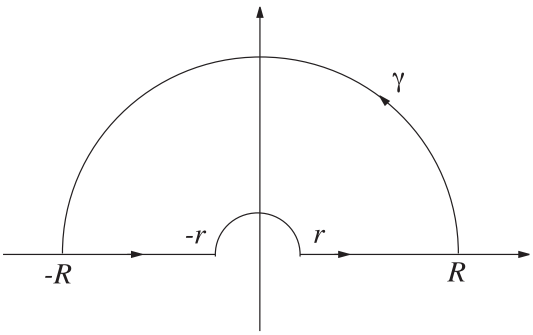

FIGURE 2.3 Contour for evaluation integral of Example 2.9.

$$\int_\gamma \frac{\log z}{z^2+b^2}dz = \int_0^\pi \frac{\log x}{x^2+b^2}dx + iR\int_0^\pi \frac{(\log R + i\theta)e^{i\theta}}{R^2e^{2i\theta}+b^2}d\theta$$

$$+\int_{-R}^{-r} \frac{\log|x| + \pi i}{(|x|e^{i\pi})^2+b^2}dx + ir\int_\pi^0 \frac{(\log r + i\theta)e^{i\theta}}{r^2e^{2i\theta}+b^2}d\theta$$

As $r \to 0$ and $R \to \infty$, the two integrals over the two semicircles vanish and the remaining integrals become

$$\int_0^\infty \frac{\log x}{x^2+b^2}dx + \int_{-\infty}^0 \frac{\log|x| + i\pi}{x^2+b^2}dx = \int_{-\infty}^\infty \frac{\log|x|}{x^2+b^2}dx + i\pi\int_{-\infty}^0 \frac{dx}{x^2+b^2}$$

$$= \int_{-\infty}^\infty \frac{\log|x|}{x^2+b^2}dx + \frac{i\pi}{2b}$$

The residue at $z = b^{i\pi/2}$ of the integrand is

$$\frac{\log z}{z^2+b^2} = \frac{\log z}{(z+ib)(z-ib)}\bigg|_{z=be^{i\pi/2}} = \frac{\log b + i\pi/2}{2ib}$$

Applying the residue theorem to the contour integral gives

$$\int_\gamma \frac{\log z}{z^2+b^2} = \frac{\pi}{b}\left[\log b + \frac{i\pi}{2}\right] = 2\int_{-\infty}^\infty \frac{\log|x|}{x^2+b^2}dx + \frac{i\pi^2}{2b}$$

that after simplifying gives

$$\int_0^\infty \frac{\log x}{x^2+b^2}dx = \frac{\pi}{2b}\log b$$

2.12.4 Argument Principle and Rouché Theorem

Let f be the meromorphic (i.e., it is analytic throughout the domain except possibly for poles) in the domain interior to a positively oriented simple closed contour C with N number of zeros and P number of poles in the interior of C. Then the *argument principle* states that

$$\frac{1}{2\pi}\Delta_C \arg(f(z)) = N - P$$

Rouché theorem: For two analytic functions $f(z)$ and $g(z)$, inside and on a simple closed contour C, if $|f(z)| > |g(z)|$ at each point on C, then the number of zeros of $f(z)$ is the same as the number of zeros of $f(z) + g(z)$, counting multiplicities inside the contour C.

2.12.5 Conformal Mapping

Conformal mapping provides a transformation of variables that converts one mathematical problem into another. Its importance lies in the greater ease with which the transformed problem may be solved than the original problem. Applications arise in steady-state conduction or diffusion problems.

Let C_1 and C_2 be two smooth curves in the z plane passing through z_0, and let α be the angle between these two curves measured in the counterclockwise direction. Let Γ_1 and Γ_2 be the images of $w = f(x)$ of C_1 and C_2 in the w plane, respectively. If the angle between the curves Γ_1 and Γ_2 measured in the counterclockwise direction is α, then the mapping $w = f(z)$ is said to be conformal.

A mapping is said to be conformal at a point z_0 if it preserves the magnitude and sense of the angle between any two smooth arcs through the point z_0. Thus, at each point z where a function $f(z)$ is analytic and $f'(z) \neq 0$, the mapping $w = f(z)$ is conformal.

Theorem 1: Suppose that the analytic function $f(z) = u(x,y) + iv(x,y)$ maps a domain D_z in the z plane onto a domain D_w in the w plane. If $h(u,v)$ is a harmonic function defined on D_w, then the function

$$H(x,y) = h[u(x,y), v(x,y)]$$

is harmonic in D_z

Theorem 2: Suppose that the analytic function $f(z) = u(x,y) + iv(x,y)$ maps an arc C in the z plane onto an arc Γ in the w plane. Let $f(z)$ be conformal on C and let a function $h(u,v)$ be differentiable on Γ. If the function $h(u,v)$ satisfies either of the conditions

$$h = c \quad \text{or} \quad \frac{dh}{dn} = 0$$

along Γ, then the function $H(x,y) = h[u(x,y), v(x,y)]$ satisfies the corresponding condition, $H = c$ or $dH/dN = 0$ along C. Here dH/dN denotes the derivative normal to C.

Theorems 1 and 2 are useful for the construction of analytic functions satisfying given boundary conditions. We will now illustrate some of the applications taken from Brown and Churchill (1996).

Example 2.10: The Dirichlet Boundary-Value Problem

Consider a thin semi-infinite plate defined by $y \geq 0$ whose faces are insulated and whose edge $y = 0$ is kept at temperature zero except for the segment $-1 < x < 1$. The segment $(-1 < x < 1)$ is kept at temperature unity. The steady-state temperature distribution $T(x,y)$ is given by the Laplace equation

$$\nabla^2 T = 0$$

for $-\infty < x < \infty$, $y \geq 0$. Then

$$T(x,0)=\begin{cases}1 & \text{when} \quad |x|<1 \\ 0 & \text{when} \quad |x|>1\end{cases}$$

Also, $|T(x,y)| < M$, where M is some positive constant. The above problem defined in the $(x - y)$ plane may be solved using conformal mapping to transform it into a problem in a suitably defined $(u - v)$ plane.

The region in the $u - v$ plane will be the image of the half-plane under a transformation $w = f(z)$ that is analytic in the domain $y > 0$ and is conformal along the boundary $y = 0$, except at the points (1,0) and (−1,0), where it is undefined. The transformation is given by

$$w=\log\left|\frac{z-1}{z+1}\right|+i\arg\frac{z-1}{z+1}$$

To see this transformation, let

$$z=1+r_1\exp(i\theta_1) \quad \text{and} \quad z=-1+r_2\exp(i\theta_2)$$

Then

$$w=\log\frac{r_1}{r_2}+i(\theta_1-\theta_2)$$

The segment $|x| < 1$, corresponding to the angle $\theta_1 - \theta_2 = \pi$, is mapped to the boundary $v = \pi$ of the strip. The remainder of the x-axis, $|x| > 1$, is mapped to the boundary $v = 0$ of the strip. The condition $T(x,0)$ for $|x| > 1$ is transformed to $T(u,\pi) = 0$ and $T(x,0) = 0$, and for $|x| > 1$ it is transformed to $T(u,0) = 0$. A bounded harmonic function of u and v, which is zero on edge $v = 0$ of the strip and unity on the edge $v = \pi$, is

$$T(u,v)=\frac{v}{\pi}$$

We have

$$\frac{z-1}{z+1}=\frac{x-iy}{x+iy}=\frac{x^2+y^2-1+2iy}{(x+1)^2+y^2}$$

and, by definition,

$$\arg z=\tan^{-1}\frac{y}{x}$$

Thus, using the transformation w expressed in terms of the x,y coordinate, we find that

$$v=\arg\frac{(z-1)(\bar{z}+1)}{(z+1)(z\mp1)}=\arg\frac{x^2+y^2-1+2iy}{(x+1)^2+y^2}=\tan^{-1}\frac{2y}{x^2+y^2+1}$$

The solution of the Laplace equation is then expressed as

$$T(x,y)=\frac{1}{\pi}\tan^{-1}\left(\frac{2y}{x^2+y^2-1}\right)$$

Example 2.11: The Neumann Boundary-Value Problem

Find the harmonic function in the first quadrant $x,y > 0$ satisfying

$$\begin{cases}\dfrac{\partial T(x,0)}{\partial y}=0 & \text{when} \quad 0<x<1\\ T(x,0)=0 & \text{when} \quad x>1\end{cases}$$

$$T(0,y)=0$$

The function

$$z=\sin w=\sin u\cosh v+i\cos u\sinh v=x+iy$$

maps the first quadrant onto the infinite strip,

$$0\le u\le\frac{\pi}{2},\quad v=0 \text{ onto } 0<x<1$$

$$u=\frac{\pi}{2},\quad v\ge 0 \text{ onto } v\ge 1$$

$$u=0,\quad v\ge 0 \text{ onto } v\ge 1$$

The boundary conditions become

$$T(0,v)=0$$

$$T(1,v)=1$$

$$\frac{\partial T(u,0)}{\partial v}=0,\quad 0<u<\frac{\pi}{2}$$

The harmonic function that satisfies the boundary conditions is

$$T(u,v)=\frac{2}{\pi}u$$

The mapping implies that

$$\frac{x^2}{\sin^2 u}-\frac{y^2}{\cos^2 u}=1$$

which is an equation of a hyperbola with vertices at (±sin u,0) and foci at (±1,0). By the definition of a hyperbola,

$$\sqrt{(x+1)^2+y^2}-\sqrt{(x-1)^2+y^2}=2\sin u$$

Substitution into $T(x,y)$ gives

$$T(x,y)=\frac{2}{\pi}\sin^{-1}\left(\frac{1}{2}\sqrt{(x+1)^2+y^2}-\sqrt{(x-1)^2+y^2}\right)$$

The reader is referred to Fisher (1999) for more applications.

2.13 INTEGRAL TRANSFORMS

The general integral transform of a function $f(t)$ is defined as follows:

$$F(\lambda)=\int_a^b K(\lambda,t)f(t)dt \tag{2.234}$$

Integral transforms are distinguished by the way the kernel, $K(\lambda,t)$, and the integration limits are defined. The kernels for different transforms are listed along with the integration limits in Table 2.5, where J_v is the Bessel function of the first kind. Generally, the Laplace transform is used to solve initial-value problems, while the Fourier transform is used to solve boundary-value problems where the domain of the independent variable used is the real line $(-\infty,\infty)$. Fourier sine and cosine transforms are most useful for problems over the half-line domain $(0,\infty)$. The Fourier sine transform is more appropriate for the Dirichlet boundary-value problems. On the other hand, the Fourier cosine transform is suitable for the Neumann boundary-value problems. Other transforms are used in connection with the geometry of the problem under consideration.

TABLE 2.5
Kernels for Different Transforms and Integration Limits

Transform	(*a*,*b*)	K(*t*,λ)
Laplace	$(0,\infty)$	$e^{-\lambda t}$
Fourier	$(-\infty,\infty)$	$\frac{1}{\sqrt{2\pi}}e^{-i\lambda t}$
Fourier cosine	$(0,\infty)$	$\sqrt{\frac{2}{\pi}}\cos(\lambda t)$
Fourier sine	$(0,\infty)$	$\sqrt{\frac{2}{\pi}}\sin(\lambda t)$
Mellin	$(0,\infty)$	$t^{\lambda-1}$
Hankel	$(0,\infty)$	$tJ_v(\lambda t),\quad v\ge -\frac{1}{2}$

Integral transforms can be used to solve ordinary differential equations by converting them to algebraic equations. In what follows, the convolution properties of the different transforms have been listed, followed by the methods of integral transform used to solve (a) one-dimensional diffusion equations in the infinite and semi-infinite domains and (b) Laplace equations in the cylindrical geometries.

2.13.1 Laplace Transform

The Laplace transform of $f(t)$ is denoted as $\mathcal{L}f(t)$, and the inversion is given by

$$f(t)=\frac{1}{2\pi i}\int_{\gamma-i\infty}^{\gamma+i\infty} e^{\lambda t}F(\lambda)d\lambda \tag{2.235}$$

where γ is chosen such that all singularities of the integrand lie to the left of γ.

2.13.1.1 Convolution Property

If $F(\lambda)$ and $G(\lambda)$ are the Laplace transforms of $f(t)$ and $g(t)$, respectively, then

$$\begin{aligned}\mathcal{L}\left[\int_0^t f(s)g(t-s)ds\right] &= \int_0^\infty e^{-\lambda t}\int_0^t f(s)g(t-s)dsdt \\ &= \int_0^\infty f(s)ds\int_s^\infty f(t-s)e^{-\lambda t}dt \\ &= \int_0^\infty f(s)e^{-\lambda s}ds\int_0^\infty g(y)e^{-\lambda y}dy \\ \mathcal{L}\left[\int_0^t f(s)g(t-s)ds\right] &= F(\lambda)G(\lambda)\end{aligned} \tag{2.236}$$

2.13.1.2 Application of Laplace Transform

The temperature distribution in a semi-infinite bar that is heated at one end is described by the solution of the following problem:

$$\frac{\partial u}{\partial t}=\frac{\partial^2 u}{\partial x^2} \tag{2.237}$$

subjected to the boundary conditions

$$-\frac{\partial u(0,t)}{\partial x}=q(t), \quad u(x,0)=0$$

Define

$$U(x,\lambda)=\int_0^\infty u(x,t)e^{-\lambda t}dt$$

and

$$Q(\lambda) = -\int_0^\infty q(t)e^{-\lambda t}dt$$

Multiply Equation (2.239) by $e^{-\lambda t}$ and integrate over $(0,\infty)$,

$$\frac{d^2U}{dx^2} - \lambda U = 0$$

$$-\frac{dU(0)}{dx} = Q$$

the solution of which is given by

$$U = \frac{Q}{\sqrt{\lambda}}e^{-\sqrt{\lambda}x}$$

Let $F(\lambda) = Q$ and $G(\lambda) = \exp(-\sqrt{\lambda}x)/\sqrt{\lambda}$. From the table of Laplace transforms (Appendix 2.C),

$$\mathcal{L}^{-1}G(\lambda) = K(x,t) = \frac{e^{-x^2/(4t)}}{\sqrt{\pi t}}$$

The application of convolution theorem yields

$$u(x,t) = \int_0^t q(\tau)K(x,t-\tau)d\tau$$

For more examples using inversion integrals, the reader is referred to Churchill et al. (1976).

2.13.2 Fourier Transform

The Fourier transform of $f(t)$ is denoted as $\mathcal{F}f(t) = F(\lambda)$, and the inversion is given by

$$f(t) = \frac{1}{\sqrt{2\pi}}\int_{-\infty}^{\infty} e^{-i\lambda t}F(\lambda)d\lambda \tag{2.238}$$

2.13.2.1 Convolution Property

If $F(\lambda)$ and $G(\lambda)$ are the Fourier transforms of $f(t)$ and $g(t)$, respectively, then

$$\begin{aligned}
\mathcal{F}\left[\int_{-\infty}^{\infty} f(t-s)g(s)ds\right] &= \frac{1}{2\pi}\int_{-\infty}^{\infty} e^{i\lambda t}\int_{-\infty}^{\infty} f(t-s)g(s)dsdt \\
&= \frac{1}{\sqrt{2\pi}}\int_{-\infty}^{\infty} g(s)ds\int_{-\infty}^{\infty} e^{i\lambda t}f(t-s)dt \\
&= \frac{1}{\sqrt{2\pi}}\int_{-\infty}^{\infty} e^{i\lambda s}g(s)ds\int_{-\infty}^{\infty} e^{i\lambda y}f(y)dy \\
\mathcal{F}\left[\int_{-\infty}^{\infty} f(t-s)g(s)ds\right] &= F(\lambda)G(\lambda)
\end{aligned} \tag{2.239}$$

2.13.2.2 Application of Fourier Transform

The fundamental solution of the heat equation, i.e., the Dirichlet problem in infinite domain, (–∞,∞), is obtained by solving

$$\frac{\partial u}{\partial t}=\frac{\partial^2 u}{\partial x^2}, \quad -\infty<x<\infty \tag{2.240}$$

subjected to the boundary conditions

$$u(x,0)=u_0(x)$$

Define

$$U(\lambda,t)=\frac{1}{\sqrt{2\pi}}\int_{-\infty}^{\infty}u(x,t)\exp(i\lambda x)dx$$

Multiplying Equation (2.242) by $e^{i\lambda x}$ and integrating over (–∞,∞) yields

$$\frac{dU}{dt}=-\lambda^2 U$$
$$U(\lambda,0)=U_0(\lambda)$$

where

$$U_0(\lambda)=\int_{-\infty}^{\infty}u_0(x)\exp(i\lambda x)dx$$

The solution is given by

$$U(\lambda,t)=U_0(\lambda)\exp(-\lambda^2 t)$$

Inverting the Fourier transform with the use of the convolution theorem yields

$$u(x,t)=\int_{-\infty}^{\infty}k(x-y,t)u_0(y)dy$$

where the function

$$k(x,t)=\mathcal{F}^{-1}[\exp(-\lambda^2 t-i\lambda x)]=\frac{1}{\sqrt{4\pi t}}\exp\left[\frac{-x^2}{4t}\right] \tag{2.241}$$

is called the fundamental solution of the diffusion equation.

2.13.2.3 Application of Fourier Sine Transform

The temperature distribution in a semi-infinite rod with one end of the rod kept at the prescribed temperature is described by the solution of the following initial-boundary-value problem:

$$\frac{\partial u}{\partial t} = \frac{\partial^2 u}{\partial x^2}, \quad 0 < x < \infty \tag{2.242}$$

subjected to the boundary conditions

$$u(0,t) = a(t)$$

$$u(x,0) = u_0(x)$$

Define

$$U(\lambda,t) = \sqrt{\frac{2}{\pi}} \int_0^\infty \sin(\lambda x) u(x,t) dx$$

$$U(\lambda,0) = U_0(\lambda) = \sqrt{\frac{2}{\pi}} \int_0^\infty \sin(\lambda x) u_0(x) dx$$

The transformed equation becomes

$$\frac{dU}{dt} + \lambda^2 U = \lambda \sqrt{\frac{2}{\pi}} a(t)$$

the solution of which is

$$U(\lambda,t) = U_0(\lambda) e^{-\lambda^2 t} + \lambda \sqrt{\frac{2}{\pi}} \int_0^t e^{-\lambda^2 (t-\tau)} a(\tau) d\tau$$

Inversion yields

$$u(x,t) = \sqrt{\frac{2}{\pi}} \int_0^\infty U(\lambda,t) \sin(\lambda x) d\lambda$$

$$= \sqrt{\frac{2}{\pi}} \int_0^\infty U_0(\lambda) \sin(\lambda x) e^{-\lambda^2 t} d\lambda + \frac{2}{\pi} \int_0^\infty \int_0^t \lambda e^{-\lambda^2 (t-\tau)} a(\tau) \sin(\lambda x) d\tau d\lambda$$

$$= \frac{2}{\pi} \int_0^\infty \int_0^\infty [e^{-\lambda^2 t} \sin(\lambda s) \sin(\lambda x)] u_0(s) d\lambda ds + \frac{2}{\pi} \int_0^t \int_0^\infty \lambda e^{-\lambda^2 (t-\tau)} \sin(\lambda x) a(\tau) d\lambda d\tau$$

Using the trigonometric property, 2 sin(A) sin(B) = cos(A – B) – cos(A + B), it follows that

$$u(x,t)=\frac{1}{\pi}\int_0^{\infty}\int_0^{\infty}e^{-\lambda^2 t}[\cos(\lambda(x-s))-\cos(\lambda(x+s))]u_0(s)d\lambda ds$$
$$+\frac{2}{\pi}\int_0^{t}\int_0^{\infty}\lambda e^{-\lambda^2(t-\tau)}\sin(\lambda x)a(\tau)d\lambda d\tau$$

The definition of $k(x,t)$ [Equation (2.243)] can be used to arrive at the following:

$$u(x,t)=\int_0^{\infty}[k(x-s,t)-k(x+s,t)]u_0(s)ds-2\int_0^{t}\frac{\partial k(x,t-\tau)}{\partial x}a(\tau)d\tau$$

where $k(x,t)$ is given by Equation (2.243).

2.13.2.4 Application of Fourier Cosine Transform

The temperature distribution in a semi-infinite rod with prescribed heat flux applied at one end can be obtained as follows. The temperature distribution in the rod is governed by the following equation:

$$\frac{\partial u}{\partial t}=\frac{\partial^2 u}{\partial x^2}+h(x,t),\quad 0<x<\infty \tag{2.243}$$

subjected to the boundary conditions

$$-\frac{\partial u(0,t)}{\partial x}=a(t)$$
$$u(x,0)=u_0(x)$$

Following the procedure similar to that described in the previous subsection, the solution obtained by the Fourier cosine transform is given as

$$u(x,t)=\int_0^{\infty}[k(x-s,t)+k(x+s,t)]u_0(s)ds-2\int_0^{t}k(x,t-\tau)a(\tau)d\tau+$$
$$\int_0^{t}\int_0^{\infty}[k(x-s,t-\tau)+k(x+s,t-\tau)]h(s,\tau)dsd\tau$$

where the $k(x,t)$ is defined by Equation (2.243)

2.13.3 Mellin Transform

2.13.3.1 Convolution Property

Let $F(\lambda)$ and $G(\lambda)$ be the Mellin transforms of $f(x)$ and $g(x)$, respectively. Then

$$\mathcal{M}\left[\int_0^{\infty}f\left(\frac{x}{y}\right)\frac{g(y)}{y}dy\right]=F(\lambda)G(\lambda) \tag{2.244}$$

2.13.3.2 Application of Mellin Transform

The steady-state temperature distribution in a wedge of radius a with the angle between the edges equal to 2α (i.e., spanning from $-\alpha$ to α) is governed by the following Dirichlet boundary-value problem in terms of polar coordinates (r,θ):

$$\frac{\partial^2 u}{\partial r^2}+\frac{1}{r}\frac{\partial u}{\partial r}+\frac{1}{r^2}\frac{\partial^2 u}{\partial \theta^2}=0 \tag{2.245}$$

subjected to the boundary conditions

$$u(r,\pm\alpha)=\begin{cases}1 & 0\le r<a\\ 0 & r>a\end{cases}$$

Define

$$U(\lambda,\theta)=\int_0^\infty u(r,\theta)r^{\lambda-1}dr$$

Multiply Equation (2.247) by $r^{\lambda+1}$ and integrate over $(0,\infty)$ to get

$$\frac{d^2}{d\theta^2}\int_0^\infty ur^{\lambda-1}dr+\int_0^\infty \frac{\partial^2 u}{\partial r^2}r^{\lambda+1}dr+\int_0^\infty \frac{\partial u}{\partial r}r^{\lambda}dr=0$$

Applying integration by parts to the last two terms yields

$$\frac{d^2U}{d\theta^2}+\lambda^2U=0$$

$$U(\lambda,\pm\alpha)=\frac{a^\lambda}{\lambda}$$

The solution is given by

$$U(\lambda,\theta)=\frac{a^\lambda\cos(\lambda\theta)}{\lambda\cos(\lambda\alpha)}$$

Following Davies (2002), the inversion gives the required temperature distribution as

$$u(r,\theta)=\begin{cases}1-\dfrac{1}{\pi}\arctan\left[\dfrac{2(ar)^{\pi/(2\alpha)}\cos(\pi\theta/(2\alpha))}{a^{\pi/\alpha}-r^{\pi/\alpha}}\right] & 0\le r<a\\[2ex] \dfrac{1}{\pi}\dfrac{2(ar)^{\pi/(2\alpha)}\cos(\pi\theta/(2\alpha))}{a^{\pi/\alpha}-r^{\pi/\alpha}} & r>a\end{cases}$$

2.13.4 Hankel Transform

2.13.4.1 Property of Hankel Transform

Let $\mathcal{B}_k$ be the Bessel differential operator of order k, i.e.,

$$\mathcal{B}_k \equiv \frac{d^2}{dr^2} + \frac{1}{r}\frac{d}{dr} - \left(\frac{k}{r}\right)^2$$

If the Hankel transform of $f(r)$ is denoted as $\mathcal{H}_k f(r) = F_k(\lambda)$, then (Zauderer, 1983; Poularikas, 2000)

$$\mathcal{H}_k[\mathcal{B}_k f(r)] = -\lambda^2 \mathcal{H}_k[f(r)] + [rf'(r)J_k(\lambda r) - \lambda r f J_k'(\lambda r)]_{r=0}^{r=\infty}$$

The second term on the right-hand side is specified using the boundary conditions. The inverse Hankel transform is given by

$$f(r) = \int_0^\infty \lambda F_k(\lambda) J_k(\lambda r) d\lambda$$

2.13.4.2 Application of Hankel Transform

The Hankel transform may be used to solve numerous boundary-value problems in a relatively straightforward way, using various properties of Bessel functions. We present here the solution to one of the boundary-value problems (Davies, 2002) of interest.

The axisymmetric steady-state temperature distribution in an infinite cylinder with one of its ends maintained at constant temperature is described by the solution of

$$\frac{\partial^2 u}{\partial r^2} + \frac{1}{r}\frac{\partial u}{\partial r} + \frac{\partial^2 u}{\partial z^2} = 0 \tag{2.246}$$

subjected to the boundary conditions

$$u(r,0) = u_0(r)$$

$$\lim_{z\to\infty} u(r,z) = 0$$

Define

$$U(\lambda, z) = \int_0^\infty u(r,z) J_0(r,\lambda) r dr$$

In addition to the stated boundary conditions, it is assumed that

$$\lim_{r\to\infty}\left[r\frac{\partial u}{\partial r} J_0(\lambda r)\right] = \lim_{r\to\infty} ruJ_0(\lambda r) = 0 \tag{2.247}$$

Multiply Equation (2.248) by $rJ_0(r\lambda)$ and integrate over $(0,\infty)$ to get

$$\frac{d^2}{dz^2}\int_0^{\infty} uJ_0(r\lambda)rdr + \int_0^{\infty}\left(\frac{\partial^2 u}{\partial r^2}+\frac{1}{r}\frac{\partial u}{\partial r}\right)J_0(r\lambda)rdr$$

The second integral is the Hankel transform of the Bessel operator of zero order. Using the property of the Hankel transform, Equation (2.248) is transformed with the conditions stated by Equation (2.249) to

$$\frac{d^2U}{dz^2}-\lambda^2 U=0$$

$$U(\lambda,0)=U_0(\lambda)=\int_0^{\infty} u_0(r)J_0(\lambda r)rdr$$

$$\lim_{z\to\infty} U(\lambda,z)=0$$

$$U(\lambda,z)=U_0(\lambda)e^{-z\lambda}$$

Inversion of the transform gives

$$u(r,z)=\int_0^{\infty} U_0(\lambda)e^{-z\lambda}J_0(r\lambda)\lambda d\lambda$$

The inverse transform can be easily obtained from the table for Hankel transforms in Appendix 2.C.

2.14 CALCULUS OF VARIATIONS

The calculus of variations is concerned primarily with determining maxima and minima of quantities that depend on functions. It can be effectively used for optimization problems (Denn, 1969). We present here a brief overview of the variational calculus followed by a simple illustrative example.

2.14.1 Euler-Lagrange Differential Equation

Consider the following integral:

$$\mathcal{F}(y)=\int_a^b F(y,y',x)dx$$

that evaluates to a real number for a given function of $F(y(x), y'(x))$. The objective of calculus of variations is to find the unknown function $y(x)$ that optimizes the integral $\mathcal{F}(y)$. The integral $\mathcal{F}(y)$ is called the *functional*, which assigns a real number for a given function y.

To seek an optimal function, it is necessary to find the stationary value of the functional about the optimal solution y:

$$\delta\mathcal{F}=\mathcal{F}(y+h)-\mathcal{F}(y)=\frac{d}{dt}\mathcal{F}(y+th)\Big|_{t=0}$$

The stationary value is obtained by solving $\delta\mathcal{F} = 0$, where $h(x)$ is an arbitrary continuously differentiable function:

$$\delta\mathcal{F} = \int_a^b \left(\frac{\partial F}{\partial y} h + \frac{\partial F}{\partial y'} h' \right) dx = 0$$

Integrating the second term by parts yields

$$\delta\mathcal{F} = \int_a^b \left(\frac{\partial F}{\partial y} - \frac{d}{dx}\frac{\partial F}{\partial y'} \right) h dx + F_{y'} h \Big|_{x=a}^{x=b} = 0 \tag{2.248}$$

There are two possibilities:

Case 1: The variational equation is subjected to the fixed end-point conditions

$$y(a) = y_a, \quad y(b) = y_b$$

that translate to

$$h(a) = h(b) = 0$$

Equation (2.250) becomes

$$\delta\mathcal{F} = \int_a^b \left(\frac{\partial F}{\partial y} - \frac{d}{dx}\frac{\partial F}{\partial y'} \right) h dx = 0 \tag{2.249}$$

Because $h(x)$ is an arbitrary continuously differentiable function, the variational equation of the *functional* requires

$$F_y - \frac{d}{dx} F_{y'} = 0 \tag{2.250}$$

that is known as a *Euler-Lagrange* equation establishing a necessary condition for $y(x)$ to be *optimal*.

Case 2: The variational equation is subjected to the conditions

$$F_{y'}\Big|_{x=a} = F_{y'}\Big|_{x=b} = 0$$

These conditions are known as the natural boundary conditions. In either case, the optimal function satisfies the Euler-Lagrange equation.

2.14.2 Euler-Lagrange Equations for a Functional of *n*-Dependent Variables

An approach similar to the one adopted in the previous subsection can be used to derive the Euler-Lagrange equations for a functional that possesses n-dependent variables $y_1, y_2, \ldots y_n$ to give the following system of equations:

$$F_{y_i} - \frac{d}{dx} F_{y_i'} = 0, \quad i = 1, 2, \ldots, n$$

2.14.3 Euler-Lagrange Equations for a Functional Involving *n*th-Order Derivative

The Euler-Lagrange equation for a functional that contains the derivatives of nth order is

$$F_y - \frac{d}{dx} F_{y'} + \cdots + (-1)^n \frac{d^n}{dx^n} F_{y^n} = 0$$

where the value of the function and its $(n - 1)$th derivatives at the end points are specified as

$$y(a) = y_a,\ y'(a) = y_a^{(2)},\ \ldots,\ y^{(n-1)}(a) = y_a^{(n-1)}$$

$$y(b) = y_b,\ y'(b) = y_b^{(2)},\ \ldots,\ y^{(n-1)}(b) = y_b^{(n-1)}$$

2.14.4 Euler-Lagrange Equations for a Functional of Two Independent Variables

The Euler-Lagrange equation for a functional of two independent variables is (Gel'fand and Fomin, 2000)

$$F_y - \frac{d}{dx_1} F_{y_{x1}} - \frac{d}{dx_2} F_{y_{x2}} = 0$$

2.14.5 Application of Calculus of Variations

Example 2.12

The area of the surface generated by rotating the curve $y(x)$ joining two given points (a,b) about the x-axis is

$$2\pi \int_a^b y\sqrt{1 + y'^2}\, dx$$

The curve that minimizes the surface area is given by the following Euler-Lagrange equation (Gel'fand and Fomin, 2000):

$$F_y - \frac{d}{dx} F_{y'} = 0$$

that is independent of x. The general solution can be obtained as follows. Multiplication by y' after expanding the derivative yields the following condition:

$$F - y'F_{y'} = c_1$$

where c_1 is a constant. Using

$$F(y, y', x) = y\sqrt{1+y'^2}, \quad F_{y'} = \frac{yy'}{\sqrt{1+y'^2}}$$

$$y\sqrt{1+y'^2} - \frac{yy'^2}{\sqrt{1+y'^2}} = c_1$$

Solving for y' gives

$$y' = \sqrt{c_1 y^2 - 1}$$

the solution of which is given by

$$y = c_1 \cosh\left(\frac{x+c_2}{c_1}\right)$$

which is an equation describing a catenary curve, where c_2 is another constant. The constants c_1 and c_2 can be determined from the condition that the curve representing the solution should pass through the two (prescribed) end points.

2.15 STOCHASTIC DIFFERENTIAL EQUATIONS

Processes in which a certain time-dependent random variable $\mathbf{X}(t)$ exists are called *stochastic processes*. Loosely, these are the processes that evolve probabilistically in time. We can measure values $\boldsymbol{x}_1, \boldsymbol{x}_2, \boldsymbol{x}_3, \ldots$, etc., of $\mathbf{X}(t)$ at times $t_1, t_2, t_3, \ldots$, and we assume that a set of joint probability densities, $p(\boldsymbol{x}_1, t_1; \boldsymbol{x}_2, t_2; \boldsymbol{x}_3, t_3; \ldots)$, exists that describes the system completely. For a treatise on stochastic processes, the reader is referred to Gardiner (2003). The applications related to chemical engineering can be followed from Rao et al. (1974a and 1974b).

The conditional probability densities can be defined in terms of the joint probability density functions as

$$p(\boldsymbol{x}_1, t_1; \boldsymbol{x}_2, t_2; \ldots | \boldsymbol{y}_1, \tau_1; \boldsymbol{y}_2, \tau_2; \ldots) = \frac{p(\boldsymbol{x}_1, t_1; \boldsymbol{x}_2, t_2; \ldots; \boldsymbol{y}_1, \tau_1; \boldsymbol{y}_2, \tau_2; \ldots)}{p(\boldsymbol{y}_1, \tau_1; \boldsymbol{y}_2, \tau_2; \ldots)} \tag{2.251}$$

The definitions in Equation (2.253) are valid independently of the ordering of the times. However, it is usual to consider only times that increase from right to left, i.e.,

$$t_1 \geq t_2 \geq t_3 \cdots \geq t_1 \geq \tau_2 \ldots \tag{2.252}$$

Stochastic differential equations then obviously describe the evolution of stochastic processes in terms of a dependent random variable $\mathbf{X}(t)$.

Conditional probabilities can be seen as predictions of the future values of $\mathbf{X}(t)$ (i.e., $\boldsymbol{x}_1, \boldsymbol{x}_2, \ldots$ at times $t_1, t_2, \ldots$) given the knowledge of the past values ($\boldsymbol{y}_1, \boldsymbol{y}_2, \ldots$ at times $\tau_1, \tau_2, \ldots$). A stochastic process is said to be completely independent if

$$p(\boldsymbol{x}_1, t_1; \boldsymbol{x}_2, t_2; \ldots | \boldsymbol{y}_1, \tau_1; \boldsymbol{y}_2, \tau_2; \ldots) = \Pi_i p(\boldsymbol{x}_{i,} t_i)$$

that means that the value of **X** at time t is completely independent of its values in the past (or future).

If a stochastic process evolves in time satisfying the ordering given by Equation (2.254) and the conditional probability is determined by the knowledge of the most recent condition, then such a process is called a *Markov* process. We have

$$p(\boldsymbol{x}_1,t_1;\boldsymbol{x}_2,t_2;\ldots|\boldsymbol{y}_1,\tau_1;\boldsymbol{y}_2,\tau_2;\ldots) = p(\boldsymbol{x}_1,t_1;\boldsymbol{x}_2,t_2;\ldots;\boldsymbol{y}_1,\tau_1) \tag{2.253}$$

2.15.1 Differential Chapman-Kolmogorov Equation

The equation that governs the conditional probability function is the differential Chapman-Kolmogorov equation:

$$\frac{\partial}{\partial t}p(z,t|\boldsymbol{y},t') = -\sum_i \frac{\partial}{\partial z_i}[A_i(z,t)p(z,t|\boldsymbol{y},t')] + \sum_{i,j}\frac{1}{2}\frac{\partial^2}{\partial z_i \partial z_j}[B_{i,j}(z,t)p(z,t|\boldsymbol{y},t')]$$

$$+\int d\boldsymbol{x}[W(z|\boldsymbol{x},t)p(\boldsymbol{x},t|\boldsymbol{y},t') - W(\boldsymbol{x}|z,t)p(z,t|\boldsymbol{y},t')]$$

where

$$W(\boldsymbol{x}|z,t) = \lim_{\Delta t\to 0} p(\boldsymbol{x},t+\Delta t|z,t)/\Delta t$$

For the quantities $W(\boldsymbol{x}|z,t)$ equal to zero, the differential Chapman-Kolmogorov equation takes the form of the Fokker-Planck equation:

$$\frac{\partial}{\partial t}p(z,t|\boldsymbol{y},t') = -\sum_i [A_i(z,t)p(z,t|\boldsymbol{y},t')] + \sum_{i,j}\frac{1}{2}\frac{\partial^2}{\partial z_i \partial z_j}[B_{i,j}(z,t)p(z,t|\boldsymbol{y},t')]$$

and the corresponding process is known as a diffusion process. The vector $\boldsymbol{A}(z,t)$ is known as the drift vector and the matrix $\boldsymbol{B}(z,t)$ as the diffusion matrix. The derivation of the equation requires that the diffusion matrix be symmetric and positive definite. The property of the diffusion process is that the sample path $y(t)$ is a continuous function of time, but it is nowhere differentiable.

2.15.2 Connection between the Fokker-Planck Equation and Stochastic Differential Equation

Given a general stochastic differential equation

$$\frac{dx}{dt} = a(z,t) + b(x,t)\xi(t) \tag{2.254}$$

or, equivalently, the stochastic integral equation

$$x - x(0) = \int_0^t a(x(t'),t')dt' + \int_0^t b[x(t'),t']dW(t') \tag{2.255}$$

the conditional probability density function for the sample path is the Fokker-Planck equation,

$$\frac{\partial}{\partial t} p(x,t|x_0,t_0) = -\frac{\partial}{\partial x}[a(x,t)p(x,t|x_0,t_0)] + \frac{1}{2}\frac{\partial^2}{\partial x^2}[b(x,t)^2 p(x,t|x_0,t_0)]$$

For a stochastic differential equation for n variables,

$$d\boldsymbol{x} = \boldsymbol{A}(\boldsymbol{x},t)dt + \boldsymbol{B}(\boldsymbol{x},t)d\boldsymbol{W}(t)$$

where $\mathbf{W}(t)$ is an n-variable Wiener process, the Fokker-Planck equation for the conditional probability density $p \equiv p(\boldsymbol{x},t|\boldsymbol{x}_0,t_0)$ is given by

$$\frac{\partial p}{\partial t} = -\sum_i \frac{\partial}{\partial x_i}[A_i(\boldsymbol{x},t)p] + \sum_{i,j}\frac{1}{2}\frac{\partial^2}{\partial x_i \partial x_j}\{[\boldsymbol{B}(\boldsymbol{x},t)\boldsymbol{B}^{\mathrm{T}}(\boldsymbol{x},t)]_{i,j}\,p\}$$

2.15.3 Îto Stochastic Integral

The solution of a stochastic differential equation is expressed in terms of the integral with respect to a sample function W(t). The stochastic integral

$$\int_{t_0}^{t} G(t')dW(t')$$

is obtained by dividing the interval $[t_0,t]$ into n subintervals such that

$$t_0 \le t_1 \le \cdots \le t_{n-1} \le t$$

where the intermediate points τ_i satisfy

$$t_{i-1} \le \tau_i \le t_i$$

The Îto stochastic integral is defined as a limit of the partial sum

$$\int_{t_0}^{t} G(t')dW(t') = \underset{n\to\infty}{\text{ms-lim}} \sum_{i=1}^{n} G(t_{i-1})[W(t_i) - W(t_{i-1})]$$

where ms-lim is the mean square limit defined as

$$\underset{n\to\infty}{\text{ms-lim}}\, X_n = X \Leftrightarrow \lim_{n\to\infty} \int p(\omega)[X_n(\omega) - X(\omega)]d\omega = 0$$

The Îto integration formula, which is presented in the next subsection, is useful for the purpose of evaluating a stochastic integral.

2.15.3.1 One-Dimensional Îto Formula

Let $X(t)$ be an Îto process given by (Oksendal, 2000)

$$dX = udt + vdW(t)$$

Let $g(t,x) \in C^2([0,\infty)\times\mathbb{R})$. Then

$$Y(t) = g(t,x)$$

is again an Îto process, and

$$dY = \frac{\partial g}{\partial t}(t,X)dt + \frac{\partial g}{\partial x}(t,X)dX + \frac{1}{2}\frac{\partial^2 g}{x^2}(t,X)\cdot(dX)^2$$

that is called the Îto formula, where $(dX)^2 = (dX) \cdot (dX)$ is evaluated using the following rules:

$$dt \cdot dt = dt \cdot dW = dW \cdot dt = 0, \quad dW \cdot dW = dt$$

The following example shows the application of the Îto integration formula to evaluate a stochastic integral.

Example 2.13

Evaluate the integral

$$\int_0^t W(t')dt'$$

Choose $X = W$ and $g(t,x) = 1/2x^2$. Then

$$Y = g(t,W) = \frac{1}{2}W^2 \Rightarrow dY = d\left(\frac{1}{2}W^2\right)$$

By the Îto formula,

$$dY = \frac{\partial g}{\partial t}dt + \frac{\partial g}{\partial x}dW + \frac{1}{2}\frac{\partial^2 g}{\partial x^2}(dW)^2 = W(t)dW(t) + \frac{1}{2}(dW)^2 = W(t)dW(t) + \frac{1}{2}dt$$

Thus,

$$\int_0^t d\left(\frac{1}{2}W^2\right) = \frac{1}{2}W^2(t) = \int_0^t W(t')dW(t') + \frac{1}{2}t$$

2.15.3.2 An Example Application of a Stochastic Differential Equation

The concentration of a species undergoing a first-order chemical reaction with the rate constant of k with noise may be described by the following stochastic differential equation:

$$\frac{dC}{dt} = -kC + C\alpha\xi(t) \quad t = 0, \quad C = C_0$$

$$dC = -kCdt + C\alpha\xi(t)dt$$

2.16 ASYMPTOTIC APPROXIMATIONS AND EXPANSIONS

Many problems in transport and chemical reaction engineering are nonlinear and cannot be solved analytically. A powerful approach to solve such problems lies in the method of matched asymptotic expansions that often provide analytical expressions for the solution. The method is based on an expansion whose convergence is based on concepts somewhat different from that usually understood. An example is considered below to clarify the nature of such expansions. Such expansions can be used in the solution of nonlinear equations for limiting values of parameters associated with the problem. Several examples are available in the chemical engineering literature (Leal, 1992, 2007; Deen, 1998; Varma and Morbidelli, 1997).

Example 2.15

A detailed treatment of this example is given by Erdelyi (1956). Let

$$S(x)\sum_{n=0}^{\infty}(-1)^n n!x^n \tag{2.256}$$

The foregoing sum is definitely divergent because of $n!$. However, let us proceed without regard for the divergence to invoke the well-known result from the theory of gamma functions,

$$n! = \int_0^{\infty} e^{-t}t^n dt \tag{2.257}$$

Using Equation (2.260) in Equation (2.59), one has

$$S(x) = \sum_{n=0}^{\infty}(-1)^n \int_0^{\infty} e^{-t}x^n t^n dt \tag{2.258}$$

Disregarding conditions required for interchanging the summation and integration, one obtains

$$S(x) = \int_0^{\infty} e^{-t}\sum_{n=0}^{\infty}(-1)^n (xt)^n dt \tag{2.259}$$

The alternating series within the integrand on the right-hand side of Equation (2.258) can now be summed exactly to write from Equation (2.259)

$$S(x) = \int_0^{\infty} \frac{e^{-t}}{1+xt} dt \tag{2.260}$$

Note that the right-hand side is a very well-behaved function for any real value of x. It was not legitimately obtained because the interchange of summation and integration cannot be performed

under the circumstances. Note also that this is not a case of an irrational procedure producing a valid result. The result is not valid because the left-hand side simply does not exist.

The issue in question is whether the series in Equation (2.256) can still approximate the function in Equation (2.260) in some way. To entertain this possibility, consider the evaluation of the left-hand side up to, say, m terms defined by

$$S_m(x) \equiv \sum_{n=0}^{m} (-1)^n n! x^n \tag{2.261}$$

Compute the foregoing sum for $m = 0,1,2,3,\ldots$ for $x = 0.1, 0.01, 0.001$ and compare it with the evaluation of the right-hand side of Equation (2.263), which is obtained by the following equation:

$$S(x) = \frac{1}{x} e^{1/x} E_1\left(\frac{1}{x}\right) \tag{2.262}$$

where

$$E_1(x) = \int_x^{\infty} \frac{e^{-t}}{t} dt \tag{2.263}$$

On the other hand, for each value of x, compare the values obtained from Equation (2.261) with increasing m. The results are presented below.

x	$S(x)$	$S_1(x)$	$S_2(x)$	$S_{25}(x)$
0.1	0.915633	0.90000	0.920000	–0.19594
0.01	0.990194	0.99000	0.990200	0.990194
0.001	0.999002	0.99900	0.999002	0.999002

The feature most worthy of notice is that while the summation with an increase in the number of terms (i.e., m) does not improve the approximation to the function, the approximation improves as the value of x itself is increased. At $x = 0.1$, the divergence has already manifested with 10 terms. Although at the lower values of x (0.01,0.001) the expansion appears to converge in the usual sense, with sufficient increase in the number of terms, one expects divergence to set in. This is then the idea behind an asymptotic expansion of a function. Here the parameter used for conveying the idea of asymptotic expansion was x. In what follows, it is more convenient to use ε as the parameter.

Consider the *asymptotic expansion* of the function $T(\mathbf{x},\varepsilon)$ with ε as a parameter. In writing the expansion, two alternative order relations, denoted O and o, are generally used. Thus we set

$$T(\mathbf{x},\varepsilon) = f_0(\varepsilon)T_0(\mathbf{x}) + f_1(\varepsilon)T_1(\mathbf{x}) + f_2(\varepsilon)T_2(\mathbf{x}) + O(f_3(\varepsilon)) \tag{2.264}$$

where the coefficients $f_n(\varepsilon)$ are called gauge functions. The neglected term $O(f_3(\varepsilon))$ simply means that it behaves as $f_3(\varepsilon)$ as $\varepsilon \to 0$. An alternative notation for the foregoing situation is $o(f_3(\varepsilon))$, which means that the (magnitude of the) largest neglected term is smaller than $|f_2(\varepsilon)|$ as $\varepsilon \to 0$. This notation is more useful when the identity of $f_3(\varepsilon)$ is unknown. Now the expansion for $T(\mathbf{x},\varepsilon)$ is not *necessarily convergent* in the usual sense of

$$\lim_{N\to\infty}\left|T(\mathbf{x},\varepsilon)-\sum_{n=1}^{N} f_n(\varepsilon)T_n(\mathbf{x})\right| = \mathbf{0} \tag{2.265}$$

but a necessary condition for asymptotic convergence is

$$\lim_{\varepsilon\to 0}\left|T(\mathbf{x},\varepsilon)-\sum_{n=1}^{N} f_n(\varepsilon)T_n(\mathbf{x})\right| = \mathbf{0}, \quad \text{fixed } N \tag{2.266}$$

This definition is consistent with the example shown earlier. A necessary condition for asymptotic convergence is given by

$$\lim_{\varepsilon\to 0}\frac{f_{n+1}(\varepsilon)}{f_n(\varepsilon)} \quad \text{for all } n \tag{2.267}$$

Suppose the expansion of $T(\mathbf{x},\varepsilon)$ is desired in a domain Ω. If the asymptotic convergence occurs for all $\mathbf{x}$ in Ω, the expansion is said to be a *regular asymptotic expansion*.

Generally, the occurrence of the regular asymptotic expansions is in finite (bounded) domains. In other situations, the convergence of a particular expansion may occur only in a subdomain. For example, the entire domain may be made up of two separate subdomains, Ω^+ separated from another denoted Ω^-, with an intersection $\partial\Omega$ separating the two domains. This is also called the *overlap region*. Thus, we may have two separate expansions of the function $T(\mathbf{x},\varepsilon)$ as follows:

$$T(\mathbf{x},\varepsilon)=\sum_{n=0}^{N^+} f_n^+(\varepsilon)T_n^+(\mathbf{x}), \quad \mathbf{x}\in\Omega^+ \tag{2.268}$$

$$T(\mathbf{x},\varepsilon)=\sum_{n=0}^{N^-} f_n^-(\varepsilon)T_n^-(\mathbf{x}), \quad \mathbf{x}\in\Omega^- \tag{2.269}$$

The expansions in the individual subdomains are known as *singular expansions*. To determine the expansion in the entire domain, it is necessary to match the two expansions in the overlap region $\partial\Omega$. There are two strategies that are possible. One is referred to as a "matching" strategy, requiring the same functional forms for the gauge functions from either side in the overlap region. Thus in this case one has

$$N^+ = N^-, \quad f_n^+(\varepsilon) = f_n^-(\varepsilon), \quad T_n^+(\mathbf{x}) = T_n^-(\mathbf{x}), \quad x\in\partial\Omega$$

A less rigorous strategy is satisfied by numerically equating the two solutions by "patching" as follows:

$$\sum_{n=0}^{N^+} f_n^+(\varepsilon)T_n^+(\mathbf{x}) = \sum_{n=0}^{N^-} f_n^-(\varepsilon)T_n^-(\mathbf{x}), \quad \mathbf{x}\in\partial\Omega$$

Generally, $T(\mathbf{x},\varepsilon)$ satisfies a nonlinear boundary-value problem. We obtain a singular perturbation problem when, upon letting $\varepsilon \to 0$, the order of the differential equation is reduced.

2.17 STEADY-STATE MULTIPLICITY AND STABILITY

Nonlinear equations may admit no real solutions or multiple real solutions. For example, the quadratic equation can have no real solutions or two real solutions. Thus, it is important to know whether a given equation governing the behavior of an engineering system can admit more than one solution, since it is related to the issue of operation and performance of the system. In this subsection, criteria for the existence of multiple steady-state solutions to the governing equations of a CSTR and tubular reactors and, subsequently, the stability of these multiple steady states are presented.

2.17.1 Steady-State Multiplicity of a Chemical Reactor

The analysis of steady-state multiplicity of a nonisothermal chemical reactor is complicated due to the number of parameters involved and the exponential nonlinearity in the temperature dependence of the kinetic function. In this and the next subsection, the results of the analysis of steady-state multiplicity are presented. The derivations of these results are detailed in a review chapter by Morbidelli et al. (1986).

2.17.1.1 Steady-State Multiplicity of a CSTR

The dimensionless steady-state equations of mass and energy balance for a CSTR are reproduced here:

$$1 - u - Dar(u,v) = 0 \tag{2.270}$$

$$1 - v + \beta Dar(u,v) = 0 \tag{2.271}$$

For the nondimensionalization, the reader is referred to Section 2.7. From the physical arguments, the dimensionless concentration u is bounded between 0 and 1, i.e., $0 \le u \le 1$. The relationship between the dimensionless concentration u and dimensionless temperature v can be obtained as

$$u = \frac{1+\beta-v}{\beta} \tag{2.272}$$

that shows the corresponding bounds on the dimensionless temperature:

$$1 \le v \le 1+\beta \quad \text{for } \beta > 0$$

$$1-|\beta| \le v \le 1 \quad \text{for } \beta < 0$$

Thus substitution of Equation (2.272) into Equation (2.271) yields

$$1 - v + \beta Dar\left(\frac{1+\beta-v}{v}, v\right) \tag{2.273}$$

For nth-order kinetics, Equation (2.273) is written as

$$F(v) \equiv \frac{(1+\beta-v)^n}{v-1}\exp\left[\gamma\left(1-\frac{1}{v}\right)\right] = \frac{\beta^{n-1}}{Da} \tag{2.274}$$

Because $F(1) = \infty$, $F(1 + \beta) = 0$, and $F(v) > 0$ for $1 \le v \le 1 + \beta$, Equation (2.292) admits a unique solution if $F(v)$ is monotonically decreasing, i.e.,

$$\frac{dF}{dv} \le 0 \quad \text{for} \quad 1 \le v \le 1+\beta \tag{2.275}$$

If the condition in Equation (2.275) is violated, then uniqueness is assured if and only if

$$G(\bar{Z}) \ge \gamma \quad \text{for} \quad 0 < Z < 1 \tag{2.276}$$

where

$$G(Z;n,\beta) \equiv \frac{(1+\beta Z)^2[(1+Z(n-1)]}{\beta Z(1-Z)}, \quad Z = \frac{v-1}{\beta}$$

and $z \equiv \bar{Z}$ is the one and only root in the interval (0,1) of the following equation:

$$\beta(n-1)Z^3 - (n-1)(2\beta+1)Z^2 - (2+\beta)Z + 1 = 0 \tag{2.277}$$

that is obtained from $G'(Z) = 0$. If the condition in Equation (2.276) is violated, then multiple solutions exist for $Da_* < Da < Da^*$, where

$$Da_* = \frac{\beta^{n-1}}{F(v_+)} \quad \text{and} \quad Da^* = \frac{\beta^{n-1}}{F(v_-)}$$

where $v_\pm = 1 + \beta Z_\pm$ and $Z_\pm$ are the roots of $G(Z) = \gamma$.

2.17.1.2 Steady-State Multiplicity of a Tubular Reactor

The analysis of multiplicity for a tubular reactor is involved because its mass and energy balances are governed by nonlinear boundary-value problems. The uniqueness conditions for a tubular reactor are more conservative than those for a CSTR. The exact bounds for the uniqueness require numerical solutions.

The dimensionless mass and energy balance in a tubular reactor are (Morbidelli et al. 1986)

$$\frac{1}{Pe_m}\frac{d^2u}{dx^2} - \frac{du}{dx} - Dar(u,v) = 0 \tag{2.278}$$

$$\frac{1}{Pe_t}\frac{d^2v}{dx^2} - \frac{dv}{dx} - \delta(v-v_c) + \beta Dar(u,v) = 0 \tag{2.279}$$

with the boundary conditions

$$\frac{du}{dx} = Pe_m(u-1), \quad \frac{dv}{dx} = Pe_t(v-1), \quad \text{at } x = 0 \tag{2.280}$$

$$\frac{du}{dx} = 0, \quad \frac{dv}{dx} = 0, \quad \text{at } x = 1 \tag{2.281}$$

where the dimensionless variables are defined as follows:

$$u = \frac{C}{C_f} \quad v = \frac{T}{T_f} \quad v_c = \frac{T_c}{T_f} \quad x = \frac{z}{L} \quad Da = \frac{Lr(C_f, T_f)}{VC_f} \quad d = \frac{UPL}{V\rho AC_p}$$

$$\beta = \frac{(-\Delta H)C_f}{\rho C_p T_f} \quad R = \frac{r(C,T)}{r(C_f,T_f)} \quad Pe_m = \frac{VL}{D_m} \quad Pe_t = \frac{VL\rho C_p}{D_t} \quad \gamma = \frac{E}{RT_f}$$

Case 1: $Pe_m = Pe_t = Pe$, $\delta = 0$

A *sufficient* condition for *uniqueness* is

$$\frac{dF}{dv} \le 0 \quad \text{for} \quad 1 \le v \le 1 + \beta \tag{2.282}$$

where

$$F(v) = \frac{r\left(\dfrac{1+\beta-v}{\beta}, v\right)}{v-1}$$

When the condition in Equation (2.282) is violated, the following condition ensures uniqueness:

$$Da \le \frac{\mu}{\beta r\left(\dfrac{1+\beta-v}{\beta}, v\right)} \quad \text{for} \quad 1 \le v \le 1+\beta$$

where $p = \lambda_1/Pe + Pe/4$ and λ_1 is the smallest root of the equation

$$\tan\sqrt{\lambda} = \frac{Pe\sqrt{\lambda}}{\lambda - Pe^2/4}, \quad 0 < \lambda_1 < \pi^2$$

Case 2: $Pe_m = Pe_t = Pe$, $\delta > 0$ (Morbidelli et al., 1986; Varma and Amundson, 1972)

A *sufficient* condition is given by

$$Da \le \frac{\mu + \delta}{\beta R'\left(\dfrac{1+\beta-v}{\beta}, v\right) + [\delta(a_1 - a_2)/2\mu]} \quad \text{for } 1 \le v \le 1+\beta$$

where μ is the same parameter as defined in the previous case and

$$a_1 = \sup \frac{\partial r}{\partial u} > 0, \quad a_2 = \inf \frac{\partial r}{\partial u} \geq 0$$

Case 3: $Pe_m \neq Pe_t$, $\delta \neq 0$

$$Da \leq \frac{-\beta\mu_m a_3 + (\mu_t + \delta)a_2 + \sqrt{\Delta}}{a_3\beta[2a_2 + a_1 \exp(|Pe_t - Pe_m|)]}$$

where

$$\Delta = \beta\mu_m a_3 + (\mu_t + \delta)^2 + 2\beta\mu_m(\mu_m + \delta)a_1 a_3 \exp(|Pe_t - Pe_m|), \quad a_3 = \sup \frac{\partial r}{\partial v} \tag{2.283}$$

where $\mu_i = \lambda_1 / Pe_i + Pe_i / 4$, $i = m, t$ and λ_1 is the same as previously defined.

The exact bounds for multiplicity can be determined by computationally solving the boundary-value problems with the use of the singularity theory.

2.17.2 Analysis of Multiplicity by Singularity Theory

Techniques based on the implicit function theorem have been used to predict the existence of multiple solutions in a CSTR (Chang and Calo, 1979). An extension of catastrophe theory known as singularity theory has also been effectively used to determine the conditions for the existence of multiple solutions in a CSTR and a tubular reactor (Balakotaiah and Luss, 1981, 1982; Witmer et al., 1986). In this subsection, the technique of singularity to find the maximum number of solutions of a single mathematical equation and its application to analysis of the multiplicity of a CSTR are presented (Luss, 1986; Balakotaiah at al., 1985). The details of singularity theory can be found in Golubitsky and Schaeffer (1985).

For the first-order reaction, the steady-state equations for mass and energy balance in a CSTR can be combined into a single equation represented as

$$f(x, \boldsymbol{p}) = 0 \tag{2.284}$$

where $\boldsymbol{p}$ is a vector of physical quantities. A singular point $(x_s, \boldsymbol{p}_s)$ of codimension k is defined as

$$f(x_s, \boldsymbol{p}_s) = \frac{df(x_s, \boldsymbol{p}_s)}{dx} = \cdots = \frac{d^k f(x_s, \boldsymbol{p}_s)}{dx^k} = 0, \quad \frac{d^{k+1} f(x_s, \boldsymbol{p}_s)}{dx^{k+1}} \neq 0 \tag{2.285}$$

The application of catastrophe theory (Hofp, 1960) predicts that in the neighborhood of a singular point of codimension k, the qualitative features represented by Equation (2.284) are similar to that of the polynomial,

$$y^{k+1} - \sum_{i=0}^{k-1} \alpha_i y^i \tag{2.286}$$

In the neighborhood of such a singular point, Equation (2.284) admits k+1 solutions if

$$\text{rank}[b_{i,j}] = k$$

where the elements $b_{i,j}$ are the coefficients of the expansion,

$$\frac{\partial f}{\partial p_i}(y, \boldsymbol{p}_s) = \sum_{j=1}^{k} \frac{b_{i,j}}{j!}(y - y_s)^{j-1} + O(|y - y_s|^k)$$

Thus, the singular points of Equation (2.284) characterized by Equation (2.285) allow one to analyze the multiplicity of Equation (2.284) from the knowledge of the polynomial Equation (2.286).

2.17.2.1 Application of Singularity Theory to the Analysis of CSTR

The mass and energy balance equations for a CSTR can be combined into a single equation,

$$x - (1 - x)Da \exp\left[\frac{Bx + \alpha y_c Da}{1 + \alpha Da + (\alpha Da + Bx/\gamma)}\right] = F(x, \boldsymbol{p}) = 0 \tag{2.287}$$

where the dimensionless variables are defined as

$$x = \frac{C_f - C_a}{C_f} \quad y_c = \frac{E}{RT_f}\left(\frac{T_c - T_f}{T_f}\right) \quad B = \frac{E}{RT_f}\frac{(-\Delta H)C_f}{\rho C_p T_f}$$

$$\gamma = \frac{E}{RT_f} \quad Da = \frac{V}{F}\exp\left[\frac{E}{RT_f}\right] \quad \alpha = \frac{hA}{\rho C_p V}\exp\left[\frac{-E}{RT_f}\right]$$

and

$$\boldsymbol{p} = (Da, B, \alpha, y_c, \gamma)$$

For adiabatic ($\alpha = 0$) CSTR

$$F(x, Da, \boldsymbol{p}_s) = \frac{\partial F}{\partial x}(x, Da, \boldsymbol{p}_s) = 0 \tag{2.288}$$

The solutions of Equation (2.288) give

$$x_{\pm} = \frac{1 - \dfrac{2}{\gamma} \pm \sqrt{1 - \dfrac{4}{B}(1 + B/\gamma)}}{2(1 + B/\gamma^2)}$$

$$Da = \frac{x_{\pm}}{1 - x_{\pm}}\exp\left(\frac{-Bx_{\pm}}{1 + Bx_{\pm}/\gamma}\right)$$

Multiplicity exists if and only if

$$B > \frac{4}{1 - 4/\gamma} > 0 \tag{2.289}$$

(i) Adiabatic CSTR, hysteresis variety

In addition to the condition for multiplicity in Equation (2.289), the condition for the existence of hysteresis variety is defined by

$$\frac{\partial^2 F}{\partial x^2}(x, Da, \boldsymbol{p}_s) = 0$$

that gives the solution

$$\alpha = \frac{1 - x_h}{x_h}\left[\frac{4Bx_h(1 - x_h)}{y^2(1 - 2x_h)}\right]\exp\left\{\gamma - \frac{2}{1 - 2x_h}\right\}$$

where

$$x_h = \frac{\frac{4B}{\gamma}\left(1 + \frac{y_c}{\gamma}\right) + 4y_c - B \pm \sqrt{D}}{2\left[4y_c - 2B + \frac{4B}{\gamma}\left(1 + \frac{y_c}{\gamma}\right)\right]}$$

and

$$D = \left[\frac{4B}{\gamma}\left(1 + \frac{y_c}{\gamma}\right)\right]^2 - 4y_c\left[4y_c - 2B + \frac{4B}{\gamma}\left(1 + \frac{y_c}{\gamma}\right)\right]$$

(ii) Isola variety

$$F(x, Da, \boldsymbol{p}_s) = \frac{\partial F}{\partial x}(x, Da, \boldsymbol{p}_s) = \frac{\partial F}{\partial Da}(x, Da, \boldsymbol{p}_s) = 0 \tag{2.290}$$

The condition in Equation (2.290) gives parametric representations by the equations

$$x_b^5 B^3/\gamma^2 - x_b^3[1 - x_b + y_c x_b/\gamma^2 - 2/\gamma]B^2 + x_b[1 + y_c(1 - x_b) - 2x_b y_c/\gamma]B - y_c = 0$$

$$\alpha = \frac{B(1 - x_b)^2}{Bx_b^2 - y_c}\exp\left\{\frac{Bx_b^2}{1 + Bx_b^2/\gamma}\right\}$$

where the parameter $0 < x_b < 1$.

(iii) Pitch-fork singular point

$$F(x,Da,\boldsymbol{p}_s)=\frac{\partial F}{\partial x}(x,Da,\boldsymbol{p}_s)=\frac{\partial^2 F}{\partial x^2}(x,Da,\boldsymbol{p}_s)=\frac{\partial F}{\partial Da}(x,Da,\boldsymbol{p}_s)=0 \qquad (2.291)$$

and

$$\frac{\partial^3 F}{\partial x^3}\frac{\partial^2 F}{\partial x \partial Da}<0$$

Solving Equation (2.291) gives

$$B=\frac{\gamma^2 y_c(1-2x)^2}{x[4(1-x)(\gamma+y_c)-\gamma^2(1-2x)]} \quad \alpha Da=\frac{Bx(1-x)}{Bx^2-y_c} \quad \text{and} \quad \gamma<\frac{8}{3}$$

where x is the root of

$$x^3+A_1x^2+A_2x+A_3=0$$

with

$$A_1=(\gamma^2-2\gamma-4y_c)/2y_c$$

$$A_2=[(\gamma^2+y_c)(4\gamma+4y_c-\gamma^2)-(\gamma^2-2\gamma-2y_c)^2]/4\gamma^2 y_c$$

$$A_3=(\gamma-2)[\gamma(\gamma-4)-4y_c]/8\gamma y_c$$

and Da is the solution of Equation (2.305) for the corresponding α, Da, B, and x.

These conditions establish the boundary of the region in the space (Da,B,α,y_c,γ). The multiplicity patterns in the interior of each region are established by solving the equation for one set of parameters in the region.

2.17.3 Stability of Steady-State Solution

The existence of multiple solutions does not ensure that these solutions are physically attainable. In order for these solutions to be physically attainable, they must be stable. The linear stability analysis presented here provides the necessary conditions for the stability. The method of Lyapunov's function can also be used to assess the stability and the magnitude of the permissible perturbations so that the reactor returns to the steady state. In the case of linear stability analysis, the eigenvalues of a differential operator determine the stability. An excellent account of the stability analysis of chemical reactors can be found in Perlmutter (1972).

2.17.3.1 Linear Stability Analysis

Linear stability analysis is carried out on dynamical equations linearized about the steady-state solution (u_s,v_s). The steady-state solution is stable if the eigenvalues of the system of linearized equations are negative, unstable if those are positive, and indeterminate otherwise.

The dynamics of the CSTR is governed by the following dimensionless equations:

$$\frac{du}{dt} = 1 - u - Dau^n e^{-\gamma/v} \tag{2.292}$$

$$\frac{dv}{dt} = (1+\delta)(1 - v + \beta Dau^n e^{-\gamma/v}) \tag{2.293}$$

where the parameters are given by

$$u = \frac{C}{C_f} \quad \delta = \frac{UA}{F\rho C_p} \quad T_m = \frac{T_f + \delta T_c}{1+\delta}$$

$$v = \frac{T}{T_m} \quad \gamma = \frac{E}{RT_m} \quad Da = \frac{kVC_f^{n-1}}{F} \quad \beta = \frac{(-\Delta H)C_f}{\rho C_p T_m}$$

The linearized equations about the steady-state solution (u_s,v_s) can be written as

$$\frac{du}{dt} = -[1 + Dae^{-\gamma/v_s}]u - \frac{Da\gamma u_s}{v_s^2} e^{-\gamma/v_s} v \tag{2.294}$$

$$\frac{dv}{dt} = (1+\delta)\left\{\beta Dae^{-\gamma/v_s} u - \left[1 - \frac{\beta Da\gamma u_s}{v_s^2} e^{-\gamma/v_s}\right] v\right\} \tag{2.295}$$

The eigenvalues of the system of Equations (2.294) and (2.295) are negative if and only if

$$1 + Dae^{-\gamma/v_s} - \beta Da\gamma u_s / v_s^2 e^{-\gamma/v_s} > 0$$

and

$$2 + \delta + Dae^{-\gamma/v_s} - (1+\delta)(\beta Da\gamma u_s / v_s^2 e^{-\gamma/v_s}) >$$

which are the necessary conditions for the steady-state solution to be stable.

2.17.3.2 Method of Lyapunov's Function

The method of Lyapunov's function consists of constructing a function $V(x,y)$ with the following properties:

(i) $$V(x,y) > 0 \quad \text{for } x, y \neq 0$$

(ii) $$\frac{dV(x,y)}{dt} = \nabla V \cdot \boldsymbol{f} < 0 \quad \text{where } \frac{dx}{dt} = \boldsymbol{f}$$

For the steady-state solution (u_s, v_s) of a CSTR, the dynamical equations in terms of deviation variables (Denn, 1975),

$$x = u - u_s, \quad y = v - v_s$$

are written as

$$\frac{dx}{dt} = -(1 + Dae^{-\gamma/v}) - Dau_s\Delta(v, v_s)y \tag{2.296}$$

$$\frac{dy}{dt} = (1+\delta)[\beta Dae^{-\gamma/v}x - (1 - \beta Da\Delta(v, v_s))y] \tag{2.297}$$

where

$$\Delta(v, v_s) = \frac{e^{-\gamma/v} - e^{-\gamma/v_s}}{v - v_s}$$

To construct a Lyapunov's function, consider $V(x,y) = (x^2 + y^2)/2$:

$$\frac{dV(x,y)}{dt} = x\{-[1 + Dae^{-\gamma/v}]x - Dau_s\Delta(v, v_s)y)\}\cdots$$

$$+ y(1+\delta)\{-[1 - \beta Dau_s\Delta(v, v_s)]y + Da\beta e^{-\gamma/v}x\}$$

$$= -\{(1 + Dae^{-\gamma/v})x^2 + Da[u_s\Delta(v, v_s) - (1+\delta)\beta e^{-\gamma/v}]xy + (1+\delta)[1 - \beta Dau_s\Delta(v, v_s)]y^2\}$$

$\dot{V}(x, y)$ is negative definite if the terms in the braces are positive definite. Thus $\dot{V}(x, y)$ is negative definite if and only if

$$1 + Dae^{-\gamma/v} > 0$$

$$4(1+\delta)(1 + Dae^{-\gamma/v})[1 - \beta Dau_s\Delta(v, v_s)] - Da^2\{u_s\Delta(v, v_s) - (1+\delta)\beta e^{-\gamma/v}\}^2 > 0$$

The first inequality is true for power law kinetics. The second inequality holds only for certain values of v. Let v_c be the value of y such that $|v_c - v_s|$ is the minimum and for which the second inequality is violated. Then, the stability is ensured for all (u,v) such that

$$(u - u_s)^2 + (v - v_s)^2 < (v_c - v_s)^2$$

Other types of Lyapunov's functions may also be constructed.

For the general treatment in regard to Lyapunov's function, the reader may see Khalil (1996).

APPENDIX 2.A: MATHEMATICAL SOFTWARE

The development of software over the decades has enabled engineers to perform increasingly complex calculations based on the solution of a variety of mathematical equations. While analytic solutions can be well handled by symbolic mathematical software, the system of equations requiring numerical solution can be tackled using a variety of software packages. Furthermore, one can recognize that some software packages are designed to address specific classes of mathematical problems and methods of solutions. The purpose of this brief appendix is to make the reader aware of such tools along with their specific utilities and their sources.

Table 2.A.1 lists various software packages along with their utility in reference to the relevant mathematics in chemical engineering. It should be noted that the table lists only the tools that the authors are aware of and that it is *not complete* by any means. Furthermore, the mathematical utility of the software packages represents only a *fraction* of their many capabilities.

APPENDIX 2.B: DIRAC DELTA FUNCTION

The Dirac delta or Dirac's delta, introduced by the theoretical physicist Paul Dirac is an interesting function with signficant utility, which is formally denoted by δ and defined as follows:

$$\delta(x) = \begin{cases} \infty & x = 0 \\ 0 & x \neq 0 \end{cases}$$

that is constrained to satisfy

$$\int_{-\infty}^{\infty} \delta(x)dx = 1$$

Thus, the function may be visualized as the one representing an infinitely sharp peak bounding unit area.

Some of the important properties are listed below:

1. $\int_{-\infty}^{\infty} f(x)\delta(x-a)dx = f(a)$
2. $\int_{-\infty}^{\infty} \delta(\alpha x)dx = \frac{1}{|\alpha|}$ for a scalar α
3. $\int_{-\infty}^{\infty} f(t)\delta(t-\tau)dt = f(\tau)$
4. $\int_{-\infty}^{\infty} f(x)\delta^n(x)dx = -\int_{-\infty}^{\infty} \frac{df}{dx}\delta^{n-1}(x)dx$
5. $\int_{-1}^{1} \delta\left(\frac{1}{x}\right)dx = 0$
6. $\delta(x) = \int_{-\infty}^{\infty} e^{-2\pi i\lambda x}dx$

APPENDIX 2.C: TABLES OF INTEGRAL TRANSFORMS

We provide here six tables of various integral transforms for ready reference. The extensive listing can be obtained from Gradshteyn and Ryzhik (1983).

TABLE 2.C.1
Laplace Transforms

$F(\lambda)=\int_0^\infty e^{-\lambda x} f(x)dx$	$f(x)=\frac{1}{\sqrt{2\pi i}}\int_{\gamma-i\infty}^{\gamma+i\infty} F(\lambda)e^{\lambda x}dx$
$\frac{1}{\lambda^{n+1}}$	$\frac{x^n}{n!},\quad n\ge 0$
$\frac{a}{\lambda^2+a^2}$	$\sin(ax)$

3.1 INTRODUCTION

Statistics finds important applications by engineers, scientists, and industrial managers when planning and executing research, plant design and operation, marketing and sales programs. Improved operations, better and more uniform products, increased safety, and additional profitability often result. Experimental data contain errors or uncertainties for a variety of factors.

In analyzing a chemical process, it is important to first establish threshold knowledge of the key operating variables, or at least most of them. Such variables affect the operating costs, amount and quality of products formed, and of course profitability. Statistics are often employed to develop mathematical models for all of the above. Plant operators frequently need to be notified, because all of the following likely vary with time: sales of products, availability and cost of feed streams, character of desired product (varies with seasons, such as type of gasoline), etc. Statistics can indicate how to maximize profits.

Numerous resources are available that describe how statistics can be best employed. These include literature references (see list of references located at the end of this chapter), software packages, and the *Handbook of Statistical Methods* prepared by the National Institute of Standards and Testing [1]. The latter consists of about 3500 pages and contains coverage of topics of technical importance, including many examples. Its Internet address is http://www.itl.nist.gov/div898/handbook/index.htm. On the Internet, it is listed as *NIST/SEMATECH e-Handbook of Statistical Methods*. It is free to all and is highly recommended. The appendix at the end of this chapter provides an outline of the topics covered in the handbook. Suitable mathematical software packages are also available from several vendors, including (most commonly used) Microsoft Excel, Mathematica, MatLab®, and JMP. Several examples in this chapter refer to Microsoft Excel, because it simplifies many statistical tasks.

3.1.1 Data Types

Data are of two categories: discrete and continuous. Each type has its own statistical parameters, probability models, and statistical tools. Some statistical tests are applicable to only one type. Data are discrete if there is a finite set of possible outcomes. A data set is continuous if the data may, at least theoretically, assume any value over an interval. Large sets of discrete data are often modeled as continuous, because statistical tools for continuous data are typically simpler.

3.1.2 Random Variables

A variable is random if it is associated with an experiment (a test in the broadest sense, such as throwing dice, measuring temperature, collecting poll data, etc.) in which the outcome may take on values according to its data type. For example, the outcome of throwing two six-sided dice and taking their sum is an integer between 2 and 12, one of several discrete outcomes. Measuring temperature at some point in a room, however, takes on a random value depending on the temperature profile of the room, since the random values are between the upper and lower temperatures in the room.

3.1.3 Probability Distributions

The statistical description of an experiment is essential to defining the probability distribution of the data. A mathematical function that connects a particular outcome of an experiment to the chance or probability that the particular outcome will occur is needed. The form of a probability distribution will depend on the type of random variable. Regardless of the type of data, the sum of the probabilities of all possible outcomes adds to unity, i.e., 1.0.

3.1.3.1 Discrete Probability Distributions

For discrete random variables, the probability distribution can often be determined using mathematical intuition, as all experiments are characterized by a fixed set of outcomes. For example, consider an experiment in which a six-sided die is thrown. The variable x denotes the number on the die face, and $P(x)$ is the probability distribution, i.e., the chance of observing x on the face following a throw. Since this random variable is discrete, if the die is fair, then the probability of any possible value is equal and is given by $1/n$, where n is the number of sides, since the sum of all possible outcomes must be unity. The distribution is, therefore, called uniform. Hence, for $n = 6$, $P(x) = 1/6$, where $x = 1, 2, 3, 4, 5$, or 6.

Example 3.1

Determine the probability distribution $P(x)$ in which two six-sided dice are thrown simultaneously, where x represents the sum of faces of the dice.

Solution

The sum for this experiment may be $x = 2, 3, 4, \ldots, 11$, or 12. With two dice, there may be multiple outcomes that result in the particular x; the probability is not uniform. Therefore, the probability of observing x is simply the number of outcomes resulting in x divided by the number of possible outcomes (totaling 36):

x	Number of Outcomes	$P(x)$
2	1	1/36
3	2	1/18
4	3	1/12
5	4	1/9
6	5	5/36
7	6	1/6
8	5	5/36
9	4	1/9
10	3	1/12
11	2	1/18
12	1	1/36

This example demonstrates the simple method by which a discrete probability distribution can be determined.

3.1.3.2 Continuous Probability Density Distributions

For a continuous variable, it is improper to speak of the probability of a *particular* outcome occurring due to the infinite number of possible outcomes. Hence, the probability of a particular outcome is zero, and is more appropriately described by a probability density distribution within a small window. For example, consider an unbiased random number generator that generates an infinite number of real numbers between 0 and 3.0. Let θ be the random number generated and define $f(\theta)d\theta$ as the probability density distribution. The relative probability of observing a particular

number is equal to that of any other number (both being between 0 and 3). Because the sum (or in the case of a continuous probability density distribution, the integral) of all probabilities is equal to unity, one can write

$$\int_0^3 f(\theta)d\theta = 1 \tag{3.1}$$

Therefore, since the distribution is uniform, $f(\theta) = 1/3$. Such distributions provide an evaluation of reproducibility for data, but not accuracy.

3.1.4 Cumulative Probability Distribution Functions

A cumulative probability distribution function characterizes a set of outcomes between an upper and a lower bound. For a discrete distribution function, the associated distribution is usually denoted as $F(a \le x \le b)$, where a and b are the lower and upper bounds, respectively. The new function F is determined by summing the probability of independent outcomes that result in x between a and b. The distribution of a continuous probability density distribution can be written in the same manner and is determined by modifying the bounds of the integral appropriately. These properties of cumulative distribution functions are illustrated in the following example.

Example 3.2

When throwing two six-sided dice and taking their sum, determine the probability of observing a sum between 7 and 10, inclusive.

Solution

Probabilities are summed for face sums of 7, 8, 9, and 10 as follows:

$$F(7 \le x \le 10) = \sum_{i=7}^{10} P(i) = \frac{1}{6} + \frac{5}{36} + \frac{1}{9} + \frac{1}{12} = \frac{1}{2} \tag{3.2}$$

Example 3.3

For the random number generator mentioned in Section 3.1.3.2 (which generates a number between 0 and 3, such that $f(x) = 1/3$), determine the probability of observing a random number between 0.4 and 1.7.

Solution

The probability density distribution is integrated between 0.4 and 1.7:

$$F(0.4 \le x \le 1.7) = \int_{0.4}^{1.7} f(\theta)d\theta = \int_{0.4}^{1.7} \frac{1}{3} d\theta = 0.4333 \tag{3.3}$$

The bounds of a cumulative distribution might be $-\infty$ or ∞ if those bounds are mathematically meaningful to the probability model. For a lower bound $a = -\infty$, the cumulative distribution is interpreted as the probability of observing a value smaller than b. The positive infinity bound is exactly opposite.

3.1.5 Characteristic Parameters of a Probability Distribution

Probability distributions are characterized by several terms: the *mean* is the expected value of a population (denoted as μ) and the *variance* is the spread, or width, of a distribution (denoted as

σ^2) for discrete and continuous random variables. The standard deviation of a probability distribution is the square root of the variance and is denoted as σ. The units of the variance are those of the mean squared, and the standard deviation has the same units as the mean. Other parameters relating to probability distributions—skewness, kurtosis, and higher-order moments—are discussed in the literature [2–4].

3.1.6 Statistics of Small Sets of Data

Often it is not feasible to collect a large set of data, and a sample of the population is taken that (hopefully) closely approximates the probability distribution. This sample has its own statistics that are analogous, though not identical, to the population parameters. Like the population parameters mentioned before, the most important sample statistics are the sample mean and sample variance, denoted $\bar{x}$ and s^2, respectively.

For a set of n data points, the ith observation is denoted x_i. The sample mean (arithmetic average), $\bar{x}$, and sample variance, s^2, are defined [2] as follows:

$$\bar{x} = \frac{\sum_{i=1}^{n} x_i}{n} \tag{3.4}$$

$$s^2 = \frac{\sum_{i=1}^{n} (x_i - \bar{x})^2}{n-1} \tag{3.5}$$

The $n - 1$ in the denominator of the sample variance equals the number of degrees of freedom. For a data set with a known sample mean, knowledge of only $n - 1$ observations is necessary to determine the nth observation, constraining the problem by one degree of freedom. The sample standard deviation, (s), like the population counterpart, σ, is the square root of the sample variance.

The sample mean and sample variance are usually not equal to the population mean and population variance, although they are similar in meaning. These sample statistics help approximate the population parameters. Statistical tests and assumptions of the expected distribution of sample data provide intervals that should confidently contain the population parameters, as discussed in Section 3.3.

3.2 PROBABILITY DISTRIBUTIONS

Probability distributions are often employed in statistical analyses. When only success or failure can occur (two discrete outcomes), the following distributions can be employed: binomial distribution, geometric distribution, and Poisson distribution. In some laboratory or industrial trials, the results are simply a success or a failure. Sections 3.3 and 3.4 discuss the preferred statistical tests and the distribution suited for each test. For example, when dealing with a sample mean, statistical tests require the t distribution or normal (Gaussian) distribution, depending on the context. Statistical tests related to the variability of products or processes generally use the chi-square and F distributions. As the variability of a product or process becomes of more interest (e.g., Six-Sigma analysis, in which one goal is reduced product variability), statistical tests applicable to measures of data variability become increasingly useful. Other probability distributions, such as the Weibull distribution, log-normal distribution, beta distribution, etc., are less commonly used [2–4].

TABLE 3.1
Definition of Population Statistical Parameters

	Discrete Random Variable	Continuous Random Variable
Population mean	$\mu = \sum_i x_i P(x_i)$	$\mu = \int_{-\infty}^{\infty} x f(x)dx$
Population variance	$\sigma^2 = \sum_i (x_i - \mu)^2 P(x_i)$	$\sigma^2 = \int_{-\infty}^{\infty} (x-\mu)^2 f(x)dx$

3.2.1 Binomial Distribution—Discrete Variable

The binomial distribution describes the probability of x successes in n trials when only success or failure occurs. This distribution assumes that each trial is independent and that the probability of a success in each trial is constant. This probability is denoted p. The probability function for a binomial distribution [2] is

$$P(x,n) = \binom{n}{x} p^x (1-p)^{n-x} \tag{3.6}$$

$$\binom{n}{x} = \frac{n!}{x!(n-x)!} \tag{3.7}$$

Equation (3.6) can be derived using intuition. The probability of observing x successes and $n - x$ failures is $p^x(1 - p)^{n-x}$, and

$$\binom{n}{x}$$

is the binomial coefficient that equals the number of arrangements of subsets of size x given a total number of elements n. "(The binomial coefficient also equals the redundancy of the experiment.)" Using the appropriate equations in Table 3.1 along with the expression for $P(x,n)$ given in Equation (3.6), the mean value of x is $\mu = np$ and the variance of x is $\sigma^2 = np(1 - p)$.

Example 3.4

Suppose that a six-sided die is thrown 20 times. What is the probability of a particular number turning up 6 times? (A success is defined as that particular number turning up, and a failure is *any other* number turning up.)

Solution

The probability of any side is $p = 1/6$, $x = 6$, and $n = 20$. Using Equation (3.6),

$$P(6,20) = \binom{20}{6}\left(\frac{1}{6}\right)^{6}\left(\frac{5}{6}\right)^{14} = 0.0647$$

3.2.2 Geometric Distribution—Discrete Variable

The geometric distribution indicates the probability of conducting x trials to obtain a success in an experiment in which there are only two possible outcomes. Like the binomial distribution, this is another Bernoulli process. Each trial is assumed to be independent, and the probability of observing a success is constant over all trials, denoted p. The probability distribution for the geometric distribution [2] is

$$P(x) = (1-p)^{x-1}p \tag{3.8}$$

Similar to the binomial distribution, Equation (3.8) can also be derived intuitively. Since there is only one set of experimental trials that results in $x - 1$ failures followed by one success, the distribution has no binomial coefficient or redundancy. Consequently, the probability of the first success occurring in the xth trial is the probability of $x - 1$ failures multiplied by the probability of one success.

The expected value of the geometric distribution is $\mu = 1/p$, and the variance is $\sigma^2 = (1-p)/p^2$ [2].

Example 3.5

For a six-sided die, what is the probability of a chosen face turning up for the first time on the fourth throw?

Solution

For each throw of the die, the probability of a given face showing is $p = 1/6$. Since we desire the first success to be on the fourth throw, $x = 4$. Hence, the solution is given by

$$P(4) = \left(\frac{5}{6}\right)^{4-1}\left(\frac{1}{6}\right) = 0.0965$$

3.2.3 Poisson Distribution—Discrete Variable

The Poisson distribution describes the probability of a discrete number of events occurring within a fixed interval, given that the probability of the event occurring is independent of the size of the interval. For example, suppose that a manufacturing defect occurs with an average rate of occurrence p and the products are manufactured over an interval n. The expected number of defects is clearly np. The Poisson distribution is one way of describing the probability that x defects will occur in an interval n. This distribution is a generalization of the binomial distribution to an infinite number of trials. The mathematical form of the Poisson distribution [2] is

$$P(x) = \frac{e^{-\lambda}\lambda^{x}}{x!} \tag{3.9}$$

where x is the number of actual events and $\lambda = np$ is the *expected* number of events in the interval n.

The expected value of the Poisson distribution and the variance both equal λ.

Example 3.6

During continuous paper production, a tear occurs on average once every 500 feet. What is the probability that five tears will occur in 1000 feet?

Solution

The average rate of tears is $p = 1/500\ (\text{ft}^{-1})$ and the interval size is $n = 1000$ ft. Therefore, the *expected* number of tears is

$$\lambda = 1000\ \text{ft} \cdot \left(\frac{1}{500\ \text{ft}} \right) = 2$$

Using Equation (3.9), the probability of $x = 5$ tears occurring in 1000 feet of product is

$$P(5) = \frac{e^{-2} 2^5}{5!} = 0.0361$$

3.2.4 Normal or Gaussian Distribution—Continuous Variable

The normal or Gaussian distribution is commonly employed for large data sets, since they generally resemble a characteristic bell-shaped curve. Although the shape of each distribution may be qualitatively different, all bell curves collapse to the same distribution when scaled appropriately. As discussed in Section 3.3, the normal distribution also describes the distribution of sample means when the population variance is known. The analytic form of the normal distribution [2] is

$$f(x) = \frac{1}{\sqrt{2\pi\sigma^2}} \exp\left(\frac{-(x-\mu)^2}{2\sigma^2} \right) \tag{3.10}$$

The mean and standard deviation of the normal distribution are μ and σ, respectively. Since the normal distribution is designed for continuous data, the cumulative distribution function is more practical than the probability density function. For a particular data population, the cumulative distribution [2] is as follows:

$$F(x) = \frac{1}{\sqrt{2\pi\sigma^2}} \int_{-\infty}^{x} \exp\left(\frac{-(x'-\mu)^2}{2\sigma^2} \right) dx' = \frac{1}{2}\left(1 + erf\left(\frac{x-\mu}{\sqrt{2\sigma^2}} \right) \right) \tag{3.11}$$

The error function, $erf(y)$, is introduced because the normal distribution cannot be integrated analytically. The error function is found in many mathematical tables and software packages [5–8]. Summarizing, $F(x)$ is the probability of an observation being less than or equal to x. Conversely, the probability of an observation exceeding x is $1 - F(x)$. From the properties of integrals, it is straightforward to show that the probability of an observation being between a and b, $F(a \le x \le b)$, can be expressed as $F(b) - F(a)$. Values of $F(x)$ are also available in the literature or suitable software. For example, the probability of an observation falling within one standard deviation of the mean, $F(\mu - \sigma \le x \le \mu + \sigma)$, is 0.683. The probability of an observation being within two standard deviations is 0.955, and that within three is 0.997, a progression often referred to as the 68-95-99 rule [2].

The normal distribution is reduced to the *standard* normal distribution by introducing the transformation variable z, defined [2] as follows:

$$z = \frac{x - \mu}{\sigma} \tag{3.12}$$

Making this substitution into Equation (3.6) or (3.7) reduces the generic normal distribution to one with mean 0 and standard deviation 1, collapsing all possible normal distributions onto a standard curve. Tabulated values of the cumulative distribution function F are usually presented in terms of the transformation variable z. Sample values of $F(z)$ are presented in Table 3.2. Microsoft Excel contains an intrinsic function, NORMSDIST, that produces the cumulative probability for a standard normal variable z given as its argument. A companion function, NORMSINV, outputs the z value for a given $F(z)$. The Microsoft Excel manual or the electronic help files [5, 6] provide command syntax and usage examples.

Example 3.7

If the fuel mileage of a particular vehicle is normally distributed with a mean of 23.2 miles per gallon (mpg) and a standard deviation of 1.75 mpg,

1. What is the probability that the fuel mileage will fall in the manufacturer-stated range of 21 to 25 mpg?
2. What is the probability that the fuel mileage will exceed 25 mpg?

Solution

Solution 1

1. Using Equation (3.12), the z values for $x = 21$ and $x = 25$ are
   $z_{low} = (21 - 23.2)/1.75 = -1.26$
   $z_{high} = (25 - 23.2)/1.75 = 1.03$
2. Using Table 3.2, the cumulative distribution values for these z are 0.89617 (or 0.896) and 0.84849 (or 0.848). Hence,
   $F(z_{low}) = 1 - F(-z_{low}) = 1 - 0.896 = 0.104$
   $F(z_{high}) = 0.848$
   The probability that the fuel mileage is less than 21 mpg is 0.104, and the probability that the mileage is less than 25 mpg is 0.848. Therefore, the probability of the fuel mileage being between 21 and 25 mpg is

$$F(21 \le x \le 25) = F(-1.26 \le z \le 1.03) = 0.848 - 0.104 = 0.744$$

Solution 2

The probability that it exceeds 25 mpg is $1 - 0.848 = 0.152$.

3.2.5 *t* Distribution of Sample Means—Continuous Variable

With only a few data points, the resulting sample mean and variance are not equal to the true population parameters. The t distribution [9] then describes the distribution of sample means, where the test statistic is

$$t = \frac{\bar{x} - \mu}{s / \sqrt{n}} \tag{3.13}$$

This distribution is often used to compute confidence intervals or perform hypothesis tests on the sample mean. Writing under the pseudonym *Student*, W. S. Gosset showed that the t-test statistic

TABLE 3.2
Cumulative Probability, α, of the Standard Normal Distribution as a Function of the Standard Variable *z*. The left column indicates *z* to the tenths digit and the top row indicates *z* to the hundredths. For example, the α value for *z* = 1.38 is 0.91621.

is distributed according to a complicated expression involving gamma functions. When $n \to \infty$, the t distribution becomes identical to the normal distribution, and a data set with n greater than about 25 is effectively normal. Qualitatively, the t distribution is similar to the normal distribution, $f(t)$ being symmetric about its maximum value at $t = 0$. The cumulative distribution function for the variable $t_{\alpha,\nu}$ is listed in Table 3.3 for given values of ν and α, $\nu = n - 1$ representing the number

of degrees of freedom and α being the percentage of the distribution lying above the particular t. The Microsoft Excel functions TDIST and TINV can be used to calculate t values or cumulative probabilities [5, 6]. The t distribution is most useful in determining the confidence interval of a measured sample mean and testing hypotheses, as described in Sections 3.3 and 3.4.

Example 3.8

Ten measurements are taken. Above what t value will 10% of the measurements fall?

Solution

As $n = 10$, $\nu = n - 1 = 9$. Because 10% of the distribution lies above the t value, $\alpha = 0.1$. Then, reading from Table 3.3, for $\nu = 9$ and $\alpha = 0.1$, $t = 1.3830$. Therefore $P(t > 1.3830) = 0.1$.

Example 3.9

Now six measurements are taken. What two t values define an area, centered at $t = 0$, in which 95% of measurements will fall?

Solution

If 95% of measurements are to be included in the t interval, 2.5% of values will fall above and below the upper and lower t values, respectively. For $\nu = 5$ and $\alpha = 0.025$, the t value is 2.5706. Therefore $F(-2.5706 < t < 2.5706) = 0.95$.

3.2.6 Chi-Square Distribution for the Sample Variance—Continuous Variable

As in the t distribution that describes the distribution of sample means, a specific probability distribution is necessary to describe the distribution of the variance of samples. The chi-square distribution [2] describes the probability distribution of the sample variance for a sample of size n, where the test statistic χ^2 is

$$\chi^2 = \frac{(n-1)s^2}{\sigma^2} \tag{3.14}$$

The chi-square distribution is used to perform statistical tests on the sample variance. It is highly asymmetric for small values of n, but becomes more symmetric and similar to a normal distribution as n becomes large, such as 20 or 30. The cumulative distribution function of the chi-square distribution is listed in Table 3.4 as a function of ν and α, where $\nu = n - 1$ is the number of degrees of freedom and α is the percentage of the distribution above the particular χ^2. Microsoft Excel has built-in functions, CHIDIST and CHIINV, that compute a chi-square distribution [5, 6].

Example 3.10

Twenty measurements are taken. Above what χ^2 value will 10% of the measurements fall?

Solution

Because $n = 20$, $\nu = n - 1 = 19$. From Table 3.4, for $\nu = 19$ and $\alpha = 0.1$, $\chi^2 = 27.2036$. Therefore, $F(\chi^2 > 27.2036) = 0.1$.

Example 3.11

Ten measurements are taken. Define the areas for which 10% of measurements will have lower χ^2 and 10% will have higher χ^2.

Solution

The two χ^2 values to be found are those for $n = 10$ ($\nu = 9$), such that 10% of the distribution lies above the higher χ^2 value and 10% of the distribution lies below the smaller χ^2 value. The higher

χ^2 is the value having $\nu = 9$ and $\alpha = 0.1$, which, from Table 3.4, is $\chi^2 = 14.6837$. The lower value is defined such that 10% of χ^2 values fall below or, equivalently, 90% fall above. This χ^2 value is that having $\nu = 9$ and $\alpha = 0.9$, which is 4.1682. These two χ^2 values describe a region containing 80% of χ^2 values for the given n. Therefore, one can write $F(\chi^2 < 4.1682) = 0.1$, $F(4.1682 < \chi^2 < 14.6837) = 0.8$, and $F(\chi^2 > 14.6837) = 0.1$.

3.2.7 *F* Distribution for the Ratio of Sample Variances—Continuous Variable

A question that may arise is whether the variability (the variance) of a measured variable changes from sample to sample. Significant changes in the variability may indicate a manufacturing problem.

Changes in variability are often quantified by examining the ratio of the variance of two samples, where a statistically significant (see Section 3.3) ratio not equal to unity indicates a change. The proper distribution to describe this ratio is the F distribution [2], which describes the ratio of two chi-square variables (e.g., a ratio of variances). The test statistic for this distribution is

$$F = \frac{s_1^2 / \sigma_1^2}{s_2^2 / \sigma_2^2} \tag{3.15}$$

where samples 1 and 2 have degrees of freedom $\nu_1 = n_1 - 1$ and $\nu_2 = n_2 - 1$, respectively. Owing to its form, the F distribution is used in statistical tests of the ratio of two sample variances. Multiple tables are required to calculate an F value because F depends on three parameters: the two degrees of freedom and the desired cumulative probability for that F value. The number of tables is reduced by the relationship [2]

$$F_{1-\alpha,\nu_1,\nu_2} = \frac{1}{F_{\alpha,\nu_2,\nu_1}} \tag{3.16}$$

where $F_{1-\alpha,\nu_1,\nu_2}$ is the F value for a cumulative probability of $1 - \alpha$ and degrees of freedom ν_1 and ν_2 in the numerator and denominator, respectively. The F distribution is highly asymmetric, but becomes normal as the number of degrees of freedom approaches infinity. Tables 3.5 through 3.9 display the F values for cumulative probabilities (α) of 0.01, 0.025, 0.05, 0.1, and 0.25, respectively. The Microsoft Excel functions FDIST and FINV provide F values and cumulative probabilities [5, 6]. Since the F distribution depends on three variables, these Excel functions are simpler to use than reading from tables.

Example 3.12

Five measurements are taken in sample 1 and seven measurements are taken in sample 2. Above what F value will 10% of the measurements fall?

Solution

Solving with a confidence level of 90% ($\alpha = 0.1$), with $\nu_1 = 5 - 1 = 4$ and $\nu_2 = 7 - 1 = 6$, and reading from Table 3.8, $F_{0.1,4,6} = 3.1808$. Therefore, 10% of F values fall above 3.1808 for the given degrees of freedom.

Example 3.13

For the same two sample sizes, what two F values define an interval for which 5% of measurements fall above the higher F value (95% fall above this F) and 5% fall below the lower F value?

Solution

We solve such that 5% of measurements fall below the lower F value and 95% fall above this F, 5% of measurements fall above the higher F value. Therefore, the two F values for this interval are $F_{0.95,4,6}$ and $F_{0.05,4,6}$. The lower F value is not listed in one of the tables, so the relationship shown in Equation (3.16) is used to replace $F_{0.95,4,6}$ with $1/F_{0.05,6,4}$. Reading from Table 3.7, $F_{0.05,4,6} = 4.5337$ and $F_{0.05,6,4} = 6.1631$. Then, $F_{0.95,4,6} = 1/F_{0.05,6,4} = 0.1623$. Therefore, 90% of F measurements fall between 0.1623 and 4.5337 for the specified samples.

3.3 CONFIDENCE INTERVALS OF POPULATION PARAMETERS

When collecting experimental data, experimental measurements are *sample* parameters and do not represent the true *population* parameters exactly. Hence, based on the experimental measurements of sample parameters, in what interval does the population parameter lie? Using the probability

distributions discussed in Section 3.2, one can estimate many population parameters. When population parameters are known, tests can be made as to some predetermined interval of confidence. Formalized hypothesis testing is discussed in Section 3.4. Both confidence intervals and hypothesis testing require a preselected *confidence level*. For most statistical analyses, the preferred confidence level is 95%. Selecting a lower confidence level increases the margin of error in statistical analysis, and vice versa.

Confidence intervals of population parameters are determined from sample parameters as follows:

1. A confidence level of the interval indicates the probability that the true population parameter lies within that interval. The confidence level is often written as $100(1 - \alpha)\%$, where $100\alpha\%$ is the probability that the population parameter lies outside the interval. With a confidence level of 95%, $\alpha = 0.05$ (so that $1.0 - 0.05$ equals 0.95).
2. The interval of the test statistic is determined from the confidence level. For a generic test statistic y, there is an interval

$$y_l \le y \le y_h \tag{3.17}$$

such that $100(1 - \alpha)\%$ of y values fall between y_l and y_h. Equivalently,

$$F(y_l \le y \le y_h) = 1 - \alpha \tag{3.18}$$

If the interval defines a region below which the population parameter lies, then y_l is replaced with $-\infty$. Likewise, y_h is replaced with ∞ to determine the minimum value of the population parameter. Both situations are termed "one-sided confidence intervals," as the interval is bounded on only one side. Otherwise, the interval is "two-sided" and the interval has bounds on two sides. Distributions, y_l and y_h are chosen to be centered about $y = 0$, so that $y_l = -y_h$.
3. The test statistic is replaced by its definition in terms of the population and sample parameters.
4. The inequality defining the confidence interval is manipulated algebraically to yield the confidence interval of the population parameter.

The following subsections describe how confidence intervals are constructed using the probability distributions discussed in Section 3.2. Confidence intervals can also be constructed with other probability distributions than those discussed here (see references [1–4]).

3.3.1 Confidence Interval of a Mean: Population Variance Known

According to the central limit theorem, the probability density distribution of $\bar{x}$ for a sample of size n will be given by a standard normal distribution with the test statistic defined [2] as

$$z = \frac{\bar{x} - \mu}{\sigma / \sqrt{n}} \tag{3.19}$$

For lower and upper z values z_l and z_h, respectively, the confidence interval for μ with confidence level $100(1 - \alpha)\%$ is defined by the following inequalities, which follow from the replacement of y by z, y_l by z_l, and y_h by z_h in Equation (3.17):

$$z_l \le \frac{\bar{x} - \mu}{\sigma / \sqrt{n}} \le z_h \tag{3.20}$$

$$\bar{x} - z_h \frac{\sigma}{\sqrt{n}} \leq \mu \leq \bar{x} - z_l \frac{\sigma}{\sqrt{n}} \quad (3.21)$$

(Equation (3.21) is obtained by rearranging Equation (3.20), which follows from applying Equation (3.17) to the standard normal variable z.) If, for instance, the confidence interval is chosen to be symmetric about μ (as is usually done), z_h is normally written as $z_{\alpha/2}$ to denote that α/2 percentage points fall above z_h. Symmetry would also provide $z_l = -z_h = z_{\alpha/2}$. The following example illustrates the process of determining the confidence interval for a population mean.

Example 3.14

For a filtration experiment, the variance of the solids collection rate is known to be $\sigma^2 = 4.50$. After three experimental runs, the collection rate was determined to have a sample mean $\bar{x} = 25.50$. Determine the two-sided confidence interval of the population mean μ for a confidence level of 95%.

Solution

1. With a two-sided confidence interval, 2.5% of the distribution is above and 2.5% is below the upper and lower bounds, respectively. Therefore, $\alpha = 0.05$.
2. Using Table 3.2, the z value is 1.96 and –1.96 for the upper and lower bounds, because $F(z \leq 1.96) = 0.975$. Because the normal distribution is symmetric, the lower bound is $z_l = -1.96$. (One could confirm this by showing that $F(z \leq -1.96) = 0.025$.)
3. Using Equation (3.7),

$$-1.96 \leq \frac{25.5 - \mu}{\sqrt{4.5} / \sqrt{3}} \leq 1.96$$

4. The 95% confidence interval for μ is calculated as

$$23.1 \leq \mu \leq 27.9$$

Since the confidence interval depends on $1/\sqrt{n}$, it becomes narrower as n increases, as the next example shows.

Example 3.15

When seven additional experimental runs are completed, n increases from 3 to 10, and the sample mean becomes $\bar{x} = 25.76$. In this case, σ, z_l, and z_h are unchanged. Determine the new 95% confidence interval for μ.

Solution

One can proceed directly to step 3. Entering $\bar{x} = 25.76$ and $n = 10$ into Equation (3.20),

$$-1.96 \leq \frac{25.76 - \mu}{\sqrt{4.5} / \sqrt{10}} \leq 1.96$$

Solving yields a slightly smaller interval:

$$24.5 \leq \mu \leq 27.1$$

Example 3.16

For a confidence level of 80% ($\alpha = 0.2$) and with $\bar{x} = 25.76$ and $n = 10$, determine the confidence interval for μ.

Solution

From Table 3.2, the z values defining the interval are $z_l = -1.28$ and $z_h = 1.28$. (These values were obtained by linear interpolation.) Therefore, Equation (3.20) becomes

$$-1.282 \le \frac{25.76 - \mu}{\sqrt{4.5} / \sqrt{10}} \le 1.282$$

The confidence interval for μ has hence narrowed as indicated next:

$$24.9 \le \mu \le 26.6$$

3.3.2 Confidence Interval of a Mean: Population Variance Unknown

When the population variance σ^2 is not known, the confidence interval for a population mean cannot be determined using a standard normal distribution, but it can be determined with the t distribution. As discussed in Section 3.2.5, one defines the test statistic t in terms of $\bar{x}$, μ, n, and the sample variance s^2 (see Equation (3.13)). By replacing the generic test statistic y in Equation (3.17) with t, the interval for μ is defined [2] by

$$t_l \le \frac{\bar{x} - \mu}{s / \sqrt{n}} \le t_h \tag{3.22}$$

or, equivalently,

$$\bar{x} - t_h \frac{s}{\sqrt{n}} \le \mu \le \bar{x} - t_l \frac{s}{\sqrt{n}} \tag{3.23}$$

Since the t value depends on $\nu = n - 1$, the number of degrees of freedom, and because the t distribution is symmetric about $t = 0$, t_l is usually written as $t_{1-\alpha/2,\nu}$ and, likewise, t_h is often written as $t_{\alpha/2,\nu}$. As in the previous section, the confidence level is $100(1 - \alpha)\%$. The t distribution is highly sensitive to the number of degrees of freedom or, equivalently, n. For samples sizes larger than about 25, though, the t distribution is almost identical to the normal distribution and will not change significantly if n increases. For large samples, one could replace the t variable with z (Equation (3.19)) and just assume that $s^2 = \sigma^2$. Sometimes the ratio $s / \sqrt{n}$ is referred to as the standard error (*SE*) and is reported rather than the standard deviation or variance. Especially for least squares regression parameters, the standard error is easier to compute than the variance and, as such, replaces $s / \sqrt{n}$ for testing a hypothesis or in the calculation of confidence intervals. The following examples indicate how a confidence interval for μ can be generated using the t distribution.

Example 3.17

In Example 3.14, the sample of size $n = 3$ had a mean of $\bar{x} = 25.50$ and a sample variance of $s^2 = 4.8$ (slightly larger than the presumed population variance used in the previous examples). Determine the two-sided confidence interval for μ for a confidence level of 95%.

Solution

1. For a confidence level of 95%, $\alpha = 0.05$.
2. Reading from Table 3.3, $F(t \le 4.303) = 0.975$ for $\nu = 3 - 1 = 2$. Since the t distribution is symmetric, $F(-4.303 \le t \le 4.303) = 0.95$. Therefore, the lower bound is $t_{1-\alpha/2,n} = -4.303$ and the upper bound is $t_{\alpha/2,\nu} = 4.303$.

3. Equation (3.22) becomes

$$-4.303 \le \frac{25.5 - \mu}{\sqrt{4.8} / \sqrt{3}} \le 4.303$$

4. The 95% confidence interval for μ is, then,

$$20.06 \le \mu \le 30.94$$

This interval is larger when defined by a *t* statistic. Some difference is due to the sample variance being slightly larger than the population variance in the previous example, but the major difference is due to the *t* distribution being much wider than the standard normal distribution when the sample size is small. The following example demonstrates the effect of sample size on confidence intervals.

Example 3.18

If the sample size for the solids collection experiment had been increased to $n = 10$, but the sample mean and sample variance were unchanged, what would be the 95% confidence interval for μ?

Solution

The lower and upper *t* values are $t_{0.975,9} = -2.262$ and $t_{0.025,9} = 2.262$ (as listed in Table 3.3). Entering the parameters into Equation (3.23), as shown below, there is a smaller interval as compared with the case of three samples:

$$25.50 - 2.262\frac{\sqrt{4.8}}{\sqrt{10}} \le \mu \le 25.50 + 2.262\frac{\sqrt{4.8}}{\sqrt{10}}$$

and the 95% confidence interval is, then,

$$23.93 \le \mu \le 27.07$$

3.3.3 Confidence Interval of the Difference of Two Means

Occasionally, an experiment should determine if two populations have different population means. For example, following process modification, has the product's specification(s) changed? Measuring the confidence interval for the difference in the population means is a statistical test that can be employed. The *t* distribution is widely used in this case [2]. Table 3.10 shows the equations to be used. Because the population variances of the two samples may differ, two sets of equations are necessary.

The variables $\bar{x}_i$, s_i^2, and n_i in Table 3.10 are the sample mean, sample variance, and number of data points of the *i*th sample, respectively. In the calculation of ν in the case of unequal population variances, the result should be rounded to the nearest integer. The *t* distribution can approximate the difference of sample means for populations with unequal population. The *t* variable is obtained via Table 3.3. Table 3.10 is also important; one should not assume that the population variances are identical without evidence. When in doubt, assume that the populations have differing variances, as this may provide a wider confidence interval (and a larger margin of error in drawing conclusions).

The most important conclusion is to determine whether there is any difference in population means. Depending on the chosen confidence level, the resulting confidence interval may contain the value zero. For such a case, at the given level of confidence, the populations do not have statistically different means, despite any difference in the sample means or variances. Conversely, if zero is not contained in the confidence interval, then the population means differ at that confidence level.

TABLE 3.10
Statistical Parameters for the Difference in Population Mean of Two Samples

Equal Population Variance $\sigma_1^2 = \sigma_2^2$	Unequal Population Variance $\sigma_1^2 \neq \sigma_2^2$
$t = \dfrac{(\bar{x}_1 - \bar{x}_2) - (\mu_1 - \mu_2)}{s_p\sqrt{\dfrac{1}{n_1} + \dfrac{1}{n_2}}}$	$t = \dfrac{(\bar{x}_1 - \bar{x}_2) - (\mu_1 - \mu_2)}{\sqrt{\dfrac{s_1^2}{n_1} + \dfrac{s_2^2}{n_2}}}$
$s_p^2 = \dfrac{(n_1 - 1)s_1^2 + (n_2 - 1)s_2^2}{n_1 + n_2 - 2}$	…
$\nu = n_1 + n_2 - 2$	$\nu = \dfrac{\left(\dfrac{s_1^2}{n_1} + \dfrac{s_2^2}{n_2}\right)^2}{\dfrac{(s_1^2/n_1)^2}{n_1 - 1} + \dfrac{(s_2^2/n_2)^2}{n_2 - 1}}$

Source: Montgomery, Douglas C., and Runger, George C., *Applied Statistics and Probability for Engineers*, 3rd ed., John Wiley & Sons, New York (2003).

Example 3.19

This example is adapted from the *NIST/SEMATECH e-Handbook of Statistical Methods*, Section 7.3.1 [1]. Two different procedures are employed to assemble a device. For procedure 1, the mean assembly time for a sample of $n_1 = 11$ is 36.1 s with standard deviation 4.91 s. Procedure 2 has mean assembly time 32.2 s with standard deviation 2.54 s for a sample of $n_2 = 9$. Are the means statistically different at a confidence level of 95% if the populations are assumed to have identical variance?

Solution

The degrees of freedom and pooled variance are calculated before computing the interval. Since the populations have equal variance, the appropriate equations are those in the left side of Table 3.10:

$$s_p^2 = \frac{(n_1 - 1)s_1^2 + (n_2 - 1)s_2^2}{n_1 + n_2 - 2} = \frac{(11 - 1)\cdot 4.91^2 + (9 - 1)\cdot 2.54^2}{11 + 9 - 2} = 16.3$$

$$v = n_1 + n_2 - 2 = 11 + 9 - 2 = 18$$

1. For a confidence level of 95%, $\alpha = 0.05$.
2. With $\nu = 18$ and $\alpha = 0.05$, the lower and upper t values (from Table 3.3) are −2.1009 and 2.1009, respectively.
3. The t variable is defined by the left side of Table 3.10. Entering this t into Equation (3.17) and yields the confidence interval

$$t_{0.975,18} \leq \frac{(\bar{x}_1 - \bar{x}_2) - (\mu_1 - \mu_2)}{s_p\sqrt{\dfrac{1}{n_1} + \dfrac{1}{n_2}}} \leq t_{0.025,18}$$

4. Entering known values and rearranging,

$$0.0922 \text{ s} \le \mu_1 - \mu_2 \le 7.71 \text{ s}$$

Since zero is not included in the confidence interval, the mean assembly time of procedure 2 is less than that of procedure 1.

Example 3.20

Repeat Example 3.19 if it is not known whether the populations have equal variances.

Solution

Since the population variances are not equal, the degrees of freedom are calculated using the appropriate equation from the right side of Table 3.10 as follows:

$$\nu = \frac{\left(\frac{s_1^2}{n_1} + \frac{s_2^2}{n_2}\right)^2}{\frac{(s_1^2/n_1)^2}{n_1 - 1} + \frac{(s_2^2/n_2)^2}{n_2 - 1}} = \frac{\left(\frac{4.91^2}{11} + \frac{2.54^2}{9}\right)^2}{\frac{(4.91^2/11)^2}{11-1} + \frac{(2.54^2/9)^2}{9-1}} = 15.53 \approx 16$$

(Note that ν is rounded to the nearest integer, as noninteger degrees of freedom are not sensible.) The upper and lower t values (from Table 3.3) are 2.1120 and −2.1120, respectively. Entering the t variable in the right side of Table 3.10 into Equation (3.17), the interval is defined by

$$t_{0.975,16} \le \frac{(x_1 - x_2) - (\mu_1 - \mu_2)}{\sqrt{\frac{s_1^2}{n_1} + \frac{s_2^2}{n_2}}} \le t_{0.025,16}$$

Entering the known values into the above equation yields

$$0.285 \text{ s} \le \mu_1 - \mu_2 \le 7.52 \text{ s}$$

Once again, zero is not included in the interval and, as such, the two procedures have differing mean assembly times. Interestingly, the interval generated without the assumption of equal population variances is smaller than the previous case, owing mainly to the large difference between the two sample standard deviations.

3.3.4 Confidence Interval for the Variance

As discussed in Section 3.2.6, the variance of a sample can be calculated using the chi-square distribution. Computing the confidence interval for the population variance from the sample statistic is straightforward using the procedure laid out in Section 3.3 with the chi-square test statistic shown in Equation (3.14). Since the chi-square distribution is not symmetric, the upper and lower bounds are not simply opposite in sign, as they are in the normal or t distributions.

Example 3.21

For the solids collection experiment in Examples 3.17 and 3.18, the variance of the collection rate of a sample of size n = 10 was stated to be 4.8. Determine the 90% confidence interval of the population variance.

Solution

1. For a confidence level of 90%, $\alpha = 0.1$.
2. From Table 3.4, the lower and upper bounds of the interval are $\chi_l^2 = 0.3.3251$ and $\chi_h^2 = 16.919$, respectively, for $\nu = n - 1 = 9$.
3. The interval is defined by

$$\chi_l^2 \le \frac{(n-1)s^2}{\sigma^2} \le \chi_h^2$$

4. Entering the known values,

$$\frac{(n-1)s^2}{\chi_h^2} \le \sigma^2 \le \frac{(n-1)s^2}{\chi_l^2}$$

the population variance is calculated to be between 2.6 and 13.

3.3.5 Confidence Interval for the Ratio of Two Variances

The confidence interval for the ratio of two variances is determined using the F distribution, as discussed in Section 3.2.7. Again, the procedure discussed in Section 3.3 is followed, using the F variable defined in Equation (3.15). Also, the F distribution is asymmetric and, as such, will have upper and lower bounds on the F variable that are not simply opposite in sign. When a confidence interval for the ratio of two variances contains unity (1.0), then, subject to the selected level of confidence, the two variances are not different.

Example 3.22

For the two procedures previously analyzed, the standard deviation of the assembly time for procedure 1 was found to be 4.91 s for a sample of size $n_1 = 11$. Procedure 2 had standard deviation 2.54 s for $n_2 = 9$. Determine the 95% confidence interval for the ratio of the population variances, σ_1^2/σ_2^2.

Solution

Following the procedure in Section 3.3, using the F variable and its definition:

1. For a confidence level of 95%, $\alpha = 0.05$.
2. The lower F variable can be denoted $F_{1-\alpha/2,\nu_1,\nu_2}$ and the upper $F_{\alpha/2,\nu_1,\nu_2}$. For these sample sizes, $\nu_1 = 10$ and $\nu_2 = 8$. Reading from Table 3.6 (or using the Microsoft Excel function FINV), $F_{0.025,10,8} = 4.2951$, and utilizing the symmetry rule of Section 3.2.7, $F_{0.975,10,8} = 1/F_{0.025,8,10}$. Again, from Table 3.6, one has $F_{0.975,10,8} = 1/3.8549 = 0.2594$.
3. Replacing the generic variable y with F,

$$F_{1-\alpha/2,\nu_1,\nu_2} \le \frac{s_1^2/\sigma_1^2}{s_2^2/\sigma_2^2} \le F_{\alpha/2,\nu_1,\nu_2}$$

4. Rearranging and entering the known values,

$$\frac{s_1^2 / s_2^2}{F_{\alpha/2,\nu_1,\nu_2}} \le \frac{\sigma_1^2}{\sigma_2^2} \le \frac{s_1^2 / s_2^2}{F_{1-\alpha/2,\nu_1,\nu_2}}$$

$$0.870 \le \frac{\sigma_1^2}{\sigma_2^2} \le 14.4$$

Hence, the ratio of population variances falls between 0.870 and 14.4. Since this interval contains unity, the ratio may be unity at a 95% confidence level and, hence, the two population variances do not differ based on this test.

3.3.6 Summary of Confidence Intervals

The confidence intervals discussed in this subsection are shown in Table 3.11 [2] in two-sided form. These intervals can be converted to one-sided form by removing the appropriate inequality and replacing the remaining $(1 - \alpha/2)$ or $\alpha/2$ term with $(1 - \alpha)$ or α. For example, the generic two-sided confidence interval $y_{\alpha/2} \le y \le y_{1-\alpha/2}$ is replaced with $y \le y_{1-\alpha}$ to define a one-sided interval with an upper bound.

TABLE 3.11
Summary of Several Two-Sided Confidence Intervals

Interval Type	Sample Parameter	Two-Sided Interval with Confidence Level 100(1 − α)%
Population mean (μ), variance (σ^2) known	$\bar{x}$	$\bar{x} - z_{\alpha/2}\frac{\sigma}{\sqrt{n}} \le \mu \le \bar{x} - z_{1-\alpha/2}\frac{\sigma}{\sqrt{n}}$
Population mean (μ), variance (σ^2) unknown	$\bar{x}$	$\bar{x} - t_{\alpha/2,n-1}\frac{s}{\sqrt{n}} \le \mu \le \bar{x} - t_{1-\alpha/2,n-1}\frac{s}{\sqrt{n}}$
Difference between population means ($\mu_1 - \mu_2$) for $\sigma_1^2 = \sigma_2^2$	$\bar{x}_1 - \bar{x}_2$	$\bar{x}_1 - \bar{x}_2 - t_{a/2,n_1+n_2-2}s_p\sqrt{\frac{1}{n_1}+\frac{1}{n_2}} \le \mu_1 - \mu_2 \le \bar{x}_1 - \bar{x}_2 - t_{1-a/2,n_1+n_2-2}s_p\sqrt{\frac{1}{n_1}+\frac{1}{n_2}}$ where $s_p = \sqrt{\frac{(n_1-1)s_1^2+(n_2-1)s_2^2}{n_1+n_2-2}}$
Difference between population means ($\mu_1 - \mu_2$) for $\sigma_1^2 \ne \sigma_2^2$	$\bar{x}_1 - \bar{x}_2$	$\bar{x}_1 - \bar{x}_2 - t_{a/2,\nu}\sqrt{\frac{s_1^2}{n_1}+\frac{s_2^2}{n_2}} \le \mu_1 - \mu_2 \le \bar{x}_1 - \bar{x}_2 - t_{1-a/2,\nu}\sqrt{\frac{s_1^2}{n_1}+\frac{s_2^2}{n_2}}$ where $\nu = \frac{\left(\frac{s_1^2}{n_1}+\frac{s_2^2}{n_2}\right)^2}{\frac{(s_1^2/n_1)^2}{n_1-1}+\frac{(s_2^2/n_2)^2}{n_2-1}}$
Population variance (σ^2)	s^2	$\frac{(n-1)s^2}{\chi^2_{\alpha/2,n-1}} \le \sigma^2 \le \frac{(n-1)s^2}{\chi^2_{1-\alpha/2,n-1}}$
Ratio of population variances (σ_1^2/σ_2^2)	s_1^2/s_2^2	$\frac{s_1^2/s_2^2}{F_{\alpha/2,n_1-1,n_2-1}} \le \frac{\sigma_1^2}{\sigma_2^2} \le \frac{s_1^2/s_2^2}{F_{1-\alpha/2,n_1-1,n_2-1}}$

3.4 STATISTICAL HYPOTHESIS TESTING

Statistical tests are available for certain populations using available information; the analyses can be performed at a given confidence level by the methods explained. When an improved mathematical model is available, better conclusions can be realized.

Statisticians often use the following terms: A **null hypothesis** is a statement proposed for test and is identified as H_0. The **alternative hypothesis**, H_1, is the competing statement regarding the data that is true if the null hypothesis is false. If the null hypothesis is correct, the **acceptance region** indicates the correct interval of desired confidence level, or $100(1 - \alpha)\%$, and the **critical region** is the interval(s) in which the null hypothesis is false.

To perform a hypothesis test:

1. Identify the parameter of interest such as the population mean, μ, or the variance, σ^2.
2. State the null hypothesis, H_0. Then identify the alternative hypothesis, H_1. (The alternative hypothesis can be two sided or one sided.)
   Examples:
   a. H_0: The mean reaction rate is 50 mol/l · s; $\mu = 50$ mol/l · s.
      H_1: The mean reaction rate is not 50 mol/l · s (two sided); $\mu \neq 50$ mol/l · s, or
      H_1: The mean reaction rate is less than 50 mol/l · s (one sided); $\mu < 50$ mol/l · s.
   b. H_0: The variance exceeds 10 cm²; $\sigma^2 > 10$ cm².
      H_1: The variances is less than 10 cm²; $\sigma^2 \leq 10$ cm².
3. Select a significance level for α. (It is critical that the significance level be chosen *before* performing the statistical test so that the statistical test does not bias the selection of a significance level, which could result in incorrect conclusions.) For example, $\alpha = 0.05$ (confidence level is 95%) or $\alpha = 0.01$ (confidence level is 99%).
4. Identify the test statistic and associated probability distribution appropriate to the hypothesis.
   Examples:
   Mean with unknown variance: t variable and t distribution
   Two variances: F variable and F distribution
5. Determine the critical region(s) in terms of the test statistic. For example, one-sided t-test: $t \leq t_{\alpha,\nu}$, or two-sided F-test: $F < F_{\alpha/2,\nu_1,\nu_2}$ and $F > F_{1-\alpha/2,\nu_1,\nu_2}$.
6. Calculate the test statistic for the sample data.
7. Accept or reject the null hypothesis H_0 based on the calculated test statistic and the bounds of the critical region.

A new hypothesis may be proposed and the procedure repeated if the null hypothesis is rejected, but the new hypothesis is biased, since it is based on previously tested information. This procedure is utilized in the following examples.

Example 3.23

For a decomposition reaction at constant volume and temperature (see Example 3.26 in Section 3.5.1.1), the concentration of species A follows a first-order exponential decay given by

$$C_A(t) = C_{A0}\exp(-kt)$$

where C_A is the concentration of species A in moles per liter, t is time in seconds, C_{A0} is the concentration of species A at $t = 0$, and k is the rate constant for the particular temperature with units of inverse seconds. In Example 3.26, k is estimated by linear regression to equal 0.503 h^{-1} with a standard error of 0.022 h^{-1} with a sample size of $n = 11$. The rate constant was thought to be 0.530 h^{-1} for the particular temperature. Does a hypothesis test support this value of k at a confidence level of 95%?

Solution

We must determine whether 0.530 s^{-1} is an acceptable value for the rate constant.

1. The value of interest is the mean value of the rate constant. For this example, the mean value will be denoted μ and is equal to 0.530 h^{-1}. The estimate of this mean is denoted $\bar{x}$ and is given by the measured value, 0.503 h^{-1}. The standard error, $SE(\bar{x})$, is 0.022 h^{-1}.
2. The two hypotheses:
   H_0: $k = 0.530\ h^{-1}$ (the given value is correct).
   H_1: $k \neq 0.530\ h^{-1}$ (the given value is incorrect).
3. Since the stated confidence level is to be 95%, the significance level is $\alpha = 0.05$.
4. For a mean with unknown population variance, the proper test statistic is the t variable, defined for this case [2] as

$$t = \frac{\bar{x} - \mu}{SE(\bar{x})}$$

5. For a linear regression, the number of degrees of freedom is $\nu = n - 2$ because two degrees of freedom are taken by the fitting parameters (see Section 3.5). Thus, $\nu = 9$. The critical region will be the upper and lower tails of the t distribution that have cumulative probability of 0.025 each. Thus, reading from Table 3.3, the lower t value is $t_{11,0.975} = -2.26$ and the upper t value is $t_{11,0.025} = 2.26$. Thus, the critical region is defined by

$$t < -2.26 \quad \text{and} \quad t > 2.26$$

   Since this hypothesis test is two sided, there are two regions in which the null hypothesis could be rejected.
6. The t variable is

$$t = \frac{\bar{x} - \mu}{SE(\bar{x})} = \frac{0.503\ h^{-1} - 0.530\ h^{-1}}{0.022\ h^{-1}} = -1.23$$

Since the t variable is neither greater than 2.26 nor less than –2.26, and therefore, falls outside the critical region, the null hypothesis should be accepted. The alternative hypothesis is rejected. At a confidence level of 95%, one may state that the mean rate constant k is 0.530 s^{-1}.

Example 3.24

During a polymerization reaction, the viscosity of a reactor effluent is measured periodically to determine the reaction progress. The measurement is repeated so that $n = 6$. If the true variance exceeds 0.8 cSt^2 (cSt = centistokes), the measurements are repeated to achieve better precision. For this sample, the mean viscosity was determined to be 106.4 cSt with variance 1.9 cSt^2. At a confidence level of 95%, does the variance exceed the desired variability?

Solution

1. The value of interest is the population variance σ^2, which is estimated for this sample of $n = 6$ with sample variance $s^2 = 1.9\ cSt^2$.
2. The hypotheses are
   H_0: $\sigma^2 \leq 0.8\ cSt^2$.
   H_1: $\sigma^2 > 0.8\ cSt^2$.
3. For a 95% confidence level, the significance level is $\alpha = 0.05$.

4. Using chi-square statistics, the test statistic [2] is

$$\chi^2 = \frac{(n-1)s^2}{\sigma^2}$$

5. The number of degrees of freedom for this sample is $\nu = n - 1 = 5$. For this one-sided test, this hypothesis should be rejected if the chi-square test statistic lies in the upper tail of the chi-square distribution for $\nu = 4$ with cumulative probability equal to 0.05. Reading from Table 3.4, this tail begins at $\chi^2_{0.05,5} = 11.1$. The critical region is therefore $\chi^2 > 11.1$.
6. For this sample, the chi-square test statistic is

$$\chi^2 = \frac{(n-1)s^2}{\sigma^2} = \frac{6(5-1)\cdot 1.9 \text{ cSt}^2}{0.8 \text{ cSt}^2} = 11.9$$

7. This chi-square value does not lie in the critical region. Therefore, at a confidence level of 95%, the variance does exceed 0.8 cSt^2. Therefore, the null hypothesis is rejected and the alternative hypothesis is accepted. The measurements should be repeated in order to reduce the measurement variability.

The previous two examples (3.23 and 3.24) implement the hypothesis-testing procedure for two straightforward statistical tests. Hypothesis testing may also be extended to the difference between the means of two samples or the ratio of two variances. The relevant test statistics for these calculations were presented in Section 3.3 of this chapter. The NIST/SEMATECH handbook [1] discusses other hypothesis tests in its Section 7, particularly Subsections 7.2 through 7.4. The textbook *Applied Statistics and Probability for Engineers*, by Montgomery and Runger [2], also presents various tests.

3.5 LEAST SQUARES REGRESSION

Regression analysis is often employed to fit experimental data to a mathematical model. The purpose may be to determine physical properties or constants (e.g., rate constants, transport coefficients), to discriminate between proposed models, to interpolate or extrapolate data, etc. The model should provide estimates of the uncertainty in calculations from the resulting model and, if possible, make use of available error in the data. An initial model (or models) may be empirical, but with advanced knowledge of reactors, distillation columns, other separation devices, heat exchangers, etc., more sophisticated and fundamental models can be employed. As a starting point, a linear equation with a single independent variable may be initially chosen. Of importance, is the mathematical model linear? In general, a function, f, of a set of adjustable parameters, $\{\beta_j\}$, is linear if a derivative of that function with respect to any adjustable parameter is not itself a function of any other adjustable parameter, that is,

$$\frac{\partial^2 f}{\partial \beta_j \partial \beta_k} = 0 \tag{3.24}$$

Some functions do not satisfy the test of Equation (3.24), but by suitable manipulation they can become linear and are termed *intrinsically* linear. Linear regression can be generalized to a straightforward analytic procedure, while nonlinear regression generally has no unique solution.

For both regression types, one begins with a set of independent variables $\mathbf{X}_i$ (bold denoting vector notation); a measured, dependent response y_i; and a regression function $\hat{y}(\mathbf{X}_i)$ with adjustable parameters $\{\beta_j\}$. Each response may be assumed to be distributed normally with variance σ_i^2. If one makes the assumption that each measurement is independent, then the joint probability of the set of n data points [2] is

$$P = \prod_{i=1}^{n}\left[\frac{1}{\sqrt{2\sigma_i^2}}\exp\left(\frac{-[y_i - \hat{y}(\mathbf{X}_i)]^2}{2\sigma_i^2}\right)\right] \tag{3.25}$$

The parameters that produce the best model maximize P. One can alternatively maximize ln$P$ instead of P and still arrive at the maximum probability. Therefore, Equation (3.25) is transformed to

$$\ln P = \ln\left(\prod_{i=1}^{n}\frac{1}{\sqrt{2\sigma_i^2}}\right) - \frac{1}{2}\sum_{i=1}^{n}\frac{[y_i - \hat{y}(\mathbf{X}_i)]^2}{\sigma_i^2} \tag{3.26}$$

Since the first term on the right-hand side does not depend on the adjustable parameters, maximizing P is equivalent to minimizing the summation in Equation (3.26). The optimal solution occurs when, for all β_j,

$$\frac{\partial}{\partial\beta_j}\left(\sum_{i=1}^{n}\frac{[y_i - \hat{y}(\mathbf{X}_i)]^2}{\sigma_i^2}\right) = 0 \tag{3.27}$$

One usually does not have values or reliable estimates of σ_i^2. Hence, the assumption that the variance of each y_i is uniform, i.e., $\sigma_i = \sigma$, is made so that Equation (3.27) reduces to

$$\frac{\partial}{\partial\beta_j}\left(\sum_{i=1}^{n}[y_i - \hat{y}(\mathbf{X}_i)]^2\right) = 0 \tag{3.28}$$

When reliable σ_i are available, the adjustable parameters may be obtained from Equation (3.27), but the derivation is more involved than the simpler case of uniform variance. More information regarding the full derivation is provided by Press et al. [10]. The remainder of this section focuses on regression analyses with the assumption of constant variance, with separate discussions of simple linear, generalized multiple linear, and nonlinear regression.

3.5.1 Simple Linear Least Squares Regression

Linear least squares regression is the most common method of fitting a response that is a function of a single independent variable. Many nonlinear functions may be transformed to simple linear functions, extending the capabilities of the simplest regression algorithm.

3.5.1.1 Basic Algorithm

For linear least squares, the following model is entered into the equations of the previous subsection:

$$\hat{y}(x) = \beta_0 + \beta_1 x \tag{3.29}$$

With this chosen model, the adjustable parameters are obtained by simultaneously solving the two equations that result from Equation (3.28). If the chosen model is intrinsically linear, it must first be transformed to the form of Equation (3.29) before proceeding. Defining the following terms (*SS* denotes "sums of squares") simplifies further analysis [10]:

$$SS_{xx} = \sum_{i=1}^{n} (x_i - \bar{x})^2 = \sum_{i=1}^{n} x_i^2 - n \cdot \bar{x}^2 \tag{3.30}$$

$$SS_{yy} = \sum_{i=1}^{n} (y_i - \bar{y})^2 = \sum_{i=1}^{n} y_i^2 - n \cdot \bar{y}^2 \tag{3.31}$$

$$SS_{xy} = \sum_{i=1}^{n} (x_i - \bar{x})(y_i - \bar{y}) = \sum_{i=1}^{n} x_i y_i - n \cdot \bar{x} \cdot \bar{y} \tag{3.32}$$

Using these terms, the values of the adjustable parameters that maximize *P* are

$$\beta_1 = \frac{SS_{xy}}{SS_{xx}} \tag{3.33}$$

$$\beta_0 = \bar{y} - \beta_1 \bar{x} = \bar{y} - \frac{SS_{xy}}{SS_{xx}} \bar{x} \tag{3.34}$$

Example 3.25

Consider the general mathematical model for a first-order exponential reaction as follows:

$$C_A(t) = C_{A0} \exp(-kt) \tag{3.35}$$

where C_A is the concentration of species *A*, *k* is the rate constant, and *t* is time. C_{A0} denotes the initial concentration. Transform this model to an intrinsically linear equation, with which one could determine *k* using linear regression.

Solution

Taking a logarithm of Equation (3.35) linearizes the equation:

$$\ln C_A(t) = \ln C_{A0} - kt \tag{3.36}$$

With Equation (3.29), $y = \ln C_A(t)$, $x = t$, $\beta_0 = \ln C_{A0}$, and $\beta_1 = -k$. One could use experimental measurements of C_A versus *t* to estimate the initial concentration and decay constant.

Example 3.26

For the decomposition of *A* according to the chemical reaction

$$A \rightarrow 2B$$

the rate of reaction at constant volume and temperature follows a first-order exponential decay given by

$$C_A(t) = C_{A0}\exp(-kt)$$

and the variables are as identified in Example 3.25. The table below lists C_A as a function of t that was measured experimentally. Determine k via a linear regression.

t (h)	$C_A(t)$ (mol/l)	$y_i = \ln C_A(t)$
0.0	7.96	2.07
1.0	4.95	1.60
2.0	3.67	1.30
3.0	2.10	0.742
4.0	1.73	0.548
5.0	0.637	–0.451
6.0	0.566	–0.569
7.0	0.224	–1.50
8.0	0.202	–1.60
9.0	0.0688	–2.68
10.0	0.0670	–2.70

Solution

The above equation is identical in form to Equation (3.35). Therefore, its intrinsically linear form is

$$\ln C_A(t) = \ln C_{A0} - kt$$

As in Example 3.25, let $y = C_A$ and $x = t$. Again, $\beta_0 = \ln C_{A0}$ and $\beta_1 = -k$. The new y values are listed in the table, and the x values are identical to those in the t column. First, the average values of x and y are $\bar{x} = 5.0$ h and $\bar{y} = -0.273$ and $n = 11$. Then, following Equations (3.30)–(3.32), the sums of squares are

$$SS_{xx} = \sum_{i=1}^{n} x_i^2 - n \cdot \bar{x}^2 = 110\ \text{h}^2$$

$$SS_{yy} = \sum_{i=1}^{n} y_i^2 - n \cdot \bar{y}^2 = 28.2$$

$$SS_{xy} = \sum_{i=1}^{n} x_i y_i - n \cdot \bar{x} \cdot \bar{y} = -55.3\ \text{h}$$

The regression coefficients, following Equations (3.33) and (3.34), are

$$\beta_1 = \frac{SS_{xy}}{SS_{xx}} = -0.503\ \text{h}^{-1}$$

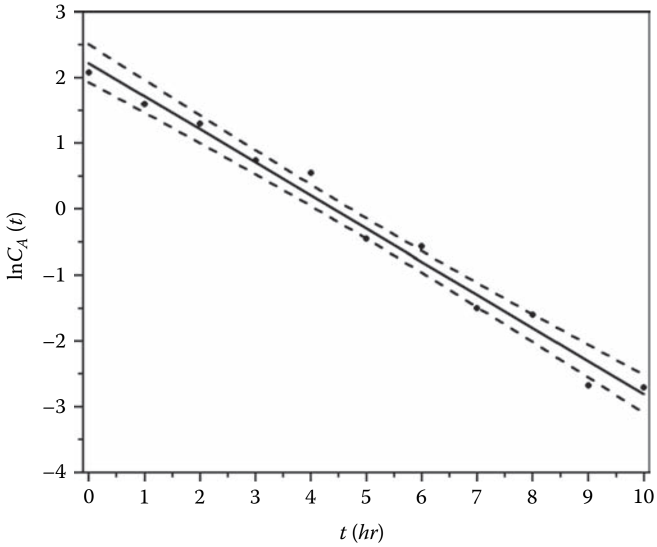

FIGURE 3.1 Linear regression for Example 3.25. Filled circles represent the experimental data and the linear model is shown with the solid line. The dashed lines mark the bounds of the 95% confidence interval on predictions for the linear model.

$$\beta_0 = \bar{y} - \frac{SS_{xy}}{SS_{xx}}\bar{x} = 2.219$$

Therefore, the reaction rate constant is

$$k = -\beta_1 = 0.503 \text{ h}^{-1}$$

Figure 3.1 indicates that the linear equation tested provides a good correlation of the experimental data.

3.5.1.2 Estimation of Uncertainty

Uncertainty in the linear regression is estimated by determining the standard errors of adjustable parameters and predictions from the linear model. With a reliable estimate of the variance of the response variable, σ^2, the known value is used for uncertainty predictions. Otherwise, the variance is estimated in terms of the sum of square residuals. The residual at each measurement is defined as

$$e_i = y_i - \hat{y}(x_i) = y_i - \beta_0 - \beta_1 x_i \tag{3.37}$$

In terms of the sum of the square residuals, the variance of the model can be estimated [2] by

$$s^2 = \frac{\sum_{i=1}^{n} e_i^2}{n-2} = \frac{SS_{yy} - \frac{(SS_{yy})^2}{SS_{xx}}}{n-2} \tag{3.38}$$

In terms of this estimated variance and the previously defined terms, the standard errors of the adjustable parameters [2] are

$$SE(\beta_0) = \sqrt{s^2\left(\frac{1}{n} + \frac{\bar{x}^2}{SS_{xx}}\right)} \tag{3.39}$$

$$SE(\beta_1) = \sqrt{\frac{s^2}{SS_{xx}}} \tag{3.40}$$

These standard error estimates determine confidence intervals for the adjustable parameters. Another measure of uncertainty is that of calculations from the resultant model (i.e., the uncertainty of $\hat{y}(x)$). This uncertainty is estimated in terms of the variance of the model calculations [2], given by

$$V(\hat{y}(x_0)) = s^2\left(\frac{1}{n} + \frac{(x_0 - \bar{x})^2}{SS_{xx}}\right) \tag{3.41}$$

where x_0 is the value of the dependent variable at which the model prediction and associated variance are calculated. Note that this variance depends on the distance between x_0 from the mean x value. The variance is wider for points far from the mean $\bar{x}$. This variance allows for the determination of a confidence interval of the true value of y in terms of the model parameters [2]

$$\beta_0 + \beta_1 x_0 - t_{\alpha/2,n-2}\sqrt{s^2\left(\frac{1}{n} + \frac{(x_0 - \bar{x})^2}{SS_{xx}}\right)} \le y \le \beta_0 + \beta_1 x_0 + t_{\alpha/2,n-2}\sqrt{s^2\left(\frac{1}{n} + \frac{(x_0 - \bar{x})^2}{SS_{xx}}\right)} \tag{3.42}$$

where α denotes the significance level.

The accuracy of the regression is often measured by the coefficient of determination (R^2) defined [2] as follows:

$$R^2 = 1 - \frac{\sum_{i=1}^{n} e_i^2}{SS_{yy}} \tag{3.43}$$

Mathematically, R^2 measures the proportion of the error in $\hat{y}(x)$ arising from the regression. When R^2 is nearly equal to unity, the model predicts the experimental data points well. It does not, however, mean that the model represents the true data trend. To evaluate the model, examine the plot comparing the predicted and experimental values.

Example 3.27

For the concentration-versus-time data given in Example 3.26, determine the standard errors of the regression parameters β_0 and β_1 and the R^2 value. Plot the 95% confidence intervals for calculations from the model.

Solution

Entering the known values from Example 3.25 into Equations (3.38)–(3.40) and (3.43),

$$s^2 = \frac{\sum_{i=1}^{n}(y_i - \beta_0 - \beta_1 x_i)^2}{n-2} = 0.0515$$

$$SE(\beta_0) = \sqrt{s^2\left(\frac{1}{n} + \frac{\bar{x}^2}{SS_{xx}}\right)} = 0.128$$

$$SE(\beta_1) = \sqrt{\frac{s^2}{SS_{xx}}} = 0.022\ \mathrm{h}^{-1}$$

$$R^2 = 1 - \frac{\sum_{i=1}^{n} e_i^2}{SS_{yy}} = 0.984$$

Because $\beta_1 = -k$, the standard error of the reaction constant is, then

$$SE(k) = SE(\beta_1) = 0.022\ \mathrm{h}^{-1}$$

The upper and lower bounds of the 95% confidence interval must be computed for several values of x_0 to provide the 95% confidence interval that surrounds the regression line. As an example, for $x_0 = t = 1$ h, the upper bound is

$$\beta_0 + \beta_1 x_0 - t_{\alpha/2,n-2}\sqrt{s^2\left(\frac{1}{n} + \frac{(x_0 - \bar{x})^2}{S_{xx}}\right)}$$

$$= 2.22 - 0.503(\mathrm{h}^{-1})\cdot 1\,\mathrm{h} - 2.262\sqrt{0.0515\left(\frac{1}{11} + \frac{(1\,\mathrm{h} - 5\,\mathrm{h})^2}{110\,\mathrm{h}^2}\right)}$$

$$= 1.966$$

This calculation (and the lower-bound calculation) is repeated for a number of data points and plotted in Figure 3.1 as the dashed lines. For this data set, the 95% confidence interval is not narrow; it is wider at its ends than at the center, as expected from Equation (3.41).

3.5.2 Generalized Multiple Linear Regression

Linear regression is limited in application. For more complex models, multiple independent variables or even combinations of several independent variables are needed. These "multiple linear" functions are particularly useful for fitting experimental data to empirical models that have no physical basis. Generalized multiple linear regression is usually accomplished via matrix algebra (see [11–13] or a linear algebra text employing matrix algebra).

3.5.2.1 Basic Algorithm

The model consists of a single measured response y_i and k independent variables $\mathbf{x}_i$ [2]. The independent variables may be any chosen independent variable or any linear function of the independent variables. For example, if pressure and temperature are independent variables P and T, respectively, then the set of independent variables $\mathbf{x}_i$ may be a combination of P, T, $P \cdot T$, P^2, T^2, etc. The model for y_i may be

$$\hat{y}(\mathbf{x}_i) = \beta_0 + \beta_1 x_{i1} + \beta_2 x_{i2} + \ldots + \beta_k x_{ik} \tag{3.44}$$

with $\{\beta_j\}$ being the set of $(k + 1)$ adjustable parameters. (The $(k + 1)$th parameter is the constant term in the model.) Solving for an optimal $\{\beta_j\}$ is accomplished more easily using a vector-matrix technique. The following vectors and matrix are defined:

$$\hat{\mathbf{y}} = \begin{bmatrix} \hat{y}(\mathbf{x}_1) \\ \hat{y}(\mathbf{x}_2) \\ \vdots \\ \hat{y}(\mathbf{x}_n) \end{bmatrix} \quad \mathbf{X} = \begin{bmatrix} 1 & x_{11} & x_{12} & \cdots & x_{1k} \\ 1 & x_{21} & x_{22} & \cdots & x_{2k} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 1 & x_{n1} & x_{n2} & \cdots & x_{nk} \end{bmatrix} \quad \beta = \begin{bmatrix} \beta_0 \\ \beta_1 \\ \vdots \\ \beta_k \end{bmatrix} \quad \mathbf{y} = \begin{bmatrix} y_1 \\ y_2 \\ \vdots \\ y_n \end{bmatrix} \quad \mathbf{x}_i = \begin{bmatrix} 1 \\ x_{i1} \\ x_{i2} \\ \vdots \\ x_{ik} \end{bmatrix} \tag{3.45}$$

For n data points, Equation (3.44) may be rewritten as

$$\hat{\mathbf{y}} = \mathbf{X}\beta \tag{3.46}$$

The residual vector is written as

$$\mathbf{e} = \mathbf{y} - \hat{\mathbf{y}} \tag{3.47}$$

Tedious manipulation indicates that the square error, $|\mathbf{e}|^2$, is minimized when the set of adjustable parameters [2] is as follows:

$$\beta = (\mathbf{X}^T\mathbf{X})^{-1}\mathbf{X}^T\mathbf{y} \tag{3.48}$$

where the superscript T denotes the transpose vector or matrix and the superscript –1 indicates the inverse matrix.

Example 3.28

For specific heat (C_p)-vs.-temperature (T) data, the following model is often employed:

$$\hat{C}_p(T) = \beta_0 + \beta_1 T + \beta_2 T^2$$

Determine its coefficients for the data in the following table:

T (K)	C_p (J/mol · K)
200	34.96
300	35.94
400	37.32
500	38.21
600	39.46

Solution

The independent "variables" are $x_1 = T$ and $x_2 = T^2$, and the dependent response is $y = C_p$. The **y** vector and **X** matrix are, then,

$$\mathbf{y} = \begin{bmatrix} 34.96 \\ 35.94 \\ 37.32 \\ 38.21 \\ 39.46 \end{bmatrix} \frac{\text{J}}{\text{mol}\cdot\text{K}} \quad \text{and} \quad \mathbf{X} = \begin{bmatrix} 1 & 200\text{ K} & 40{,}000\text{ K}^2 \\ 1 & 300\text{ K} & 90{,}000\text{ K}^2 \\ 1 & 400\text{ K} & 160{,}000\text{ K}^2 \\ 1 & 500\text{ K} & 250{,}000\text{ K}^2 \\ 1 & 600\text{ K} & 360{,}000\text{ K}^2 \end{bmatrix}$$

Substituting **y** and **X** into Equation (3.48), the optimal set of parameters is found to be

$$\beta_0 = 32.7 \frac{\text{J}}{\text{mol}\cdot\text{K}}$$

$$\beta_1 = 1.01\times10^{-2} \frac{\text{J}}{\text{mol}\cdot\text{K}^2}$$

$$\beta_2 = 3.57\times10^{-7} \frac{\text{J}}{\text{mol}\cdot\text{K}^3}$$

3.5.2.2 Estimation of Uncertainty

The uncertainty of a multiple linear model can be estimated with a reliable estimate of the variance of y; a σ^2 value can also be used for uncertainty predictions. Otherwise, one requires an approximation based on the sum of square residuals. The residual vector for a multiple linear model was previously given in Equation (3.47). In terms of **e** and other previously defined quantities, the variance may be estimated [2] by

$$s^2 = \frac{\mathbf{e}^T\mathbf{e}}{n-k-1} = \frac{\mathbf{y}^T\mathbf{y} - \beta^T\mathbf{X}^T\mathbf{y}}{n-k-1} = \frac{\sum_{i=1}^{n}(y_i - \hat{y}(\mathbf{x}_i))^2}{n-k-1} \tag{3.49}$$

All other uncertainty quantities are given in terms of the covariance matrix **C**, defined [2] by

$$\mathbf{C} = (\mathbf{X}^T\mathbf{X})^{-1} = \begin{bmatrix} C_{00} & C_{01} & \cdots & C_{0k} \\ C_{10} & C_{11} & \cdots & C_{1k} \\ \vdots & \vdots & \ddots & \vdots \\ C_{k0} & C_{k1} & \cdots & C_{kk} \end{bmatrix} \tag{3.50}$$

which is a symmetric matrix, i.e., $C_{ij} = C_{ji}$. In terms of the elements of **C**, the estimated standard error of the jth adjustable parameter [2] is

$$SE(\beta_j) = \sqrt{s^2 C_{jj}} \tag{3.51}$$

and the covariance of any two adjustable parameters [2] is

$$\text{cov}(\beta_i, \beta_j) = s^2 C_{ij} \quad i \neq j \tag{3.52}$$

Predictions from the model [2] have variance

$$V(\hat{y}(\mathbf{x}_0)) = s^2 \mathbf{x}_0{}^T \mathbf{C} \mathbf{x}_0 \tag{3.53}$$

The confidence interval for predictions from the model is

$$\hat{y}(\mathbf{x}_0) - t_{\alpha/2,n-k-1}\sqrt{s^2 \mathbf{x}_0{}^T \mathbf{C}\mathbf{x}_0} \le y \le \hat{y}(\mathbf{x}_0) + t_{\alpha/2,n-k-1}\sqrt{s^2 \mathbf{x}_0{}^T \mathbf{C}\mathbf{x}_0} \tag{3.54}$$

Model adequacy may again be measured using R^2 (coefficient of determination), which is given by Equation (3.43). The interpretation of R^2 for multiple linear regression is identical to that used in the simple linear version of least squares.

Example 3.29

Referring to Example 3.28, where C_p was fit to a polynomial function of T, determine the standard error of each regressor β_j and the variance of the model's prediction for T = 200 K.

Solution

To determine the standard error of each β_j, one first needs the covariance matrix and s^2. Entering the **X** matrix determined in Example 3.28 into Equation (3.50), the covariance matrix **C** is

$$\mathbf{C} = (\mathbf{X}^T\mathbf{X})^{-1} = \begin{bmatrix} 15.8 & -8.40\times10^{-2}\,\text{K}^{-1} & 1.00\times10^{-4}\,\text{K}^{-2} \\ -8.40\times10^{-2}\,\text{K}^{-1} & 4.67\times10^{-4}\,\text{K}^{-2} & -5.71\times10^{-7}\,\text{K}^{-3} \\ 1.00\times10^{-4}\,\text{K}^{-2} & -5.71\times10^{-7}\,\text{K}^{-3} & 7.14\times10^{-10}\,\text{K}^{-4} \end{bmatrix}$$

Following Equation (3.49), the variance estimator is

$$s^2 = \frac{\mathbf{y}^T\mathbf{y} - \beta^T\mathbf{X}^T\mathbf{y}}{n-k-1} = \frac{0.0434\left(\dfrac{\text{J}}{\text{mol}\cdot\text{K}}\right)^2}{5-2-1} = 0.0217\left(\frac{\text{J}}{\text{mol}\cdot\text{K}}\right)^2$$

Therefore, via Equation (3.51), the standard errors of the adjustable parameters are

$$SE(\beta_0) = \sqrt{s^2 C_{00}} = 0.586\,\frac{\text{J}}{\text{mol}\cdot\text{K}}$$

$$SE(\beta_1) = \sqrt{s^2 C_{11}} = 3.18\times10^{-3}\,\frac{\text{J}}{\text{mol}\cdot\text{K}^2}$$

$$SE(\beta_2) = \sqrt{s^2 C_{22}} = 3.94\times10^{-6}\,\frac{\text{J}}{\text{mol}\cdot\text{K}^3}$$

For the data at T = 200 K, the $\mathbf{x}_0$ vector (a column vector identical to the first row of **X**; see Equation (3.45)) is

$$\mathbf{x}_0 = \begin{bmatrix} 1 \\ 200\ \text{K} \\ 40{,}000\ \text{K}^2 \end{bmatrix}$$

Then, by Equation (3.53), the variance of the model prediction at T = 200 K is

$$V(\hat{y}(\mathbf{x}_0)) = s^2 \mathbf{x}_0^T \mathbf{C} \mathbf{x}_0 = 0.886 \left(\frac{\text{J}}{\text{mol} \cdot \text{K}} \right)^2$$

The variance estimation could be repeated for multiple $\mathbf{x}_0$ points to determine confidence intervals for predictions from the model.

3.5.3 Analysis of Variance

Analysis of variance (ANOVA) is a method of testing a regression. With a regression model, a simplified hypothesis test examines the forms of uncertainty; some uncertainty arises from the regression, while some uncertainty is unexplained by the model. One determines whether the regression model is significant by comparing the significance of each uncertainty source. First, the following error terms [2] are defined:

$$SS_\text{T} = \mathbf{y}^T \mathbf{y} - n(\bar{y})^2 \tag{3.55}$$

$$SS_\text{R} = \hat{\mathbf{y}}^T \mathbf{y} - n(\bar{y})^2 \tag{3.56}$$

$$SS_\text{E} = \mathbf{y}^T \mathbf{y} - \hat{\mathbf{y}}^T \mathbf{y} \tag{3.57}$$

where SS_T denotes the *total corrected sum of squares*, while SS_R and SS_E denote the *regression sum of squares* and *error sum of squares*, respectively. It is straightforward to show that $SS_\text{T} = SS_\text{R} + SS_\text{E}$. Second, the number of degrees of freedom of each sum-of-squares term is determined. The number of degrees of freedom of SS_T is equal to $n - 1$. SS_R and SS_E have degrees of freedom k (k being the number of regressors) and $n - k - 1$, respectively. Third, the *mean square* terms, MS_R and MS_E, are calculated by dividing the SS_R and SS_E terms by their respective number of degrees of freedom [2]:

$$MS_\text{R} = \frac{SS_\text{R}}{k} \tag{3.58}$$

$$MS_\text{E} = \frac{SS_\text{E}}{n - k - 1} \tag{3.59}$$

Lastly, the ratio MS_R/MS_E is computed and denoted F_0. Since F_0 is a ratio of two variance terms, it is distributed according to an F distribution with degrees of freedom $\nu_1 = k$ and $\nu_2 = n - k - 1$. Thus, if that ratio exceeds a predetermined critical F value, the regression is significant. Equivalently, if the cumulative probability that the F variable exceeds the given ratio (usually

TABLE 3.12
Table Form Summary of ANOVA Procedure

Source of Variance	Degrees of Freedom	Sum of Squares	Mean Square	F_0	P
Regression	k	SS_R	$MS_R = SS_R/k$	MS_R/MS_E	$P(F > F_0)$
Error	$n - k - 1$	SS_E	$MS_E = SS_E/(n - k - 1)$	…	…
Total	$n - 1$	SS_T	…	…	…

Source: Montgomery, Douglas C., and Runger, George C., *Applied Statistics and Probability for Engineers*, 3rd ed., John Wiley & Sons, New York (2003).

denoted P) is smaller than the significance level α, the regression is significant. The ANOVA procedure is usually presented as a table, such as the summary given in Table 3.12.

Example 3.30

With a significance level of $\alpha = 0.05$ (95% confidence level), use an ANOVA table to determine whether the multiple linear regression model determined in Example 3.28 is significant.

Solution

For the multiple linear regression in Example 3.28, there were five data points and three regressors for $n = 5$ and $k = 2$. From the model and basis data in that example, the following sums of squares were computed via Equations (3.55 through 3.57):

For example,

$$SS_T = \mathbf{y}^T\mathbf{y} - n(\bar{y})^2 = [34.96 \quad 35.94 \quad 37.32 \quad 38.21 \quad 39.46]\begin{bmatrix} 34.96 \\ 35.94 \\ 37.32 \\ 38.21 \\ 39.46 \end{bmatrix}\left(\frac{\text{J}}{\text{mol}\cdot\text{K}}\right)^2$$

$$-\ 5\left(\frac{34.96 + 35.94 + 37.32 + 38.21 + 39.46}{5}\frac{\text{J}}{\text{mol}\cdot\text{K}}\right)^2 = 12.744\left(\frac{\text{J}}{\text{mol}\cdot\text{K}}\right)^2$$

Then,

$$SS_T = 12.744\left(\frac{\text{J}}{\text{mol}\cdot\text{K}}\right)^2$$

$$SS_R = 12.701\left(\frac{\text{J}}{\text{mol}\cdot\text{K}}\right)^2$$

$$SS_E = 0.043\left(\frac{\text{J}}{\text{mol}\cdot\text{K}}\right)^2$$

Computing the mean square terms and entering the data into an ANOVA table yields

Source of Variance	Degrees of Freedom	Sum of Squares	Mean Square	F_0	P
Regression	2	12.744	6.351	292.67	3.41×10^{-3}
Error	2	0.043	0.0217	…	…
Total	4	12.701	…	…	…

Since the P value of the ANOVA test does not exceed the chosen significance level $\alpha = 0.05$, the regression is deemed significant. For this example, the FDIST function in Microsoft Excel [5, 6] was used to determine the P value, 3.41×10^{-3}, of the ANOVA table (see Table 3.12).

3.5.4 Nonlinear Regression

Since no general algorithm or procedure is available for least squares regression when the mathematical fitting function is nonlinear, one begins with Equation (3.26) and assumes that $\sigma_i = \sigma$ (uniform variance); the model probability will be maximized when the sum of square error (e.g., Equation (3.57)) is minimized. Completing the regression then becomes a problem of functional minimization. Algorithms for functional minimization in literature sources include the quasi-Newton method, the Levenburg-Marquardt algorithm, or the method of steepest descent [10]. Software such as JMP (produced by SAS) or the Solver feature of Microsoft Excel may be helpful. One starts with an estimate (ideally based on intuition) and repeats the calculations until some solution criterion is satisfied. Common to all the techniques, though, is the fact that functional minimization techniques are not guaranteed to produce the *global* minimum of the objective function. The solution produced by such an algorithm could very well be a *local* minimum in the parameter space, unless the entire parameter space has been thoroughly searched. If multiple local minima exist, then the algorithm could arrive at any minimum, depending on the starting guess. Although nonlinear regression is difficult to implement, it remains useful.

3.6 STATISTICAL ANALYSIS OF ERROR PROPAGATION

Often, the quantity of interest in an experiment is not measured directly, but is computed via a mathematical equation or model. For example, the overall heat-transfer coefficient (say, U) of a specific heat exchanger might be determined indirectly by measuring the inlet and outlet temperatures. Repeated experiments provide an estimate of the variance of U, but this variance does not account for possible experimental errors (e.g., the thermocouple errors in the temperature measurements). The error in each measurement accumulates in the overall error of a calculated quantity in a manner known as *propagation of error*. Measurement error can arise from random variability or instrument sensitivity. There is, however, a mathematical approach to deal with these errors.

Suppose that a number of variables, $(x_1, x_2, \ldots, x_n)$, are measured and used to calculate a quantity y according to the relationship

$$y(x_1, x_2, \ldots, x_n) = a_1x_1 + a_2x_2 + \cdots + a_nx_n = \sum_{i=1}^{n} a_ix_i \tag{3.60}$$

For this mathematical model, the variance of the computed value of y is given by Barry [14]

$$\sigma^2(y) = \sum_{i=1}^{n} a_i^2 \sigma^2(x_i) + 2\sum_{i=1}^{n}\sum_{j=i+1}^{n} a_i a_j Cov(x_i, x_j) \tag{3.61}$$

where $\sigma^2(x_i)$ is the variance of the ith measured variable, and Cov(x_i,x_j) is the covariance of the i–j pair of measurements. The covariance term in Equation (3.61) allows for the measured variables (x_1,x_2,…,x_n) to be correlated. The measured variables are often uncorrelated, which allows for removing the second summation term in Equation (3.61). If the measured variables are indeed correlated, the covariance relationship between two variables may be unknown, seemingly leaving Equation (3.61) useless. One may, however, simplify the problem by assuming that the covariance terms are zero, reducing Equation (3.61) to

$$\sigma^2(y) = \sum_{i=1}^{n} a_i^2 \sigma^2(x_i) \tag{3.62}$$

Thus, for a computed value that is linearly dependent on all measured variables, the variance of the computed value can be predicted in a straightforward fashion from the variance of the individual measured variables.

Since the relationship between a computed quantity and measured variables is often nonlinear, an approximate method is needed to calculate the variance of the computed quantity. Suppose that a quantity y is given by a nonlinear function and that the individual measured quantities (x_1,x_2,…,x_n) are independent. (The assumption of independence removes the need for covariance terms.) Then the variance of y may be approximated [15] as

$$\sigma^2(y) = \left(\left.\frac{\partial y}{\partial x_1}\right|_{\{x_j\}}\right)^2 \sigma^2(x_1) + \left(\left.\frac{\partial y}{\partial x_2}\right|_{\{x_j\}}\right)^2 \sigma^2(x_2) + \cdots + \left(\left.\frac{\partial y}{\partial x_n}\right|_{\{x_j\}}\right)^2 \sigma^2(x_n) = \sum_{i=1}^{n}\left(\left.\frac{\partial y}{\partial x_i}\right|_{\{x_j\}}\right)^2 \sigma^2(x_i) \tag{3.63}$$

where $\{x_j\}$ indicates that the partial derivatives of y are evaluated at the current set of measured variables (x_1,x_2,…,x_n). (Equation (3.63) reduces to Equation (3.62) for the case of a linear function. Despite this similarity, Equation (3.63) is still an approximation [15].)

With Equations (3.62) and (3.63), one can determine estimates of the variance of a calculated value from the variance of measured variables. The individual variance terms, $\sigma^2(x_i)$, might not be known, however, and one must make estimates. Through repeated experiments, $\sigma^2(x_i)$ could be estimated by $s^2(x_i)$, the sample variance of variable x_i. If one has information about the sensitivity of a measuring device, this previous knowledge could be input as a variance term.

Example 3.31

For a fully developed laminar flow in a pipe, the Hagen-Poiseuille equation is used to calculate the pressure drop per unit length ($\Delta P/L$) at a given volumetric flow rate $\dot{V}$, pipe diameter D, and fluid viscosity μ:

$$\left(\frac{\Delta P}{L}\right) = \frac{\pi D^4}{128\mu\dot{V}} \tag{3.64}$$

From this equation, determine an expression for the variance of ($\Delta P/L$) in terms of the variances of D, $\dot{V}$, and μ.

Solution

In terms of Equation (3.63), $y = (\Delta P/L)$, and the x variables are $x_1 = D$, $x_2 = \dot{V}$, and $x_3 = \mu$. Therefore, Equation (3.63) becomes

$$\sigma^2\left(\frac{\Delta P}{L}\right)=\left(\frac{\partial}{\partial D}\left(\frac{\Delta P}{L}\right)\bigg|_{\{D,\dot{V},\mu\}}\right)^2\sigma^2(D)+\left(\frac{\partial}{\partial \dot{V}}\left(\frac{\Delta P}{L}\right)\bigg|_{\{D,\dot{V},\mu\}}\right)^2\sigma^2(\dot{V})+\left(\frac{\partial}{\partial \mu}\left(\frac{\Delta P}{L}\right)\bigg|_{\{D,\dot{V},\mu\}}\right)^2\sigma^2(\mu)$$

For the Hagen-Poiseuille equation (Equation (3.64)), the above becomes

$$\sigma^2\left(\frac{\Delta P}{L}\right)=\left(\frac{4\pi D^3}{128\mu\dot{V}}\right)^2\sigma^2(D)+\left(\frac{-\pi D^4}{128\mu\dot{V}^2}\right)^2\sigma^2(\dot{V})+\left(\frac{-\pi D^4}{128\mu^2\dot{V}}\right)^2\sigma^2(\mu)$$

With knowledge of the variances of the measured variables, one can compute the variance of the pressure drop per unit length. The computed variance can then be used to determine confidence intervals or perform hypothesis tests.

3.7 DESIGN OF EXPERIMENTS

Statistics has an increasing role in the design of experiments and equipment. One first evaluates available information relative to proposed experiments or the equipment. The process being considered could be chemical reactions or reactors; separation processes, including distillation, absorption, stripping, adsorption, etc.; and heat exchangers, etc.

To employ statistics, the first step is to develop a mathematical model for the unit or process. With a well-established process that has been operating for a considerable period of time, a mathematical model that is highly fundamental based on well-determined steps or reactions can often be developed. For example, Hougen and Watson [16] many years ago showed how the numerous steps in catalytic reactions can be modeled in a relatively fundamental manner. For distillation units, relatively fundamental models can generally be developed to indicate how changes of the following affect operations: reflux ratio, process conditions, cost of feed streams, product and feed compositions, demand for product, etc.

With a new process or product, empirical models are often employed in the initial stages. The objective of a research program is to obtain key information as rapidly and cheaply as possible.

3.7.1 Design Matrices

A designed experiment provides a plan of the runs to be performed and the order in which they will be executed. The operating conditions of each run are specified, and replicates are included. The proposed design lists the levels selected for each factor in a given run. It is called the *design matrix* **D**, and is often similar to the **X** matrix of linear regression (see Section 3.5); it does not include the columns of ones for the pure constant term, nor does it include the high-order columns for squares and other functions of the factors. The design matrix is composed of a column vector for each run and is identical to the corresponding column of the **X** matrix for $\beta_j x_j$ terms. It retains this form even if a direct proportionality term is not included in the model. For example, if x enters the model only as $\ln x$ (a logarithm), the design matrix contains a column of x's rather than the $\ln x$.

If the design matrix is in a coded form (i.e., the values of the x_j terms are scaled or changed to a simpler number), the coding equations must be designated.

3.7.2 Design for One-Factor Experiment

The preferred choice of conditions for experiments depends on the model. Some designs for several simple models are discussed next. The experiments are hopefully conducted to minimize the random error of the response, and σ^2 is therefore estimated by s^2.

3.7.2.1 $\hat{y} = \beta_0 = \bar{y}$

For this constant-value model, the only consideration is how many times to replicate, since the conditions are constant. The selection of n can be logically determined from the confidence interval equation. The width of this interval is proportional to $t_{\alpha/2,\nu}$ (the t variable for chosen confidence level and number of runs) and $s/\sqrt{n}$, the standard error of the average. More runs reduce the confidence interval in two ways. Increasing n decreases the standard error, since it is inversely proportional to the square root of n. Also, the value of $t_{\alpha/2,\nu}$ decreases with increasing n as the number of degrees of freedom, $\nu = n - 1$, increases. After selecting n to obtain a desired confidence interval, it is a trial-and-error calculation, since $t_{\alpha/2,\nu}$ depends upon n and is obtained from Table 3.3. Of course, an estimate of the experimental error is needed. An estimate is normally based on knowledge of the process to obtain a preliminary value. After a few runs are completed, an experimental value of s^2 is calculated, and a revised value can be determined.

3.7.2.2 $\hat{y} = \beta_1 x$

For this proportionality model, first determine the confidence interval of the slope, which is a fixed value that is calculated by

$$V(\beta_1) \propto \frac{1}{\sum_{i=1}^{n} x^2} \tag{3.65}$$

since the matrix **C** is 1×1 for this case. Sufficient runs are made to obtain reliable values to minimize the confidence interval. At $x = 1$, the confidence interval on the response is equal to the confidence interval on β_1.

3.7.2.3 $\hat{y} = \beta_0 + \beta_1 x$

The general straight-line model is often used as a starting point for model development. The confidence interval often widens at the ends (see Section 3.5). More levels of the factor act to reduce the confidence interval. Equally spaced levels are often tested. The number of levels depends on the complexity of the model or on the number of additional terms to be considered. Enough levels should be provided for left-out terms. The number of levels should exceed the number of parameters expected. Even if a straight line is likely, more than three levels should be considered, plus some replication.

3.7.3 Design for Several Factors

With several factors to study, the size of the experimental design becomes large, time consuming, and expensive. Two levels are often selected for an exploratory design.

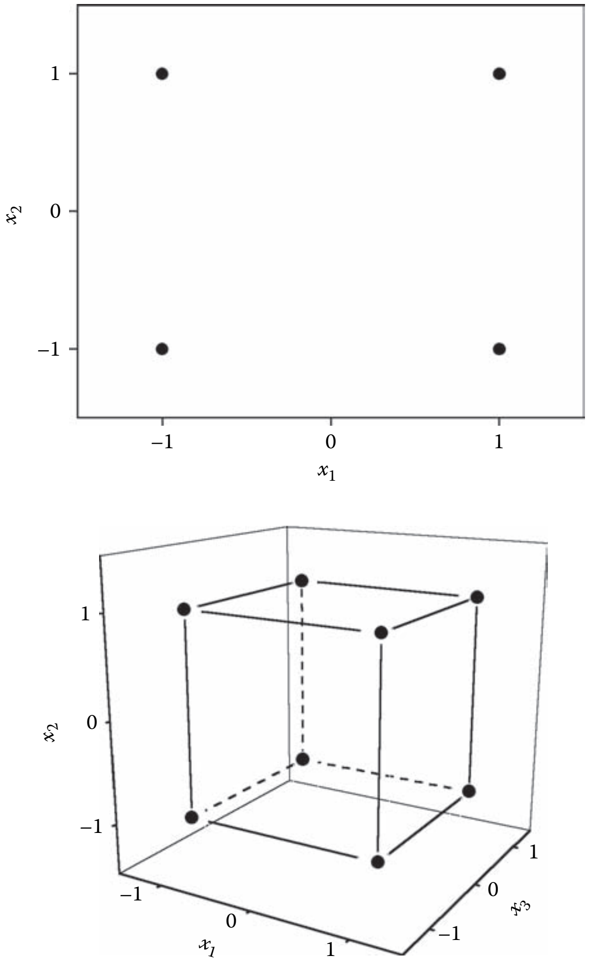

FIGURE 3.2 Two-level factorial design for (a) two factors and (b) three factors.

The arrangement of runs for these designs is illustrated for a full-factorial design. In a complete factorial, all combinations of all levels of the factors are tested. For a two-level factorial design with two factors, there are four treatments, as seen in Figure 3.2(a). The levels of each factor, often called *low* and *high*, are coded as $x = -1$ and $x = +1$, respectively. (Since only 1's enter the matrix when there are two levels of each factor, a short form of the x matrix may show only the – and + signs and omits the 1's.) All combinations of these two-level factors are displayed in *factor space* in Figure 3.2(a). Figure 3.2(b) shows the corresponding factorial design for three factors at two levels each, i.e., a total of eight experiments. The number of treatments required by a factorial design is given by the product of the number of levels l for each factor, 1 to k, or

$$\text{Number of Treatments} = l_1 \times l_2 \times l_3 \times \cdots \times l_k \tag{3.66}$$

For two-level factorial designs, the number of treatments (or experiments) simplifies to 2^k, where k is the number of factors or variables considered. Using only two levels greatly reduces the number of experiments required. Table 3.13 compares required treatments for a factorial design with several levels of each factor. The number of treatments increases both with the number of factors and the number of levels per factor. Five levels of more than two factors is usually prohibitive.

TABLE 3.13
Number of Treatments Required for Factorial Design with the Same Number of Levels for Each Factor

	2 Levels		3 Levels		5 Levels	
Number of Factors	Design	Treatments	Design	Treatments	Design	Treatments
1	2^1	2	3^1	3	5^1	5
2	2^2	4	3^2	9	5^2	25
3	2^3	8	3^3	27	5^3	125
4	2^4	16	3^4	81	5^4	625
5	2^5	32	3^5	243	5^5	3125

Some replicates also need to be considered. Error may be estimated by replicating only a few of the treatments. If there is no separate estimate of error, the number of runs required must exceed the number of treatments shown in Table 3.13.

As noted, the number of treatments increases rapidly as the number of factors and levels of treatments increases with a full-factorial model. To convert to a factorial design having fewer treatments, the experimenter must evaluate the data after each run and seek how to reduce the number of experiments by reducing factors (or operating variables), levels to be investigated, etc. As a general rule, runs in the design program should be conducted in a random order, since the following problems may occur as experimentation proceeds: degradation of the feed stocks, change in operating techniques (either worsen or improve), variation in utilities used (e.g., temperature of cooling water), etc. Further replicate experiments are always needed.

Experimental programs increase in size (and cost) as the number of pretreatments and factors increase. Considerations should be made to reduce both pretreatments and factors. Partial-factorial designs are often employed by selecting only some runs of the full design and designating them as –1 or +1. Tables 3.14 and 3.15 indicate one method to change from full factorial to half-factorial. With four factors at two levels each, the runs are reduced from 16 to 8 by removing

treatments according to the alias **D** = **ABC**. Treatments in Table 3.14 with this alias (and the equivalent aliases **AD** = **BC**, **BD** = **AC**, **CD** = **AB**, **A** = **BCD**, **B** = **ACD**, **C** = **ABC**, and **I** = **ABCD**) are selected for the half-factorial design; all other treatments are removed. Fewer interactions of factors are investigated, but when interesting results are obtained, more runs are added and, hence, investigated. Montgomery and Runger [2] thoroughly discuss the method of aliasing for reducing factorial designs.

3.7.4 Factorial Design with More Levels

Attempts should always be made to use theoretical mathematical models, but generally only empirical ones need to be employed in the initial investigation. When a factor causes curvature of the results, at least three levels must be investigated. Initially, it is likely that the factor(s) causing the curvature is unknown. The center point at $x_1 = 0$ and $x_2 = 0$ is often a good one to investigate first, since it does not alter the orthogonality. Replicates are often run at the center, and they are interspersed with other treatments. (Complete orthogonality is maintained when runs at the zero level in all factors are added to the **X** matrix.)

Although a central point offers a measure of curvature, it cannot distinguish which factor is responsible for the curvature. Additional levels of each of the factors are needed to provide sufficient treatments to assess the model. A quadratic form of the model containing all possible terms to the second order is convenient and can fit many response behaviors:

$$\hat{y} = \beta_0 + \beta_1 x + \beta_2 x_2 + \beta_{12} x_1 x_2 + \beta_{11} x_1^2 + \beta_{22} x_2^2 \quad (3.67)$$

Added terms are often planned in a *star design*, with high- and low-level treatments in each factor out from the center point. Figure 3.3(a) shows one design with treatments of the star design in solid. With two factors, these can be two scaled-units from the center, and the result is a 3 × 3 factorial design rotated 45°. With three or more factors, the *composite design* of the two-level factorial and the star radiating from the center has fewer treatments than a three-level factorial (see Figure 3.3(b)). Sufficient treatments are offered for fitting the full quadratic model extension of Equation (3.67) in more factors. The spacing of the treatments of the star design can be varied, but typically these are between 1 and 2 units from the center in the coded scale.

An important extra advantage of this composite design is that the level of the star-design treatments can be individually adjusted to provide five levels for any or all factors. Extending the range of a factor beyond the –1 to +1 levels aids in determining curvature and can offer advantages in narrowing the confidence interval on the response.

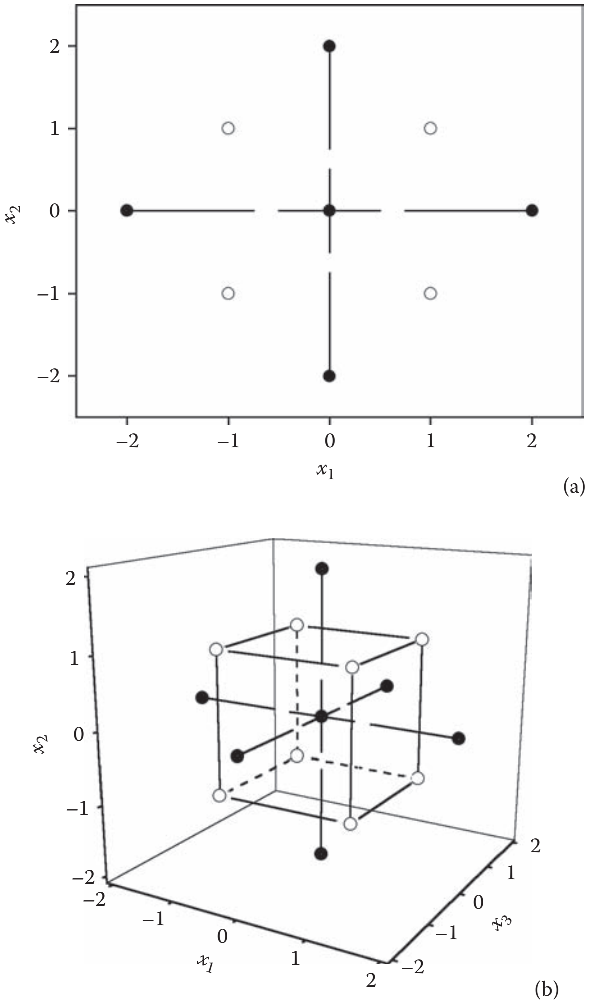

FIGURE 3.3 Composite designs, two-level factorial plus star design, for (a) two factors and (b) three factors.

3.7.5 Blocks and New Duplicates

Sometimes a block of runs is performed to estimate reproducibility. For example, one block (or group) of runs is made with one feedstock or one reactor system. In these cases, partial factorial runs may act as different blocks, or replicates are performed.

3.7.6 Computer-Aided Experimental Design

Several computer software packages are helpful in designing experiments. A current commonly used software is JMP, produced by SAS [17]. Typically, design-of-experiments software will ask the user to input the number of factors and levels and the size of the design, e.g., 1/2 or 1/4 factorials or even smaller. Afterward, the software self-selects those terms to alias and then will usually display the model appropriate to the factorial design. The software may also randomize the order of experiments or enter the experiments into blocks if the user desires. JMP is particularly useful, as it contains both the experimental-design software and multiple linear regression algorithms, and both are designed to work in tandem, providing a platform for experimental design and follow-up mathematical modeling.

APPENDIX

As indicated in the introduction to this chapter, the freely available *NIST/SEMATECH e-Handbook of Statistical Methods* (available online at http://www.itl.nist.gov/div898/handbook/index.htm) is recommended as a resource for readers. This large handbook provides valuable information to engineers and scientists on the application of statistics to real-world problems. The main headings of its Table of Contents are as follows:

1. Exploratory Data Analysis
   a. Introduction
   b. Assumptions
   c. Techniques
   d. Case Studies
2. Measurement Process Characterization
   a. Characterization
   b. Control
   c. Calibration
   d. Gauge R&R Studies
   e. Uncertainty Analysis
   f. Case Studies
3. Production Process Characterization
   a. Introduction
   b. Assumptions
   c. Data Collection
   d. Data Analysis
   e. Case Studies
4. Process Modeling
   a. Introduction
   b. Assumptions
   c. Data Collection
   d. Data Analysis
   e. Interpretation & Use
   f. Case Studies
5. Process Improvement
   a. Introduction
   b. Assumptions
   c. Choosing an Experiment Design
   d. Analysis of DOE Data
   e. Advanced Topics
   f. Case Studies
6. Process or Product Monitoring and Control
   a. Introduction
   b. Test Product for Acceptability
   c. Univariate and Multivariate Control Charts
   d. Time Series Models
   e. Tutorials
   f. Case Studies
7. Product and Process Comparisons
   a. Introduction
   b. Comparisons: One Process

   c. Comparisons: Two Processes
   d. Comparisons: Three + Processes
8. Assessing Product Reliability
   a. Introduction
   b. Assumptions/Prerequisites
   c. Reliability Data Collection
   d. Reliability Data Analysis

ACKNOWLEDGMENT

The author is grateful to the late Robert Eckert for notes that assisted in the compilation of this handbook chapter.

4.1 PRINCIPLES OF THERMODYNAMICS

4.1.1 Introduction

Thermodynamics has played an increasingly important role over the years in the engineering analysis and synthesis of chemical processes. There has been an expansion of this role with the success of vapor-pressure-fitted van der Waals equations of state and group contribution methods. By far the major part of computer time in chemical process design is now devoted to thermodynamic calculations. This chapter presents the thermodynamic methods needed to perform the analysis and synthesis, to start from basic principles, to describe the phenomena, to develop the methods, and to illustrate applications.

In a brief review of the terminology of thermodynamics, the portion of the universe that is studied is called a *system*. The rest of the universe that interacts with the system is the *surroundings*.

The system is *open* if it exchanges mass with its surroundings. A *closed* system cannot exchange mass with its surroundings. The system is *adiabatic* if it does not exchange heat with the surroundings. A system is *isolated* if it is precluded from exchanging mass or energy with its surroundings.

A system at *equilibrium* does not change with time, and no transport flux of momentum, heat, or mass occurs. An equilibrium system is characterized by a *reversible* response to differential changes in external forces. A small increase of applied pressure produces a compression effect on the fluid; a small decrease of pressure produces an expansion effect. For a system at pressure p, either reversible compression or reversible expansion takes place, depending on the sign of dp. Similarly, with a differential increase in temperature of the surroundings from its equilibrium temperature, heat is absorbed by the equilibrium system; conversely, heat is rejected by the system with an infinitesimal decrease in temperature of the surroundings. Thus reversible exchange of heat with a system at T can be either heat input from a source at $T + |dT|$ or output to a sink at $-|dT|$. A reversible process is an ideal process taking place at near zero speed in an equilibrium system. Equilibrium and reversibility go hand in hand.

A system can be composed of several phases. A *phase* is a homogeneous part of a system. The phases of a system at equilibrium are also at equilibrium. An *extensive property* of a system is the sum of the parts of the system. Thus volume is extensive. The extensive property of an equilibrium phase is directly proportional to its mass m. An *intensive property*, like density, temperature, or pressure, is independent of extension and assumes a uniform value in an equilibrium phase.

The *state* of an equilibrium phase is specified by its chemical composition and a relatively few intensive properties, generally two, e.g., temperature and pressure, temperature and mass density, or density and pressure. The number and kind of intensive properties required are determined by experience. To specify the state of a nonequilibrium system generally requires more than the values of a few intensive properties. Thus a system undergoing heat transfer may require a mathematical function to describe its temperature distribution and thus its state.

State properties are functions of the state and are independent of the previous history of the system; state properties are reproducible and have no memory. The density of water at a fixed state is the same any time it is measured; the density of water is a state property. However, the hardness of a specimen of steel is not a state property, inasmuch as it assumes different values at the same state, depending on its history of heat treatment.

A change of state is called a *process*. A system goes through an *adiabatic* process if no heat exchange occurs during the change of state. An *isothermal* process takes place at a constant temperature, and an *isobaric* process occurs at constant pressure.

4.1.2 Temperature and the Ideal Gas

Temperature is a measure of the degree of hotness of an object. Objects at various degrees of hotness can be assigned numbers, one to each object, in order of increasing hotness. This sequence of numbers represents temperature. Two objects in thermal contact eventually reach a state of the same hotness. They are at thermal equilibrium and at the same temperature. Two objects that are separately at thermal equilibrium with a third object are also at the same temperature.

A temperature scale can be set up by reference to an observable effect of temperature on an object, for example, thermal expansion, thermoelectric effect, or intensity of radiation of energy. Thus the thermal expansion effect can be observed by partially filling a glass capillary with mercury. The height of the meniscus of the mercury rises or falls as the hotness rises or falls. The capillary tube can be marked with numbers as a linear progression of distance to indicate temperature. Many devices can be devised for the measurement of temperature. The fundamental problem is to find a temperature scale that is independent of any arbitrarily selected measuring device employing an arbitrarily selected medium.

The answer is the ideal-gas temperature scale defined as follows: Measure the volume V of a fixed quantity of gas or gas mixture at a sequence of low pressures p at the temperature of the

object to be determined; form the pV products and extrapolate to determine a zero-pressure limiting value; call it β. Repeat this experiment at the steam point to determine a benchmark value β_S. Repeat again at the ice point to determine another benchmark value β_I. The temperature of the object on the ideal-gas temperature scale in kelvins, K, is given by

$$T = 100\beta / (\beta_S - \beta_I) \tag{4.1}$$

In Equation (4.1), the steam-point temperature and the ice-point temperature are defined to differ by 100°K. The ideal-gas temperature is independent of the species and quantity of gas and of the apparatus used for the measurement. Substituting β_I for β in Equation (4.1), the ice point has been found to be 273.15° and, similarly, the steam point to be 373.15°K.

In terms of ideal-gas temperature, it follows from Equation (4.1) that all gases are described by

$$\lim_{p \to 0} pv = \kappa T \tag{4.2}$$

where κ is a constant in the equation but depends on the quantity of gas. The quantity assumes a universal constant value for 1 mole of gas by Avogadro's law, which states that equal volumes of gas of any chemical species measured at the same temperature and pressure contain equal numbers of molecules at ideal-gas conditions,

$$\lim_{p \to 0} pv = RT \tag{4.3}$$

where v denotes molar volume and R is a universal constant determined to be 8.314510 J/(mol·K).

For real gases, the pV product attains the limiting value RT at zero pressure, where intermolecular potential energy vanishes. The extrapolation to zero pressure frees the pV product from the effect of intermolecular forces. An ideal gas is defined as one that is free of intermolecular potential energy at finite pressures. For the ideal gas, the pv product equals RT at all pressures, and is called the ideal-gas equation,

$$pv = RT \tag{4.4}$$

This equation is an approximation of real gas behavior at high temperatures or low pressures. The approximation remains good at lower temperatures at progressively lower pressures. Where the degree of approximation is acceptable, the equation is in common use for its simplicity.

A real gas or real liquid is said to be in the ideal-gas state when its intermolecular potential is ignored. The properties of the fluid in the ideal-gas state can be calculated with ease using Equation (4.4). One simple universal equation applies to all substances, requiring no substance-specific parameters. However, for most real states, the ideal-gas equation is inadequate, and real-fluid properties are obtained by adding to the ideal-gas equation the contribution of intermolecular potential in the form of deviation functions, also called residual functions. A major objective of Section 4.2 is to derive the deviation functions from the equation of state of the substance. Because the ideal-gas properties are known, to find the deviation function is as good as finding the state function of a real substance. In this way the ideal-gas equation is used universally in all equation-of-state calculations of thermodynamic functions.

4.1.3 First Law of Thermodynamics and Internal Energy

The first law of thermodynamics states that energy can be converted from one form to another or transported from one system to another, but the sum of the energies involved—kinetic energy,

potential energy, electric energy, internal energy (which is a state function), and other forms—is always conserved and remains constant. Energy is neither destroyed nor created. Thus the change in the total energy of a system including mechanical energy and internal energy is equal to the flow of energy into the system in the form of heat or work. Let U denote internal energy and E denote mechanical energy, including potential energy, kinetic energy, and the like. Let Q denote heat, the flow of energy due to a temperature difference. Let W be the work, or mechanical energy in transition. By the first law,

$$dU + dE = \delta Q + \delta W \tag{4.5}$$

We follow the convention of assigning a positive sign to Q or W for flow into the system. A negative value for δQ designates heat loss from the system; a negative value of δW denotes work done by the system. With the use of δ rather than d, the differential δQ or δW indicates a differential quantity that is not the differential of a state function and, therefore, is not an exact differential. Equation (4.5) brings out the essence of the first law by using dU for the differential of U.

Applying Equation (4.5) to the surroundings by changing the signs of the flow terms,

$$dU_{sur} + dE_{sur} = -\delta Q - \delta W \tag{4.6}$$

Adding Equation (4.5) and Equation (4.6),

$$d(U + E) + d(U + E)_{sur} = 0 \tag{4.7}$$

Integrating,

$$(U + E) + (U + E)_{sur} = C \tag{4.8}$$

where C is a constant showing that the total energy of the system and surroundings is always conserved. Energy can be converted from one form to another, but it cannot be created from nothing, nor annihilated into nonexistence. The first law is a generalization of the principle of conservation of mechanical energy that applies to mechanical systems in the absence of dissipative forces. By introducing internal energy as a state function, the first law turns the principle of conservation of energy into a general principle.

Being of a molecular nature, internal energy is made up of:

- Kinetic energy of motion of molecules
- Potential energy of interaction of molecules
- Energy of rotation of atoms and groups of atoms within molecules
- Energy of vibration of the chemical bonds
- Chemical energy of bonding of atoms
- Excitation of electrons
- Energy of the atomic nuclei

Since not all of these energies have been completely elucidated, the absolute value of internal energy is not known, nor is it of urgent concern, as it is the *change* of internal energy that accompanies a process that is of interest, rather than the absolute value. When values of internal energy need to be tabulated or reported, they are based on a convenient datum state.

Of the various forms of molecular energy, ideal gas is unique in lacking potential energy of molecular interaction; the molecules do not appreciably attract or repulse one another. Since the

potential energy of the molecules is the only form of molecular energy that is volume dependent, the internal energy of the ideal gas is independent of pressure or density, but is a function of temperature only:

$$(\partial U / \partial p)_T = 0 \tag{4.9}$$

$$(\partial U / \partial \rho)_T = 0 \tag{4.10}$$

While the intermolecular forces are absent, the internal structure of the molecule and the attendant energies remain unaltered from the real gas. The internal energy, heat capacity, and related functions retain their specific values for each substance in the ideal-gas state.

For the phenomena addressed in this chapter, changes in the mechanical energy of a substance are insignificant compared with changes in the internal energy; mechanical energy contents will not be included in the first law equation in the rest of the chapter. We will simply write

$$dU = \delta Q + \delta W \tag{4.11}$$

A change of volume is always associated with the phenomena addressed in this chapter; we will consider volume change as the only means by which work is exchanged with the surroundings, $\delta W = -pdV$, the sign convention being for the work to be positive when done on the system. Thus

$$dU = \delta Q - pdV \tag{4.12}$$

As a state function, how does U change with state? Let us express dU in terms of the state variables and V,

$$dU = (\partial U / \partial V)_T dV + (\partial U / \partial T)_V dT \tag{4.13}$$

Combining the two equations, we express the heat exchange in terms of changes of state,

$$\delta Q = [(\partial U / \partial V)_T + p]dV + (\partial U / \partial T)_V dT \tag{4.14}$$

Let C_V denote heat capacity at constant volume defined by

$$(\delta Q = C_v dT)_v \tag{4.15}$$

Comparison of Equation (4.14) and Equation (4.15) shows that

$$C_V = (\partial U / \partial T)_V \tag{4.16}$$

At constant volume, the change of U with a change of from state 1 to 2 is given by

$$U_2 - U_1 = \int_1^2 C_v dT \tag{4.17}$$

C_V can be measured calorimetrically or, for the ideal gas, calculated from spectroscopic data. For a real gas or liquid, it can be obtained by combining the ideal-gas value with equation-of-state calculations to be discussed in Section 4.2.7, where the isothermal variation of U with V will also be discussed.

4.1.3.1 Open Systems

A closed system has been considered to define internal energy and to develop the fundamental differential form of internal energy. When internal energy is added to a system by transfer of mass from the surroundings into the system, the system is said to be open. The energy conservation equation, Equation (4.11), is extended to open systems by considering the addition of a differential number of moles dn_{in} in an input stream to the system and the leaving of a differential number of moles dn_{out} in a stream out of the system. By the principle of conservation of energy—adding the differential internal energy and the associated differential pv work of propelling the streams into the system to Equation (4.11) for any number of input streams and likewise subtracting the leaving streams—we obtain the differential change dU of the system

$$dU = \delta Q + \delta W + \sum_{in} u_{in} dn_{in} + \sum_{in} p_{in} v_{in} d_n - \sum_{out} u_{out} dn_{out} - \sum_{out} p_{out} v_{out} dn_{out} \tag{4.18}$$

By explicitly expressing the pv work associated with the input and output flows in separate terms so as to exclude them from the work term W, the meaning of W in Equation (4.11) remains unchanged as it reappears in Equation (4.18).

We now define a new energy function, called the enthalpy, H, by

$$H = U + pV \tag{4.19}$$

Accordingly, Equation (4.18) can be rewritten as

$$dU = \delta Q + \delta W + \sum_{in} h_{in} dn_{in} - \sum_{out} h_{out} dn_{out} \tag{4.20}$$

Reexpressed in time rate of change,

$$\dot{U} = \dot{Q} + \dot{W} + \sum_{in} h_{in} \dot{n}_{in} - \sum_{out} h_{out} d\dot{n}_{out} \tag{4.21}$$

at steady conditions, with all flows at a constant rate and the system unchanging in time, $\dot{U}$. Rearranging the equation, we obtain

$$\sum_{out} \dot{H}_{out} = \sum_{in} \dot{H}_{in} + \dot{Q} + \dot{W} \tag{4.22}$$

This equation, known as enthalpy balance, is extensively used in engineering analyses of processes. The system under consideration is then the whole chemical plant or process. Thus the enthalpy balance displays the sources and destinations of energy in the plant or the process. Chemical reactions commonly produce large enthalpy changes and heat effects. Often, the enthalpy balance of chemical processes is dominated by the thermal chemistry of the process. In the following, several examples illustrate the application of the first law of open systems.

Example 4.1: Throttle

A throttle is a device (such as a partly closed valve or porous plug) that reduces the pressure of a flowing fluid without any shaft work or significant acceleration of the fluid (i.e., no appreciable change in the kinetic energy of the fluid). With a single inlet and outlet stream, and assuming that these streams and the heat transfer are negligible, Equation (4.22) reduces to

$$h_{out} = h_{in} \tag{4.23}$$

A throttle does not change the enthalpy of the fluid; throttling is an isenthalpic process. For a given input state and a specified outlet pressure, one finds the outlet temperature by conducting a one-dimensional search for a temperature at which the enthalpy is equal to the input enthalpy. An enthalpy chart provides a convenient means for the search. Another method of solution is to apply the Joule-Thompson coefficient, μ_{JT}, defined by

$$\mu_{JT} = \left(\frac{\partial T}{\partial P}\right)_h \tag{4.24}$$

The sign of the above partial derivative determines whether a fluid expanded through a throttle experiences a temperature drop. For an ideal gas, $\mu_{JT} = 0$, so that there is no change for a given pressure drop. For real gases, at high enough temperatures (depending upon the substance of interest), $\mu_{JT} < 0$, so that the temperature of the gas increases upon expansion. Below some inversion temperature, μ_{JT} becomes positive, so that the gas now cools upon expansion through a throttle. For example, this inversion temperature is about 1319 for CO_2 and about 40 for He. Typically, another inversion temperature exists at even lower temperatures, where μ_{JT} again becomes negative. Also, there is usually a single inversion pressure, where above that pressure μ_{JT} is always negative. For example, this inversion pressure is 884 bar for CO_2 and around 27.5 bar for He. Typically, a throttle is used to cool a gas upon expansion. If the temperature drop is large enough, the gas can be partially liquefied.

Example 4.2: Heat Exchangers

Consider a heat exchanger operating with two streams, A and B, with steady flow rates of $\dot{n}_A$ and $\dot{n}_B$. Since the volume of the heat exchanger is constant and no shaft work is performed, $\dot{W} = 0$. Also, assuming that all transfer of heat occurs between the two streams inside the heat exchanger, so that no heat is lost to the surroundings, then $\dot{Q} = 0$. With kinetic and potential energy changes being small, the energy balance reduces to

$$\Delta h_A \dot{n}_A + \Delta h_B \dot{n}_B = 0 \tag{4.25}$$

where $\Delta h_i = h_{i,out} - h_{i,in}$. If the incoming and outgoing pressure of a stream is the same, then Δh_i can be calculated from

$$\Delta h_i = \int_{T_{i,in}}^{T_{i,out}} C_{p,i} dT$$

Example 4.3: Venting of an Insulated Tank

Consider a rigid (constant-volume), well-insulated (adiabatic) tank containing a gas at some initial high pressure. Then a valve is opened and the gas is slowly vented through a pipe. Assuming that the changes in kinetic energy are small (as compared with the enthalpy fluxes and internal energy changes of the system), Equation (4.20) reduces to

$$dU = -h_{out}\delta n_{out} = h_{out}dN$$

where N denotes the number of moles in the tank. In general, the enthalpy of the exiting stream, h_{out}, may not have the same properties of the gas remaining in the tank. If we now assume that the venting is slow and the contents of the tank are well mixed, we can replace h_{out} with the molar enthalpy of the contents of the entire tank, h. The internal energy of the gas in the tank varies because both mass is removed and its properties (such as and p) change; the first law can be written as

$$dU = d(Nu) = Ndu + udN = hdN$$

or

$$\frac{du}{h-u} = \frac{dN}{N} \tag{4.26}$$

where u is the molar internal energy. The above expression is a general relation describing how the molar internal energy of the contents of the tank varies with a change in the mass, or moles, of the system.

If the gas in the tank is ideal, where $h\ u = Pv = RT$ and $du = C_v dT$, then Equation (4.26) is given by

$$\frac{C_v}{R}\frac{dT}{T} = \frac{dN}{N}$$

which upon integration yields (assuming a constant heat capacity)

$$\left(\frac{N_f}{N_i}\right) = \left(\frac{T_f}{T_i}\right)^{C_v/R} \tag{4.27}$$

The above relation can be rewritten in terms of the pressure of the tank. Noting that the volume of the tank is fixed, and that for an ideal gas $PV = NRT$, Equation (4.27) can be rewritten as

$$\left(\frac{P_f}{P_i}\right) = \left(\frac{T_f}{T_i}\right)^{C_p/R} \tag{4.28}$$

where, for an ideal gas, $C_P = C_v + R$.

Example 4.4: Filling of an Insulated Tank from a Constant-Temperature and -Pressure Source

Consider a rigid (constant-volume), well-insulated (adiabatic) tank that is initially evacuated ($N_i = P_i = 0$). The tank is to be filled with a gas from some external source, assumed to be large enough that the temperature and pressure of the gas entering the tank do not vary throughout the process. Gas enters the tank until the pressures of the tank and the external source are the same. Neglecting heat transfer and changes in kinetic energy, Equation (4.20) now reduces to

$$dU = h_{in}\delta n_{in} = h_{in}dN$$

where we have also made use of the mass balance equation. In this example $dN > 0$. Since the enthalpy of the incoming stream, h_{in}, is constant, we may integrate both sides of the above equation to obtain

$$U_f - U_i = h_{in}(N_f - N_i)$$

Because $N_i = 0$, $U_i = 0$, so that the above reduces to

$$U_f = N_f u_f = h_{in} N_f$$

or

$$u_f = h_{in} = u_{in} + p_{in} v_{in} \tag{4.29}$$

The first term on the far right side represents the molar internal energy that entered the tank, while the second term represents the work done by the incoming stream as it enters the tank.

For an ideal gas, $pv = RT$ and $du = c_v dT$, so that Equation (4.29) becomes (by using an average heat capacity)

$$u_f - u_{in} = c_v(T_f - T_{in}) = p_{in} v_{in} = RT_{in}$$

or

$$T_f = \frac{c_p}{c_v} T_{in} \tag{4.30}$$

Because $C_P > C_v$, then $T_f > T_{in}$. This problem clearly illustrates one of the differences between open and closed systems and of the importance of the work due to flow (which, in this example, is responsible for the increase of the final temperature above that of the external source). As an example, air, modeled as a pure-component ideal gas, is well represented by $c_v = (5/2)R$ and $c_p = (7/2)R$, so that $T_f = (7/5)T_{in}$, a 40% temperature rise above T_{in}.

4.1.4 Second Law of Thermodynamics and Entropy

The second law according to Planck is widely cited: *It is impossible to construct a machine operating in cycles that will convert heat into work without producing any other changes in the surroundings*. Another form of the second law is: *It is impossible to operate any process solely to transfer heat from a lower temperature to a higher one*. It can be shown that both are equivalent and both are deducible from the following statement:

There exists an extensive state function called entropy S *that is defined by*

$$dS = \delta Q / \theta \tag{4.31}$$

where δQ *is the differential heat absorbed reversibly from the surroundings and* θ *is the thermodynamic temperature of the system.* The thermodynamic temperature is an absolute temperature that can never be less than zero, and is otherwise unspecified. It will be shown shortly that it is identical to the ideal-gas temperature.

The entropy change made by a process, whether reversible or irreversible, of a closed system is given by

$$dS = d_eS + d_iS \tag{4.32}$$

where $d_eS = \delta Q/\theta$ denotes entropy change due to transfer of heat into the system and θ is the temperature where the heat transfer takes place; d_iS is the entropy generated due to other processes taking place within the system,

$$d_iS > 0 \quad \text{for irreversible and possible processes} \tag{4.33}$$

$$d_iS = 0 \quad \text{for reversible and possible processes} \tag{4.34}$$

$$d_iS < 0 \quad \text{never} \tag{4.35}$$

The second law gives a direction to changes: change proceeds in the direction that increases entropy, but never to decrease entropy. The fundamental criterion is established for the completion of irreversible changes and the attainment of equilibrium, thus providing the basis for the study of equilibrium phenomena.

The temperature θ of the second law, called the thermodynamic temperature, will be shown to be identical to the ideal-gas temperature T. To proceed, we consider the Carnot cycle to produce mechanical work from heat. The Carnot cycle is an idealized reversible cycle by which a working fluid is confined in a cylinder-piston device to (a) absorb heat from a high-temperature source while producing mechanical work and (b) reject heat to a low-temperature sink while being compressed toward the original state. The successive steps of a Carnot cycle are as follows:

1. Isothermal expansion at a high temperature θ_1, absorbing heat Q_1. The change of entropy of the working fluid $\Delta S = Q_1/\theta_1$ by Equation (4.31).
2. Adiabatic expansion to cool down to a low temperature θ_2, absorbing no heat. The change of entropy equals zero.
3. Isothermal compression at θ_2, absorbing heat Q_2 (a negative quantity from the sign convention). The entropy change $\Delta S = Q_2/\theta_2$.
4. Adiabatic compression designed to bring the system back to the original state at θ_1. The entropy change equals zero.

Let $-W$ denote the total work done by the system in going through one complete cycle. The first law requires

$$\Delta U = Q_1 + Q_2 + W \tag{4.36}$$

Since U is a state function, its change for the cycle is zero, $\Delta U = 0$, and

$$Q_1 + Q_2 = -W \tag{4.37}$$

Since entropy is a state function, its change is also zero. Adding up the entropy changes for all four steps of the cycle,

$$Q_1/\theta_1 + Q_2/\theta_2 = 0 \tag{4.38}$$

The cycle is characterized by the absorption of heat at only one temperature and by the rejection of heat at only one temperature, such that the effect of temperature on the quantity of heat absorbed or rejected can be revealed. By Equation (4.38), the effect is a simple proportionality,

$$Q_1/\theta_1 = -Q_2/\theta_2 \tag{4.39}$$

The efficiency of the cycle is defined to be the fraction of the heat absorbed at the high temperature that is converted into work, $(-W)/Q_1$. By combining Equation (4.37) and Equation (4.38), the efficiency of the Carnot cycle is obtained,

$$(-W)/Q_1 = (\theta_1 - \theta_2)/\theta_1 \tag{4.40}$$

The theoretical efficiency of the ideal reversible cycle is seen to depend only on the temperatures of the heat source and sink, and is independent of the working fluid confined in the piston-cylinder device.

Let us use an ideal gas in a Carnot cycle and find the efficiency of the cycle by using ideal-gas properties in enumerating the changes in the four steps of the cycle. Let us designate the intial state of step 1 with the subscript A, the initial state of step 2 with B, and so on. The high temperature at step 1, which is $_1$ on the thermodynamic temperature scale, will be T_1 on the ideal-gas temperature scale. The low temperature of step 3 will be T_2, corresponding to θ_2. The work and heat terms of a step will be designated with subscripts 1, 2, 3, or 4.

1. Isothermal expansion at a high temperature T_1:

$$U_B - U_A = 0$$

$$W_1 = -\int pdV = -nRT_1 \ln (V_B/V_A)$$

$$Q_1 = -W_1$$

2. Adiabatic expansion to cool down from T_1 to T_2:

$$Q_2 = 0$$

$$U_C - U_B = W_2$$

3. Isothermal compression at a low temperature T_2:

$$U_D - U_C = 0$$

$$W_3 = -\int pdV = -nRT_2 \ln (V_D/V_C)$$

$$Q_3 = -W_3$$

4. Adiabatic compression to heat up to the high temperature T_1:

$$Q_4 = 0$$

$$U_A - U_D = W_4$$

Since $U_A = U_B$ and $U_C = U_D$, $W_2 = -W_4$. These two work terms cancel when the work terms of the cycle are summed, leaving the total work done on the working fluid to be

$$W = W_1 + W_3 \quad (4.41)$$

Forming the efficiency by dividing $-W$ with Q_1,

$$-W/Q_1 = [T_1 \ln (V_B/V_A) + T_2 \ln (V_D/V_C)]/[T_1 \ln (V_B/V_A)] \quad (4.42)$$

The volumes V_B and V_C are related because B and C are on an adiabatic line,

$$nRT \ln (V_B/V_C) = C_V \ln (T_2/T_1) \quad (4.43)$$

Similarly V_A and V_D are related to the same temperature ratio; the two volume ratios are equal, $V_B/V_C = V_A/V_D$. Upon rearranging,

$$V_B/V_A = V_C/V_D \quad (4.44)$$

The efficiency of the ideal-gas Carnot cycle is found upon substituting Equation (4.43) into Equation (4.42),

$$(-W)/Q_1 = (T_1 - T_2)/T_1 \quad (4.45)$$

The ideal-gas Carnot cycle is a particular case of the Carnot cycle; its efficiency must be given by the general formula of Carnot cycles. Comparison of Equation (4.45) with Equation (4.40) shows

$$\theta_1/\theta_2 = \theta_1/\theta_2 \quad (4.46)$$

$$\theta_1/\theta_1 = \theta_2/\theta_2 \quad (4.47)$$

Since the two temperatures 1 and 2 are arbitrary, Equation (4.47) reveals that the two temperature scales are proportional,

$$\theta/T = k \quad (4.48)$$

where k is a constant. For convenience, k is set to be equal to 1 to give

$$\theta = T \quad (4.49)$$

The thermodynamic temperature is identical to the ideal-gas temperature. Both will be referred to as the absolute temperature. From here on we will use the absolute temperature for the calculation of entropy change according to $dS = \delta q/T$.

The efficiency of the Carnot cycle is the highest among all machines for the production of work from heat working between any two given temperatures. When reversible and operating

between the same high temperature T_1 and low temperature T_2, it *absorbs* heat Q_2 at T_2 and *rejects* heat Q_1 at T_1 while *consuming* work W. The ratio W/Q_1 remains the same as before. Suppose an irreversible machine exists that has a higher efficiency than the Carnot cycle. Let it absorb heat Q_1' at T_1 and produce the same work W as consumed by the reversed Carnot. Then, as supposed,

$$W/Q1' > W/Q1 \tag{4.50}$$

$$Q1' < Q1 \tag{4.51}$$

If the reversed Carnot cycle were coupled to the irreversible machine and driven by it, there would be a net amount of heat $Q_1 - Q_1' > 0$ flowing into the reservoir from this coupled machine. There being no net work production, this amount of heat is obtained from the low-temperature reservoir at T_2. The coupled machine would be pumping heat from a lower temperature to a higher temperature while producing no other changes in the surroundings. But such a result is impossible by the second law.

The efficiencies of all reversible machines are equal. For, if any one should have a different efficiency, the machine with the higher efficiency can be operated to drive the one with lower efficiency in reverse. The combined machine would be capable of pumping heat from a lower temperature to a higher temperature without producing any other changes in the surroundings, hence violating the second law.

The Carnot cycle reveals a fundamental difference of heat from mechanical energies. Whereas the conversion of mechanical energy to heat can be readily completed, the conversion of heat to work is incomplete, even under ideal conditions. Only part of the heat can be converted, and the rest has to be rejected to a lower temperature sink. In thermodynamics, work denotes all forms of energy that are interconvertible without any theoretical limit on the degree of convertibility. Thus potential energy, kinetic energy, electrical energy, surface energy, etc., belong to the category of work.

4.1.5 Equilibrium Energy Functions

Consider the change of entropy of a system that is isolated and cannot exchange heat or work with the surroundings. Not being able to exchange work means a constant volume, $dV = 0$. Following from the further restriction of no heat exchange, the first law requires no change of internal energy, $dU = 0$. By the second law, there can be no entropy change due to heat exchange with the surroundings. But entropy can increase due to irreversible processes within the system,

$$(dS > 0)_{U,V} \tag{4.52}$$

The increase persists as long as irreversible processes take place until entropy reaches a maximum

$$(dS = 0)_{U,V} \tag{4.53}$$

and the system attains an equilibrium state. Equilibrium criteria are described in the following subsections.

4.1.5.1 Equilibrium Criterion I

At fixed U and V, a system seeks equilibrium by increasing its entropy until equilibrium is attained as S attains a maximum.

Figure 4.1 shows an S-V-U space. The equilibrium states are represented by a surface in this space. The space on the concave side of the equilibrium surface is taken up by nonequilibrium

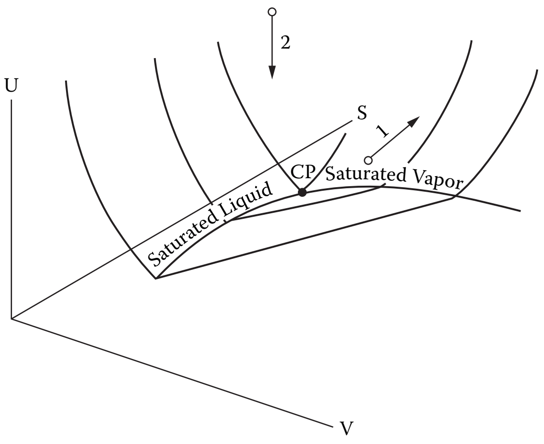

FIGURE 4.1 [*S*-*V*-*U*] space.

states, such as a system at a nonuniform temperature distribution or at varying compositions from one region to the next. A point in this space represents an isolated system that is being propelled by irreversible processes to move up in *S* toward the equilibrium surface, as indicated by arrow 1. The ascent in *S* comes to a stop upon reaching the equilibrium surface. The final point on the surface represents the equilibrium state specified by the variables *U* and *V*. The space on the other side of the surface cannot be reached.

Alternatively, an equilibrium state in the *S*-*V*-*U* space can be specified by the variables *S* and *V*. In the first-law equation, Equation (4.11),

$$dU = \delta Q + \delta W$$

we replace δQ with $\delta Q \le TdS$, in which, by the second law, the equal sign (=) applies for reversible processes, while the less-than sign (<) applies for irreversible processes. At the same time, replace δW with $-pdV$. There follows

$$dU \le TdS - pdV \tag{4.54}$$

At fixed values of *S* and *V*,

$$(dU \le 0)_{S,V} \tag{4.55}$$

In Figure 4.1, change of the system at constant *S* and *V* is illustrated by arrow 2 pointing in the direction of descending *U* as a result of irreversible processes taking place in the system. The descent in *U* comes to a stop upon reaching the equilibrium surface. The point of landing on the surface is the equilibrium state at the specified *S* and *V*. There,

$$(dU = 0)_{S,V} \tag{4.56}$$

Equation (4.56) states another criterion of equilibrium: equilibrium criterion II.

4.1.5.2 Equilibrium Criterion II

At fixed *S* and *V*, a system seeks equilibrium by decreasing internal energy until the equilibrium state is attained as *U* reaches a minimum.

Subsequent to landing on the equilibrium surface, movement on the surface is achieved by varying *S* or *V*, or both, according to Equation (4.54) with the equal sign,

$$dU = T\,dS - p\,dV \tag{4.57}$$

The coefficients of the differentials of the independent variables are given by the geometry of the *U*(*S*,*V*) surface. Thus

$$T = (\partial U / \partial S)_v \tag{4.58}$$

and

$$p = -(\partial U / \partial V)_s \tag{4.59}$$

where *S* and *V* are used as state variables to describe a process, and *U* is the state function that expresses the changes in the system in a most useful way. To illustrate, the work that can be extracted from a fluid will be found for a reversible adiabatic nonflow process. The differential work done by a fluid in a nonflow process is given by

$$-\delta W = pdV \tag{4.60}$$

In a reversible adiabatic process, $\delta Q = 0$ and $dS = 0$; the process is isentropic. Comparison with Equation (4.57) shows

$$(\delta U = dW)_s \tag{4.61}$$

Integration gives

$$(-\Delta U = -W)_S \tag{4.62}$$

The decrease in *U* is the measure of reversible nonflow work that can be extracted from a fluid upon isentropic expansion. The state function *U*, upon being measured or calculated for various states, becomes useful for engineering design of work-production processes that expand the fluid from one state to another that are tabulated or calculated.

Equation (4.57) indicates the fundamental differential relation of equilibrium *U* to the variables *S* and *V*. The simplicity and directness of the relation indicate that *U* is best suited for the exploration of phenomena expressed in the independent variables [*S*,*V*]. Equilibrium *U* is said to be the natural, or canonical, energy function of its natural variables *S* and *V*. We set out to find energy functions that are natural to other variables. The variables of greatest general usefulness are the sets [*S*,*V*], [*S*,*P*], [*T*,*V*], and [*T*,*p*]. Having had the fundamental differential equation and natural energy function for the first set of variables [*S*,*V*], our method is to change variables one at a time, starting from the known, to successively find new ones.

Switching to the variables [*S*,*P*], we find enthalpy to be just the natural energy function. Enthalpy has been defined in Equation (4.19) as

$$H = U + pV \tag{4.63}$$

The differential of *H* is

$$dH = dU + p\,dV + V\,dp \tag{4.64}$$

Substitution of Equation (4.54) into Equation (4.64) gives

$$dH \le T\,dS + V\,dp \tag{4.65}$$

In Equation (4.65) we have changed variables to [*S*,*p*] by Legendre transformation.

The less-than-or-equal-to sign (≤) in Equation (4.65) applies to two processes: The "equal" portion of the sign refers to reversible processes, while the less-than sign applies to irreversible processes. At fixed [*S*,*p*], Equation (4.65) reduces to

$$(dH)_{S,p} < 0 \tag{4.66}$$

Enthalpy continues to decrease, with irreversible processes taking place in the system until equilibrium is attained as the enthalpy reaches a minimum,

$$(dH)_{S,p} = 0 \tag{4.67}$$

Here we arrive at the third criterion of equilibrium.

4.1.5.3 Equilibrium Criterion III

At fixed S and p, a system seeks equilibrium by decreasing enthalpy until the equilibrium state is attained at which enthalpy is a minimum.

In [*H*,*S*,*p*] space, equilibrium states are represented by a surface. Space above the surface is occupied by nonequilibrium states; space below the surface is unattainable. Motion on the surface is propelled by changes *dS* or *dp*, or both, according to Equation (4.65) with the equal sign,

$$dH = T\,dS + V\,dp \tag{4.68}$$

Equation (4.68) shows that the natural energy function of the set of variables [*S*,*p*] is *H* and that the natural variables of *H* are *S* and *p*.

The geometry of the equilibrium surface is determined by the coefficients of Equation (4.68),

$$(\partial H / \partial S)_p = T \tag{4.69}$$

and

$$(\partial H / \partial p)_s = V \tag{4.70}$$

An immediate application of *H* as the natural energy function of *S* and ρ is its use as a measure of the work of expansion at reversible adiabatic flow conditions. The differential work of expansion at flow is given by –*Vdp*. Comparison with Equation (4.68) shows that

$$(-dH = -dW)_s \tag{4.71}$$

Integrating,

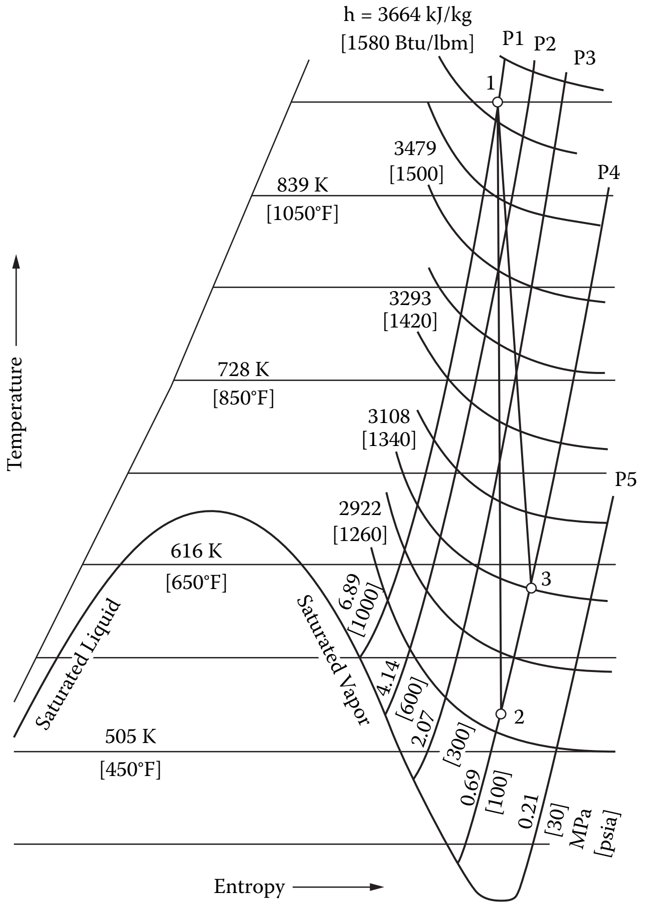

FIGURE 4.2 T-S chart for steam. (From Keenan, J. H., Keyes, F. G., Hill, P. G., and Moore, J. G. *Steam Table, Thermodynamic Properties of Water, Including Vapor, Liquid, and Solid Phases*. New York: John Wiley, 1969. With permission.)

$$(-\Delta H = -W)_s \tag{4.72}$$

The decrease of enthalpy is the measure of reversible work that can be extracted from a flowing fluid upon expansion.

Example 4.5: Work of Expansion of Steam

Steam at 6.89 MPa and 849° (1150°F) is expanded adiabatically to 0.69 MPa in a turbine. How much reversible flow work can be extracted from 1 kg of steam?

Solution

The reversible adiabatic flow work done by the steam is given by $(H_1 - H_2)$. From Figure 4.2, $H_1 = 3687$ kJ/kg and $H_2 = 2961$ kJ/kg. Therefore, $-W = 3687 - 2961 = 726$ kJ/kg.

If the expansion is adiabatic and irreversible, entropy increases during the expansion. Point 3 shows a possible final state. The enthalpy of the final state would be greater than the H_2 given above, and the work produced, being equal to the decrease in H, would be reduced.

Example 4.6: Enthalpy as a Measure of Heat Effect

Enthalpy is useful as a measure of the heat effect of constant-pressure processes. By the first law, $dU = \delta q - p\,dV$ when pV work is the only work term. At a condition of constant pressure, $p\,dV =$

$d(pV)$. Moving the pV term to the same side with U and combining, $d(U + pV) = \delta q$, or $dH = \delta q$. Integrating, we obtain $\Delta H = Q$. Enthalpy change is equal to the heat effect at constant pressure. The calculation of heat effect by using enthalpy is illustrated in Example, *Section I..G.*

Heat capacity at constant pressure C_p is defined to be $(\delta q/dT)_p$. In view of the above discussion, we obtain $C_p = (dH/dT)_p$.

The natural variables S and V of U are transformed to T and V by Legendre transformation of U to the energy function A, called the Helmholtz free energy, or Helmholtz energy. By definition,

$$A = U - TS \tag{4.73}$$

Differentiation gives

$$dA = dU - T\,dS - S\,dT \tag{4.74}$$

From Equation (4.54)

$$dU - T\,dS \le -p\,dV \tag{4.75}$$

Substitution of Equation (4.75) into Equation (4.74) gives

$$dA \le -S\,dT - p\,dV \tag{4.76}$$

The equal sign applies to reversible processes and the less-than sign to irreversible processes.

It follows at constant T and V that

$$(dA \le 0)_{T,V} \tag{4.77}$$

Helmholtz energy decreases as irreversible processes take place in the system at constant T and V, until the irreversible processes are exhausted and the system attains equilibrium at which

$$(dA = 0)_{T,V} \tag{4.78}$$

The criterion of equlibrium is obtained.

4.1.5.4 Equilibrium Criterion IV

At constant T and V, a system seeks equilibrium by decreasing A until equilibrium is attained at a state of minimum A.

Subsequent to attaining equilibrium, changes in A are propelled by dT or dV, or both, according to Equation (4.76) with the equal sign

$$dA = -S\,dT - p\,dV \tag{4.79}$$

Helmholtz energy is displayed as the natural energy function of its natural variables T and V. The geometry of the equilibrium surface is expressed by the coefficients of the differentials,

$$(\partial A/\partial T)_v = -S \tag{4.80}$$

and

$$(\partial A/\partial V)_T = -p \tag{4.81}$$

Equation (4.80) and Equation (4.81) are useful for calculating the Helmholtz energy at various states.

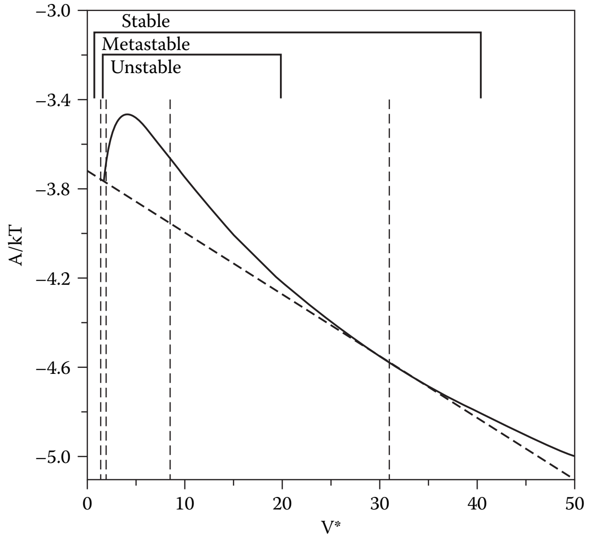

FIGURE 4.3 Helmholtz energy of the Lennard-Jones fluid at a condensation temperature T* = 1 (From Watson, B. S., and Chao, K. C. *J. Chem. Phys.* 96: 9046, 1992. With permission.).

Figure 4.3 shows the molar Helmholtz energy of a fluid at a constant T in the condensation range. The curve represents the A of equilibrium states as a function of volume. A point above the curve represents a nonequilibrium state. The natural tendency is for the point to move down until it settles on the curve.

Example 4.7: Mechanical Instability

An equilibrium state of a homogeneous phase system is not stable if its Helmholtz energy is lowered by separating into two equilibrium phases of different densities. Thus in Figure 4.3 the equilibrium state at point *a* splits into two phases *d* and *e*, the saturation states. Points *b* and *c* show a possible intermediate state in separation. Line *d-e* is tangent to the equilibrium curve at both *d* and *e*. The Helmholtz energy reaches a minimum at point *f on the line d-e* at the conclusion of the separation. The slope of the tangent is the vapor pressure.

The Helmholtz energy isotherm of a sub-critical fluid is made up of five regions: (1) Unstable region in which

$$(\partial^2 A / \partial V^2)_T < 0 \tag{4.82}$$

Unstable states do not exist in practice. No homogeneous fluid phase can be found in this density range. (2) Meta-stable region—There are two meta stable regions, one on either side of the unstable region. The second derivative is greater than zero in the metastable region. The metastable region is bounded on one side by the spinodal point where the second derivative of A is zero, and by the saturation point on the other side. Because its equilibrium A stands above the common tangent *d-e*. A metastable state naturally decomposes into saturated states like *d* and *e*, but can be obtained experimentally with care to exdlude nucleation. Super-heated liquid and supersaturated vapor are metastable. (3) Stable region—The second derivative of A with respect to v is positive in this region. There are two stable regions; each is bounded by a saturation point. Vapor phase exists at densities below the saturation value, and liquid at densities above.

Finally, we look for the natural energy function for the variables T and p. The Helmholtz energy of the natural variables T and V offers a starting point. We define the state function Gibbs free energy G by

$$G = A + pV \tag{4.83}$$

Differentiation of Equation (4.83) gives

$$dG = dA + p\,dV + V\,dp \tag{4.84}$$

Using Equation (4.75) to eliminate dA from Equation (4.84) gives

$$dG \le -S\,dT - V\,dp \tag{4.85}$$

The equal sign applies for reversible processes, while the less-than sign applies for irreversible processes. At constant T and p, if not at equilibrium, the system seeks to decrease its Gibbs energy,

$$(dG \le 0)_{T,p} \tag{4.86}$$

As the system eventually reaches equilibrium, G attains a minimum,

$$(dG = 0)_{T,p} \tag{4.87}$$

Equation (4.86) and Equation (4.87) express a criterion of equilibium.

4.1.5.5 Equilibrium Criterion V

At constant T and p, a system seeks equilibrium by decreasing G until equilibrium is attained at a state of minimum G.

Equilibrium states in the space $[G,T,p]$ are represented by a surface. A change of G on the equilibrium surface is given by Equation (4.85) with the equal sign,

$$dG = -S\,dT + V\,dp \tag{4.88}$$

The equation displays the Gibbs energy as the natural energy function of its natural variables T and p. The coefficients of the differentials in this equation reflect the geometry of the equilibrium surface,

$$(\partial G/\partial T)_p = -S \tag{4.89}$$

$$(\partial G/\partial p)_T = V \tag{4.90}$$

The equations are useful for finding the change of G as T or p is changed; the equations are also useful for deriving the change of functions that will be defined based on G.

Figure 4.4 shows the Gibbs energy of a binary mixture at a constant T and p with the datum state of either component selected to be the pure fluid at the given T and p. The equilibrium states are on the curve. The nonequilibrium states are above the curve and seek to descend to the equilibrium curve. For instance, to form a mixture of composition m from the pure fluids, the initial state of the two fluids upon being put together before molecular mixing takes place is m with $G = 0$. Molecular mixing irreversibly lowers the G of the mixture until mixing is complete and G reaches a minimum at point n on the equilibrium curve.

Example 4.8: Diffusional Instability

Not all of the equilibrium states in Figure 4.4 are stable; some will seek to decompose into two equilibrium phases of different compositions. Take point c. The shape of the curve at c is such that,

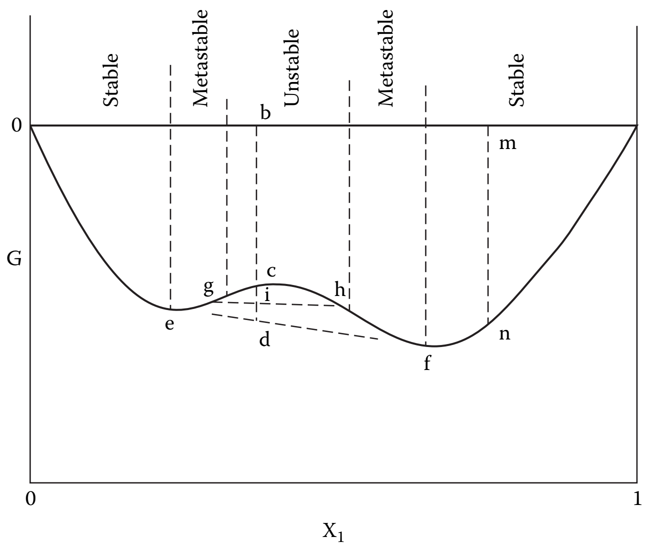

FIGURE 4.4 Gibbs energy of a partially miscible solution at a constant [*T*,*p*].

should a small difference in composition develop in any small part of the fluid due to molecular diffusional fluctuation, the difference will be promoted by a decrease in *G*. The difference grows, and two parts of the solution will be formed to become more and more different until they eventually separate into two phases *e* and *f*. Points *g* and *h* show an intermediate stage of the separation process. The Gibbs energies of *g* and *h* add up to a total *G* of the system at *i*, which is lowered from *c*. The separated phases come to a stop at *e* and *f*, yielding a minimal total *G* at *d*. Points *e* and *f* are the two immiscible mixtures at equilibrium.

The sufficient condition of diffusional instability is

$$(\partial^2 G / \partial x^2)_{T,p} < 0 \tag{4.91}$$

The equation applies to the equilibrium states in the unstable region of *x*. To the outside of *e* and *f*, we find the stable states for which the second derivative of *G* with respect to *x* is greater than 0. The states between the unstable region and *e* or *f*, despite having a positive value for the second derivative of *G* with respect to *x*, seek to decompose into the two phases at *e* and *f* to lower their Gibbs energy. These states are metastable.

The state variables *T* and *p* are particularly suited for systems at heterogeneous phase equilibrium because equilibrium phases coexist at uniform *T* and *p*. As the natural energy function of [*T*,*p*], the Gibbs energy and derived functions will be used to describe phase equilibrium.

The state functions *U*, *H*, *A*, and *G* are called energy functions. Each is associated with a pair of natural variables. To map the energy functions of a substance over a range of states by experimental measurement, by correlation of data, or by theoretical calculations, it is advantageous to develop *one* energy function as a function of its natural variables. Then all other energy functions can be obtained by elementary mathematical operations. The procedure is illustrated in the following, with Helmholtz free energy *A* having been worked out as a function of [*T*,*V*]. From the defining differential equation of *A*, Equation (4.79), the partial derivatives have been identified in Equation (4.80) and Equation (4.81): $S = -(\partial A \partial T)_V$, $p = -(\partial/\partial V)_T$. Substitution in the defining equations of the energy functions leads successively to

$$G = A + pV = A[T,V] - V(\partial A / \partial V)_T \tag{4.92}$$

$$U = A + TS = A[T,V] - T(\partial A/\partial T)_V \tag{4.93}$$

$$H = A + TS + pV = A[T,V] - T(\partial A/\partial T)_V + V(\partial A/\partial V)_T \tag{4.94}$$

In this manner, all energy functions other than A are obtained, all in terms of state variables $[T,V]$ in the region in which A is known.

4.1.6 Open System and Chemical Potential

An open system can exchange mass with its surroundings, and mole numbers of the chemical substances are the new state variables required for the specification of the system. Consider the Gibbs energy of an open system. In addition to its natural state variables T and p, there are the state variables, $n_1, n_2, \ldots, n_i, \ldots, n_\nu$, where n_i stands for mole number of species i, and n is the number of chemical species in the system,

$$G = G[T, p, n_1, \ldots] \tag{4.95}$$

A differential change of G is expressed by

$$dG = (\partial G/\partial T)_{p,ni}\,dT + (\partial G/\partial p)_{T,ni}\,dp + \sum_i (\partial G/\partial n_i)_{T,p,nj}\,dn_i \tag{4.96}$$

Since the mole numbers are constants in a closed system, the first two partial derivatives in Equation (4.96) are identical to the respective partial derivatives for the system if closed. Reference to Equation (4.88) shows

$$(\partial G/\partial T)_{p,ni} = -S \tag{4.97}$$

$$(\partial G/\partial p)_{T,ni} = V \tag{4.98}$$

Substituting back into Equation (4.96) gives

$$dG = -S\,dT + V\,dP + \sum_i \mu_i dn_i \tag{4.99}$$

where we have defined

$$\mu_i = (\partial G/\partial n_i)_{T,p,nj} \tag{4.100}$$

The constancy of T and p in the partial derivative identifies μ_i as the partial molar Gibbs energy. Because of its key importance in phase equilibrium and chemical equilibrium, μ is given the name chemical potential.

The other energy functions are related to G by

$$G = A + pV = H - TS = U + pV - TS \tag{4.101}$$

Differentiation of Equation (4.101) and combination with Equation (4.99) gives

$$dU = T\,dS - p\,dV + \sum_i \mu_i dn_i \tag{4.102}$$

$$dH = T\,dS + V\,dp + \sum_i \mu_i dn_i \tag{4.103}$$

$$dA = -S\,dT - p\,dV + \sum_i \mu_i dn_i \tag{4.104}$$

$$dG = -S\,dT + V\,dp + \sum_i \mu_i dn_i \tag{4.105}$$

These four equations complete the Gibbs fundamental forms. It follows from these equations that μ_i is also the partial mole number derivative of U, H, or A in addition to that of G,

$$\mu_i = (\partial U / \partial n_i)_{S,V,nj} = (\partial H / \partial n_i)_{S,p,nj} = (\partial A / \partial n_i)_{T,V,nj} \tag{4.106}$$

However, the partial differentiations here are not at constant T and p; consequently, μ_i is not partial molar U, nor partial molar H, nor partial molar A. The conditions of the partial differentiation for U and H cannot be physically interpreted, making the partial derivatives of U and H of little interest for the description of real systems. But the partial differentiation of A is at a physically meaningful condition that makes the partial derivative useful for the calculation of chemical potential.

Chemical potential plays a fundamental role in phase and chemical equilibria. Consider a heterogeneous system at a constant T and p consisting of a number of phases that are open and are at equilibrium with respect to one another. The chemical potential, like any intensive property, must assume a uniform value in any phase because each phase is at equilibrium. The chemical potential is the same value in different phases at equilibrium, so that diffusional mass transfer does not take place between the phases. Consider the transport of dn_i, moles of i from phase α of higher μ_i to phase β of lower μ_i. The change of G is

$$dG = [(\partial G_\beta / \partial n_i)_{T,p,nj} - (\partial G_\alpha / \partial n_i)_{T,p,nj}]dn_i \tag{4.107}$$

$$= [\mu_{\beta,i} - \mu_{\beta,i}]dn_i \tag{4.108}$$

showing that $dG < 0$. By equilibrium criterion V, a system at constant T and p seeks equilibrium by decreasing G. Mass transfer then occurs, and the system is not at equilibrium. For the phases to be at equilibrium, $dG = 0$, it is necessary that $\mu_{\alpha,1} = \mu_{\beta,1}$. Therefore, the condition of phase equilibrium is expressed by

$$T_\alpha = T_\beta = \ldots \quad \text{for all phases} \tag{4.109}$$

$$p_\alpha = p_\beta = \ldots \quad \text{for all phases} \tag{4.110}$$

$$\mu_{\alpha,1} = \mu_{\beta,1} = \ldots \quad \text{for all phases} \tag{4.111}$$

$$\mu_{\alpha,2} = \mu_{\beta,2} = \ldots \quad \text{for all phases} \tag{4.112}$$

for all chemical species.

These equations are the basis for phase equilibrium. To develop methods of calculation of phase equilibrium on this basis, efforts will be made in two stages:

1. Transforming chemical potential to a more convenient quantity, called fugacity, as the measure of equilibrium; and learning how fugacity depends on the species and state of the mixture. These are the subjects of Sections 4.2 and 4.3.
2. Searching for the state at which the fugacities are matched in between the phases while satisfying the specified conditions of temperature, pressure, moles, enthalpy, or other factors. This is the subject of Section 4.4.

Gibbs developed the fundamental criterion of chemical equilibrium in terms of chemical potentials. Consider a chemical reaction in the general form

$$\sum_i \nu_i M_i = 0 \tag{4.113}$$

where ν_i denotes the stoichiometric coefficient of species i in the reaction, and M_i is the molecular formula. By usual convention, ν_i is positive for the products and negative for the reactants. The stoichiometry of the reaction is expressed by

$$dn_i / \nu_i = d\xi \quad \text{for all } i \tag{4.114}$$

where ξ is the degree of advancement or extent of the reaction. All mole number changes can be expressed in terms of ξ, from Equation (4.114),

$$dn_i = \nu_i d\xi \quad \text{for all } i \tag{4.115}$$

For the reaction at constant T and V to be at equilibrium, by criterion V, Helmholtz energy must be at a minimum, $dA = 0$,

$$dA = -SdT - pdV + \sum_i \mu_\iota dn_i \tag{4.116}$$

$$= \left(\sum_i \mu_\iota \nu_i \right) d\xi \tag{4.117}$$

$$= 0 \tag{4.118}$$

Since $d\xi$ is arbitrary, Equation (4.117) requires

$$\sum_i \mu_i \nu_i = 0 \tag{4.119}$$

Hence the sum of chemical potentials of the reactants must balance the sum of the products.

By considering the reaction system at constant T and p, and equilibrium criterion V, $dG = 0$, one arrives at the same conclusion that Equation (4.119) is the condition of chemical reaction equilibrium.

Equation (4.119) is the fundamental equation of chemical equilibrium. To make progress toward a useful description of chemical equilibrium, efforts are required in two stages:

1. Replace chemical potential with fugacity and find out how fugacity depends on the species and the state of the mixture. This the subject of Sections 4.2 and 4.3.
2. Search for the state at which the fugacities satisfy the criterion of chemical equilibrium while meeting the specified conditions of temperature, pressure, moles, enthalpy, or other factors. This is the subject of Section 4.5.

4.1.7 Partial Molar Quantities and the Gibbs-Duhem Relation

The fundamental differential form for Gibbs energy can be integrated to express Gibbs energy as a sum of contributions by the components. From Equation (4.99),

$$dG = -SdT + Vdp + \sum_i (\partial G / \partial n_i)_{T,p,nj} dn_i \tag{4.120}$$

upon integration at constant T, p, and composition, and thus constant μ_i,

$$G = \sum_i (\partial G / \partial n_i)_{T,p,nj} n_i = \sum_i \mu_i n_i \tag{4.121}$$

By Equation (4.121), the partial molar Gibbs energy of component i represents the contribution of i to the total Gibbs energy of the mixture.

An extensive property Y in general can be similarly represented in terms of contributions by the components. Let Y be a state function of T, p, and the mole numbers n_i: $Y(T,p,n_1,n_2,\ldots)$, where n_i denotes a mole number. The differential of Y at constant p is

$$dY = \sum_i (\partial Y / \partial n_i)_{T,p,n_j} dn_i \tag{4.122}$$

This equation is integrated at constant T, p, and composition, and thus at constant $(\partial Y/\partial n_i)_{T,p,nj}$, in a homogeneous phase to give

$$Y = \sum_i (\partial Y / \partial n_i)_{T,p,n_j} n_i = \sum_i Y_i n_i \tag{4.123}$$

where $Y_i = (\partial/\partial n_i)_{T,p,nj}$ stands for the partial molar Y of i in a homogeneous phase. Thus, for a phase,

$$U = \sum_i U_i n_i \tag{4.124}$$

$$H = \sum_i H_i n_i \tag{4.125}$$

$$A = \sum_i A_i n_i \tag{4.126}$$

$$V = \sum_i V_i n_i \tag{4.127}$$

An extensive property of a mixture is the sum of the mole number times the partial molar quantity of the components for a phase. A component in mixture exists in a partial state, assuming partial property values; it contributes to the property of the mixture by its partial value.

The partial molar quantities are not independent, but are mutually related and related to T and p by the Gibbs–Duhem equation. Starting with Gibbs energy, we differentiate Equation (4.121) to obtain

$$dG = \sum_\iota \mu_i dn_i + \sum_\iota n_i d\nu_i \tag{4.128}$$

Comparing this equation with dG of Equation (4.105), we have, for a homogeneous phase,

$$\sum_\iota n_i d\mu_i = -S\,dT + V\,dp \tag{4.129}$$

For enthalpy, we differentiate H as a state function of T, p, and n_i, i = 1,2,…,

$$dH = (dH\,/\,dT)_{p,n_i} dT + (dH\,/\,dp)_{T,n_i} dp + \sum_i H_i dn_i \tag{4.130}$$

We next diffferentiate Equation (4.125) to give

$$dH = \sum_i H_i dn_i + \sum_i n_i dH_i \tag{4.131}$$

Comparing the two equations, we have

$$\sum_i n_i dH_i = (dH\,/\,dT)_{p,n_i} dT + (dH\,/\,dp)_{T,n_i} dp \tag{4.132}$$

At constant T and p, expressing only the effect of composition change,

$$\sum_i n_i dH_i = 0 \tag{4.133}$$

The method of derivation for H is generally useful for extensive properties to relate the effect of intensive properties on partial molar properties.

Example 4.9: Heat Generated by Adding a Stream to a Tank

In a batch-feed operation, 100 mol of pure liquid is added at the rate of 2 mol/min to a tank of liquid solution initially containing 100 mol of pure A. The tank is stirred, and its contents are assumed to be thoroughly mixed and uniform in composition at all times. The tank is jacketed to provide for heat removal to keep the tank contents at a constant temperature of 300°K. The pressure is constant at 1 atm.

Find the rate of evolution of heat of dilution as a function of time from $t = 0$ to $t = 50$ min in units of kJ/min. Find the total heat evolved.

Given:

Partial Molar Enthalpy at 300

Mol % of	H_B, kJ/mol
0	–6,240
10	–17,556
20	–25,916
30	–31,768
40	–38,038
50	–43,890
60	–46,816
100	–56,430

No information is given about the partial enthalpy of A.

Solution

For the mixing process at constant pressure, the heat release is equal to the decrease in enthalpy upon mixing according to Example I.E-2. We need to find the enthalpy change of mixing. For the addition of dn moles of into the body of mixture containing n_A moles of A and n_B moles of B, the initial state enthalpy is

$$H_i = (n_A H_A + n_B H_B) + H_B^0 dn_B$$

where the superscript 0 denotes pure liquid and subscripts A or B denote a partial molar quantity of A or B, respectively. The final state enthalpy is

$$H_f = (n_A H_A + n_B H_B) + d(n_A H_A + n_B H_B)$$

The differential change of enthalpy upon mixing is

$$dH = H_f - H_i = d(n_A H_A + n_B H_B) - H_B^0 dn_B$$

$$= (H_A dn_A + n_A dH_A + n_B dH_B + H_B dn_B) - H_B^0 dn_B$$

The first term in the last equation vanishes because n_A is unchanged. The second and third terms add up to zero according to the Gibbs-Duhem equation. There is left only

$$dH = (H_B - H_B^0)\, dn_B$$

that says that only the change of state of the differential moles of B added needs to be considered. The rate of heat production is

$$Q = (H_B - H_B^0) dn_B/dt$$

Substituting the table values of H_B and H_B^0, we find a large quantity of heat is produced, like the mixing of sulfuric acid into water. The numerical calculation is left as an exercise for the reader.

The total heat evolved is given by integrating the differential heat evolution,

$$Q = \int_0 (H_B - H_B^0) dn_B$$

Even with the addition of a finite quantity of B changing the composition from pure A to 50% A, the total enthalpy change does not involve changes in the partial enthalpy of A. To verify the formula for Q, we find the total change of H with the mixing of 50 mol A and 50 mol B:

$$Q = H_{\text{total mix}} - (n_A H_A^0 + n_B H_B^0)$$

$$= (n_A H_A + n_B H_B) - (n_A H_A^0 + n_B H_B^0)$$

Let us develop the integral formula

$$Q = \int_0 (H_B - H_B^0) dn_B$$

Because H_B^0 is constant,

$$= \int_0 H_B dn_B - H_B^0 n_B$$

By partial integration,

$$= (H_B n_B)\Big|_0 - \int_0 n_B dH_B - H_B^0 n_B$$

Using Gibbs–Duhem equation for the integrand,

$$= H_B n_B + \int n_A dH_A - H_B^0 n_B$$

n_A is constant:

$$= H_B n_B + n_A H_A - n_A H_A^0 - H_B^0 n_B$$

Thus the integral is verified to agree with the total enthalpy calculation. Although only H_B is used in the integral method of calculation, information about H_A and the molar of the mixture are implied in H_B and can be explicitly revealed by integrating H_B to yield H_A, and subsequently adding the two partials to obtain the molar of the mixture.

For 1 mole of a binary mixture, in general, by the Gibbs-Duhem equation at constant and p,

$$x_A\, dH_A + xB\, dH_B = 0$$

Transporting the second term to the other side and integrating,

$$H_A - H_A^0 = -\int_0 (x_B / x_A)(dH_B / dx_B)dx_B$$

Having found H_A, the total mixture is obtained by summing,

$$= x_A H_A + x_B H_B$$

The enthalpy of the mixture becomes completely known as soon as the partial molar enthalpy of one component is determined.

4.2 VOLUMETRIC AND THERMODYNAMIC PROPERTIES

4.2.1 Pressure–Volume–Temperature Relationship

A substance can exist as a gas, liquid, or solid. The gas state exists at low pressure. Within a range of temperature, depending on the substance, as the pressure is increased at a constant temperature, the gas condenses into a liquid. At temperatures above the range, the gas stays unchanged in phase state to very high pressures. At temperatures below the range, the gas condenses upon compression directly into a solid.

Figure 4.5 shows the pressure variation with volume at various constant temperatures for a typical substance. The isotherms are ordered: the higher the temperature, the higher is the isotherm; the isotherms do not intersect. At T_1, the highest temperature shown, the substance is a gas at all pressures, and the ideal-gas law is often a good approximation. This isotherm approximates a hyperbola.

At a lower temperature T_2, the gas state exists at low pressures. As the pressure is increased to point 5 in Figure 4.5, the vapor becomes saturated and begins to condense. With further reduction of volume, more condensation occurs while the pressure stays unchanged. The intensive properties of the vapor and liquid phases remain constant until condensation is complete at point 6. At higher pressures, a compressed liquid is found that changes volume only slightly upon further compression.

At temperature T_3 lower than T_2, the low-pressure gas becomes condensed as it is compressed, just like at T_2. Upon being sufficiently compressed, the liquid begins to solidify at point 9. The pressure stays constant as volume is reduced while solidification progresses along the line segment 9 to 10 until solidification is complete at point 10. Only solid exists at higher pressure in the p–V space beyond the line f-g-h.

At temperature T_4 lower than T_3, the low-pressure gas condenses directly into a solid at a usually low pressure called the *sublimation pressure*. The condensation proceeds as volume is reduced at constant pressure until the condensation is complete at point 12. Further reduction of volume of the solid requires application of high pressure. The gas states are found in the area marked G, generally at low pressure and high temperature. Liquids are found in the area marked L, and solid states in S.

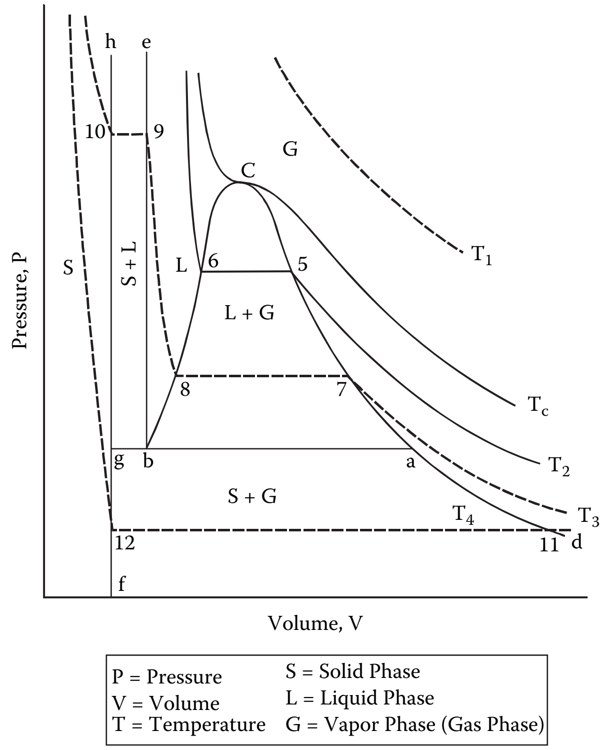

FIGURE 4.5 *p-V* diagram for pure component.

The saturated vapor states are on line c-a-d. On segment c-a, the saturated vapor condenses to a liquid "dew" as the first liquid drops appear. On segment a-d, the saturated vapor condenses into a solid "frost." The saturated liquid states are on line c-b, where the last vapor bubbles are disappearing. On line b-c, the liquid is saturated and begins forming a solid. On line g-h, the solid is imminently melting into a liquid; on line f-g, it is subliming to a vapor. Two phases coexist in three areas in Figure 4.5: liquid and gas labeled, L+G; solid and gas, labeled S+G; and solid and liquid, labeled S+L. Three phases, gas, liquid, and solid, coexist on one line: a-b-g. Temperature and pressure remain constant at the triple point, while volume may vary.

The two saturation lines—c-a representing saturated gas and c-b representing saturated liquid—meet at c, which is the highest point of the L+G two-phase area. Point c is the gas-liquid *critical state*. As temperature is increased from below to approach the critical, the flat gas-liquid coexistence segment of the isotherm shrinks to the point c at the critical temperature. The critical point is a point of inflection of the isotherm. At c,

$$\left(\frac{\partial p}{\partial V}\right)_T = 0 \tag{4.134}$$

and

$$\left(\frac{\partial^2 p}{\partial V^2}\right)_T = 0 \tag{4.135}$$

Below the critical temperature, the liquid state and gas state are clearly separated in the L+G region. The transition from one state to the other must go through a phase change, but at temperature above the critical, only one fluid state exists. A gas can become a liquid without going through a phase transition when heated to a supercritical temperature, compressed, and cooled to a subcritical temperature. Conversely, a liquid can become a gas without going through a phase change by following the reverse route. The solid state separates from the fluid states, either gas or liquid, by a phase transition. The solidification line f-g-h extends to the highest pressure that has been observed.

For a state to be mechanically stable, by Equation (4.82),

$$\left(\frac{\partial^2 A}{\partial V^2}\right)_T \geq 0 \tag{4.136}$$

By Equation (4.79), $dA = -SdT - pdV$. The coefficient of the last differential in this equation is identified as

$$\left(\frac{\partial A}{\partial V}\right)_T = -p \tag{4.137}$$

Differentiating with respect to V,

$$\left(\frac{\partial^2 A}{\partial V^2}\right)_T = -\left(\frac{\partial p}{\partial V}\right)_T \tag{4.138}$$

Comparing Equation (4.127) and Equation (4.138) shows that mechanical stability requires

$$\left(\frac{\partial p}{\partial V}\right)_T \leq 0 \tag{4.139}$$

The isotherms must have a negative or zero slope. In Figure 4.5 the slope is negative for single-phase states and zero for the two-phase states.

Figure 4.6 shows the *pVT* relationship in the *pT* plane with lines of constant volume called isochores. The isochore v_1 is a high-density line; it starts from the two-phase coexistence line of the S+L regions to enter into the liquid region, rapidly gaining pressure as temperature is increased. The isochores v_2 and v_3 are at successively larger volume or lower density; both start from the two-phase coexistence line of L+G, which is the *vapor pressure curve*, to enter into the liquid region. The slope of the isochore drops successively from v_1 to v_3. The isochores v_4 and v_5, with successively larger volume and both being larger than the critical, likewise start from the L+G coexistence line, but go into the gas region. The isochore v_6, starting from the two-phase line S+G, becomes a sublimed vapor as p and T increase; its volume is the largest shown.

Isochores with $v < v_c$ are above the L+G two-phase coexistence line; isochores with $v > v_c$ are below the line. The isochore with $v = v_c$ coincides with the L+G coexistence line over the entire range from the triple point t to the critical point c. Beyond the critical point it is a continuous extension of the coexistence line. The isochores are remarkable by their near linearity. The curvature, generally small, is the largest at states close to the two-phase line.

The S+G two-phase coexistence line, or the *sublimation pressure curve*, *f-t*, starts from the triple-point t to proceed downward toward the left. The S+L two-phase coexistence line, *t-h*, is the *melting point curve*. Typically the melting temperature is higher at elevated pressure, as shown in

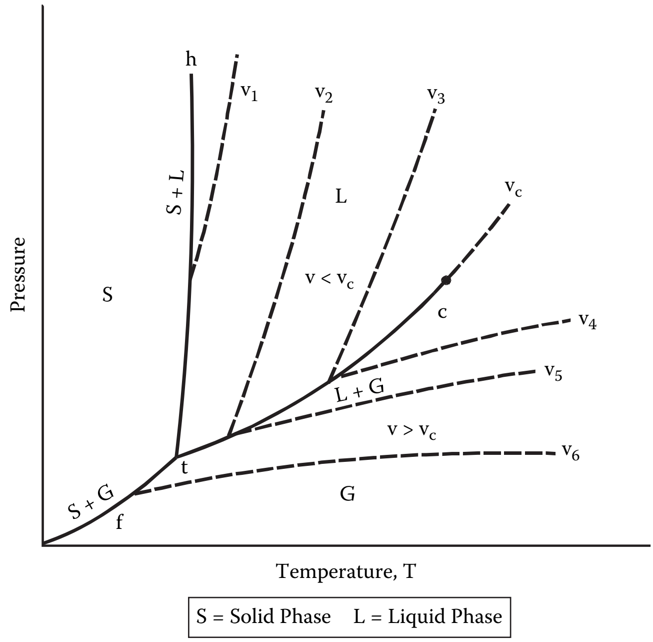

FIGURE 4.6 *T* diagram for pure component.

Figure 4.6. An important exception is found with water; its melting temperature is lowered as pressure is raised. The melting curve extends without limit in the direction of high pressure. All three two-phase coexistence curves—the S+G, S+L, and L+G—meet at the triple point where the three phases S, L, and G coexist.

4.2.2 Principle of Corresponding States

The experimentally observed similarity of the pressure-volume-temperature behavior of many fluids can be represented by the principle of corresponding states (PCS), according to which various substances behave in the same way when expressed on suitable reduced scales. Thus the *pVT* surfaces of different substances superimpose upon reduction with appropriate scale factors. The reducing scale factors commonly employed are the properties of the fluid at a singular point such as the critical point. On the reduced scale, one general *pVT* relationship is followed by a number of substances, i.e., p_r is the same function of T_r and v_r, where the subscript *r* denotes a reduced dimensionless quantity and the subscript *c* the quantity at the critical point:

$$P_r = p/p_c \tag{4.140}$$

$$T_r = T/T_c \tag{4.141}$$

$$v_r = v/v_c \tag{4.142}$$

For practical calculations, the *pVT* relationship is conveniently expressed in a compressibility-factor *z* chart, where $z \equiv pv/RT$. Figure 4.7 shows *z* as a function of p_r at various T_r. This figure well represents the simple fluids Ar, Kr, and Xe, but is at best an approximate for other fluids.

For an ideal gas, $z = 1$. All real-fluid isotherms approach $z = 1$ as $p_r \to 0$. The high T_r isotherms are close to being horizontal and stay close to the line $z = 1$ at all values of p_r. This is the behavior of common gases such as air, hydrogen, and helium at ambient and higher temperatures. As T_r

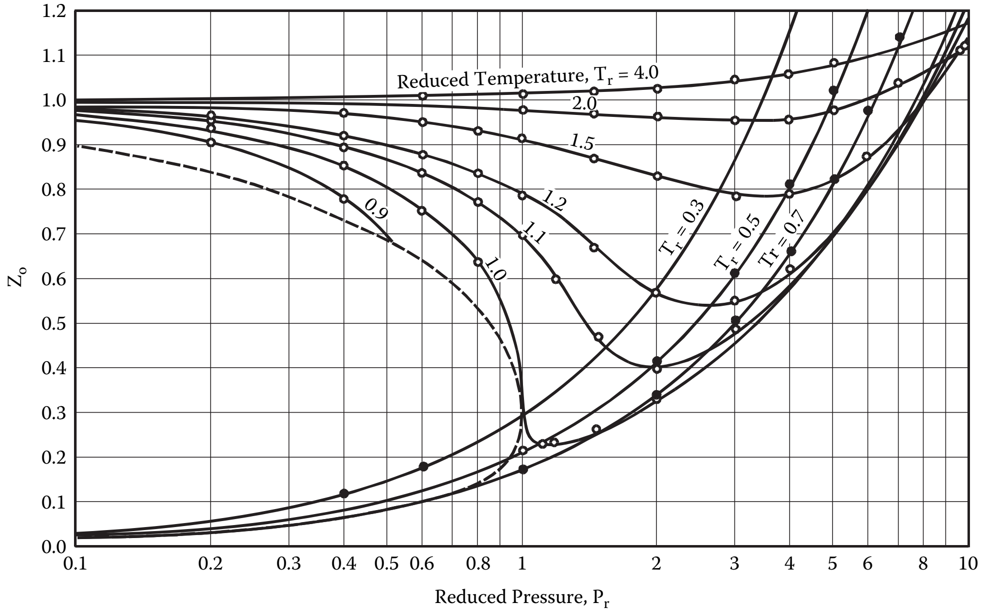

FIGURE 4.7 z_o for simple fluids. (From Lee, B. I., and Kesler, M. *AIChE J.* 21: 510–527, 1975. With permission.)

decreases, the isotherms become lower. At the Boyle point, the isotherm becomes horizontal at p_r = 0, which defines the Boyle point. Below the Boyle point, the isotherms approach p_r = 0 with a negative slope. Until the temperature is lowered to T_r = 1, the isotherms are continuous from p_r = 0 to high pressure. Below T_r = 1, the isotherms extends smoothly from p_r = 0 only to the point of saturation of the vapor, where it descends vertically at a constant pressure until it reaches the saturated liquid state. Increase of pressure beyond the vapor pressure sends the isotherm up steadily due to the small compressibility of the liquid, eventually to large values of z.

To extend the PCS correlation to fluids other than the simple fluids, it is observed that deviation from the PCS correlation of the simple fluids occurs in a systematic way, depending on the shape, size, and chemical nature of the molecule. A prominent example is the reduced vapor pressure p_{rs} as a function of the reduced temperature T_r. Although it is almost exactly the same function for the three simple fluids, the reduced-vapor-pressure lines of other substances are lower with more elongated or more polar molecules. Pitzer and Brewer [1] adopt the lowering of the reduced-vapor-pressure curve of a substance from that of the simple fluids as the basis for defining a parameter to extend the PCS correlation to substances other than simple fluids. At the reduced temperature of 0.7, the reduced vapor pressure of simple fluids equals 0.1 and –log p_{rs} = 1. Taking the difference at T_r = 0.7 between the (–log p_{rs}) of a substance and that of the simple fluids, Pitzer and Brewer defined the acentric factor

$$\omega \equiv (-\log p_{rs}) - 1 \tag{4.143}$$

The minus value of log p_{rs} is used to make it a positive number. The lower the reduced-vapor-pressure curve of a substance, the larger is the positive value –log p_{rs} and, hence, the larger ω for the substance. The acentric factor is zero for the simple fluids and increases as the molecules are more nonspherical or more polar.

With the use of ω as the third parameter (in addition to T_c and p_c), the pVT relationship of nonpolar and weakly polar substances, called normal fluids, is correlated on the basis of PCS by extending the z correlation of simple fluids according to

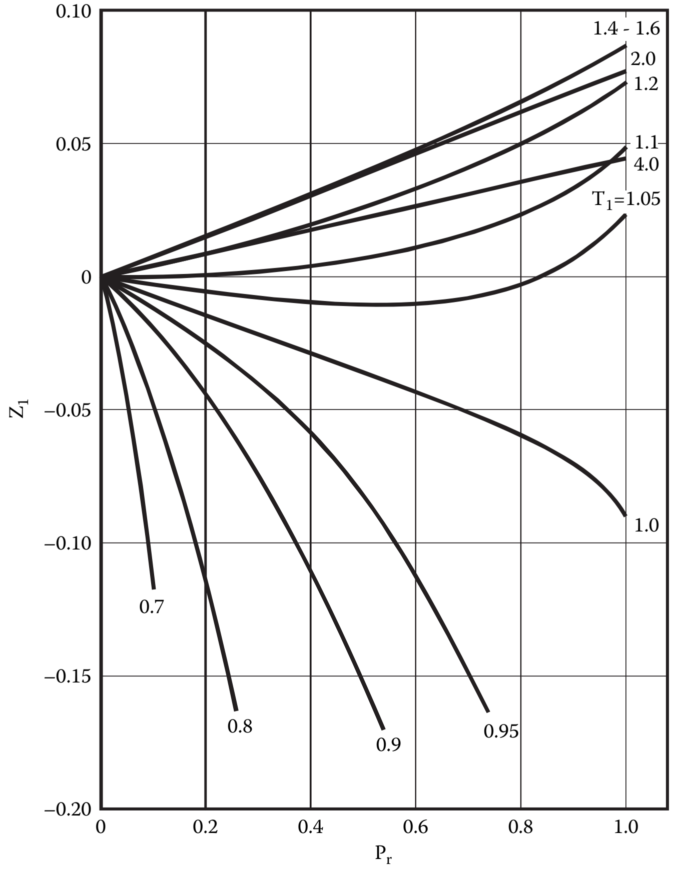

FIGURE 4.8 z_1 for normal fluids at $p_r < 1$. (From Lee, B. I., and Kesler, M. *AIChE J.* 21: 510–527, 1975. With permission.)

$$z\ [T_r,p_r] = z_0[T_r,p_r] + \omega z_1[T_r,p_r] \tag{4.144}$$

where z_0 is the generalized compressibility factor of simple fluids, and z_1 is the generalized correction function for normal fluids The square brackets indicate the independent variables. Figure 4.7 presents z_0; Figure 4.8, z_1 for $p_r < 1$; and Figure 4.9, z_1 for $p_r > 1$.

Normal fluids are hydrocarbons, ethers, esters, and many organic halides. Strongly hydrogen-bonded substances like water, acetic acid, and hydrogen fluoride are not normal fluids; neither are quantum fluids like helium and hydrogen. Lee and Kesler [2] developed an equation to represent the three-parameter generalized correlation. The equation is presented in Section 4.2.5, entitled "Equations of State." Figures 4.7, 4.8, and 4.9 are based on the Lee and Kesler equation.

Example 4.10

Find the Density of Compressed Methane at 300 and 68 atm

Solution

From Chapter 1 ("Physical and Chemical Properties"), we obtain for methane:

$$T_c = 190.7°\text{K},\ p_c = 45.8\ \text{atm},\ \omega = 0.013.$$

The reduced variables are found: $T_r = 300/190.7 = 1.573$ and $p_r = 68/45.8 = 1.49$. From Figure 4.8, $z_0 = 0.89$. From Figure 4.9, $z_1 = 0.14$. By Equation (4.144), $z = 0.89 + (0.013)(0.14) = 0.892$ and

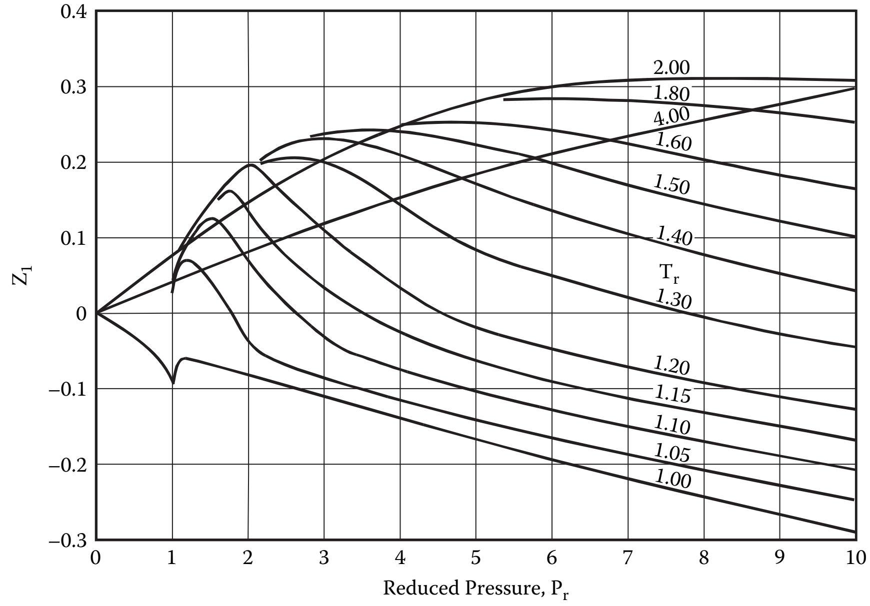

FIGURE 4.9 z_1 for normal fluids at $p_r > 1$. (From Lee, B. I., and Kesler, M. *AIChE J.* 21: 510–527, 1975. With permission..

$$\nu = zRT/p = (0.892)(82.0)(300)/68 = 323 \text{ cm}^3/\text{mol} = 20.2 \text{ cm}^3/\text{gm}$$

For methane, ω is small, and the correction from z_0 is small.

4.2.3 Phase Rule

The phase rule due to J. Willard Gibbs gives the number of intensive variables that can be specified to completely fix the intensive state of a system at heterogeneous phase equilibrium. The number of intensive variables that can be specified is called the degree of freedom *F*. Experience tells us that for a given material existing as a one-phase gas, liquid, or solid, it requires two intensive variables to be specified, for example *T* and *p*, or *T* and ρ, to fix the intensive state of the system; thus $F = 2$. But for a pure substance, for instance steam and liquid water, to coexist in two equilibrium phases, only one intensive variable can be specified, for example *T* or *p*. By fixing the temperature, the pressure is fixed at the vapor pressure, and all intensive properties of the coexisting vapor or liquid, such as the density of the vapor, density of the liquid, etc., are all fixed; thus $F = 1$.

To find the degree of freedom in general for a system consisting of *C* components coexisting in *P* phases, Gibbs considered the conditions of the phases in coexistence, Equations (4.145) to (4.147). There are in total $(2 + C)(P - 1)$ equations. For each phase there are $2 + (C - 1)$ independent variables, e.g., *p*, and $(C - 1)$ compositions variables, adding up for the *P* phases to a total number of $P(2 + C - 1)$. How many independent variables can be specified for the equations to have a solution? The answer is: the number of variables minus the number of equations,

$$F = P(2 + C - 1) - (2 + C)(P - 1) \tag{4.145}$$

or

$$F = C - P + 2 \tag{4.146}$$

Equation (4.146) expresses the *Gibbs phase rule* in the absence of chemical reactions, surface effects, or membrane partitions. It is the most used form of the phase rule.

For a chemically reacting system at reaction equilibrium, the chemical potentials of the reactants are related by the equilibrium equations, Equation (4.119), there being one such equation for each independent reaction. The number of equations governing the chemical potentials is increased by the number of independent reactions R, correspondingly reducing the degree of freedom by R. The phase rule for reacting systems is, therefore,

$$F = C - P + 2 - R \tag{4.147}$$

The phase behavior of a one-component system will illustrate the phase rule. In the pT diagram of Figure 4.6, the single-phase states are in the areas labeled G, L, or S, representing gas, liquid, or solid, respectively. By Equation (4.146), $F = C - P + 2 = 1 - 1 + 2 = 2$. There are two degrees of freedom, e.g., T and p, or T and ρ. Specifying two intensive variables completely fixed the intensive state of the phase.

There is one degree of freedom on a two-phase coexistence line, L+G, S+L, or S+G in Figure 4.6. Specifying T or p of both phases, or ρ of one of the phases, completely fixed the intensive states of both phases at the triple point (point t), where the three phases (G, L, S) are in coexistence; then $F = C - P + 2$ with zero degrees of freedom.

4.2.4 Phase Behavior of Mixtures

The phase behavior of single-component systems has been discussed as part of the pVT relationship presented in Section 4.2.1. Examining the phase behavior of mixtures, we observe that, with mixtures, phase behavior remains one facet of the pVT relationship. But a new phenomenon is encountered with mixtures: phases at equilibrium are generally of different compositions. These mixtures show a great variety of phase behavior that can often be exploited to make separations. We examine in broad terms the qualitative features of the phase behavior of binary mixtures of various types. Experience has shown a wealth of phenomena displayed by binary mixtures.

We start with gas-liquid equilibrium (gle). For simple mixtures of similar components, gas-liquid coexistence states are observed at a wide range of T and p that are bounded at the high-temperature side by the critical states and at the low-temperature side by the formation of solids. In mixtures of large difference in molecular attractive forces, liquid immiscibility takes place. On the high-temperature side, liquid-liquid equilibrium (lle) either merges into gas-liquid equilibrium (gle) or becomes bounded by separate critical states. With extremely dissimilar molecules, the liquid-liquid coexistence phenomenon persists without limit to high temperature, where it turns into gas-gas equilibrium (gge).

4.2.4.1 Gas-Liquid Equilibrium

A simple case of gas-liquid equilibrium is shown in Figure 4.10. The dashed lines on the planes of $x_B = 0$ and $x_B = 1$ are the vapor pressure curves of the components A and B. The curves end up at the critical points C_A and C_B. Two-phase border loops are shown at T_1 and T_2. The upper branch of a loop is the *bubble-point curve*, upon which are the states of imminent formation of gas bubbles. Above the bubble point, only liquid exists. The lower branch is the *dew-point curve*, or the states of imminent formation of a liquid dew. Below the dew point, only gas exists. Enclosed within the loop are the states at heterogeneous phase coexistence. A pair of coexisting phases at equilibrium are located at the end points of a horizontal line segment in the loop. To illustrate, one such segment in the loop T_1 is shown to have one end point 3 on the dew-point curve and the other end point f on the bubble-point curve. A mixture at point g is at a heterogeneous coexistence state, and is made

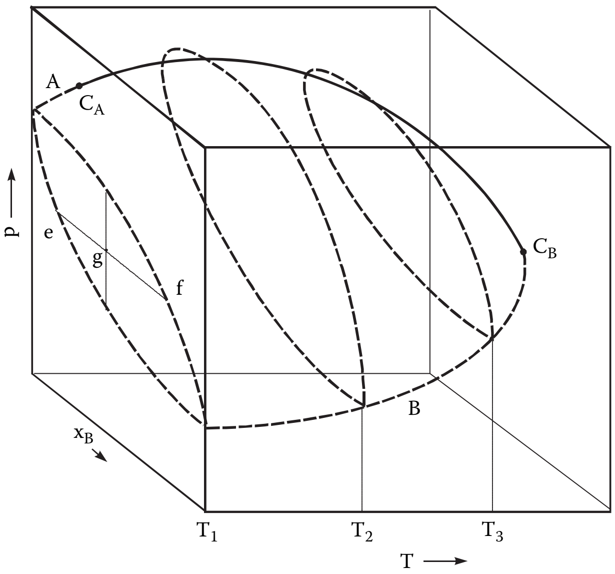

FIGURE 4.10 Gas-liquid equilibria of a binary system.

up of a phase at *e* and another phase at *f*, both phases being at different compositions. The total composition of the two phases is represented by *g*.

More than one phase border loop exists at one temperature for some mixtures of components of greater disparity. Figure 4.11 shows the isothermal gle of n-heptane + ethanol at 313° and 333°K. Two connected loops occur at each temperature. Both branches of the lower curves are dew-point states; the upper curve, bubble-point states. The dew state and bubble state on the same branch of the saturation loop and at the same T and p are at phase equilibrium. To illustrate, two phases are at equilibrium at 313°K and 20 kPa and also at 333° and 50 kPa. All four pairs are shown with dashed line segments.

At the connection point of the two saturation loops, the gas and the liquid at equilibrium are of the same composition but different densities. The mixture of equal gas and liquid composition is called an azeotrope. The azeotrope composition changes with p and T. It is a minimum boiling azeotrope when boiling occurs at a temperature less than those of the two components. Maximum boiling azeotropes are also found, though not as often.

To examine gle at elevated pressures we return to Figure 4.10. At T_1, which is below the critical temperature of both A and B, the bubble- and dew-point curves both start at the low-pressure end at the vapor pressure of B, which is the less volatile component. At higher pressure, the two curves diverge and finally both end at the vapor pressure of A, the more volatile component. At T_2, which is between the critical temperatures of A and B, the bubble- and dew-point curves at the low-pressure end still start at the vapor pressure of B, but at the higher-pressure side they meet at the mixture critical state. The critical points of mixtures of varying composition form the *mixture critical loci*, a space curve that connects the critical states of A and B.

Unusual behavior is observed even for simple mixtures in the near critical region. Depending on the relative location of the critical state, the vaporization-condensation process in the near critical region known as *retrograde condensation* occurs, and two dew points are found on the constant-pressure line. Between the dew points is a point of maximum condensation. Thus heating the fluid causes a liquid to appear, to increase to a maximum, then to decrease, and finally to disappear. Cooling the fluid along the same line produces the opposite sequence of events. The phenomenon is also often observed upon expanding or compressing the fluid at a constant temperature; it is called *retrograde condensation of the first kind*. In contrast, *Retrograde condensation of the second*

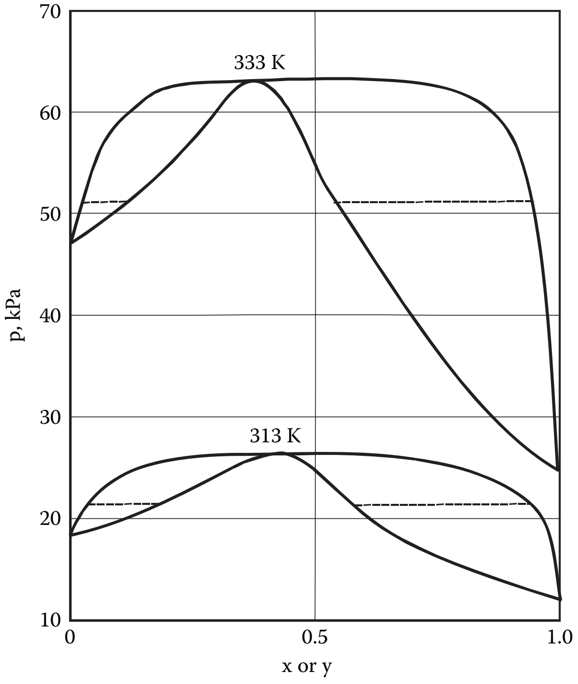

FIGURE 4.11 A maximum-pressure azeotrope.

kind is when a vapor phase first appears, increases to maximum, and then decreases. The retrograde phenomenon is employed in natural gas engineering for the recovery of condensables from a high-pressure natural gas. The maximum recovery is obtained by separating the phases after a suitable expansion from the high underground pressure.

The critical loci of mixture systems are of much interest because they define the boundary in *pT* space for light alkanes. They are approximately parabolic, connecting the critical points of the pure components and rising to a point of maximum pressure in between. This simple behavior is observed for binary mixtures of light n-paraffins, including methane and a C_2–C_5 paraffin, ethane and C_3–C_{18} n-paraffin, and propane and some other n-paraffins. For mixtures of greater difference in molecular sizes or attractive forces, the critical loci are more complex due to the formation of solids or immiscible liquids that terminate the critical locus.

4.2.4.2 Liquid-Liquid Equilibrium

Many liquids are only partially miscible. Two liquid phases are formed when the two pure liquids are brought together in some proportions. Figure 4.12 shows the T–X diagram of a mixture at low pressures (and lower temperatures). According to the phase rule, for a binary system the degree of freedom F is equal to $(4 - P)$, where P is the number of phases. If we consider two liquid phases coexisting, $F = 2$. At a fixed pressure P_1, we can fix the temperature to completely determine the intensive state of the two-phase system. Thus the saturated liquid compositions are functions of T only. If component A is the less volatile and B the more volatile, the boiling point of A at P_1 is T_g; the boiling point of B is T_h; and $T_g > T_h$. The boiling point of the two-liquid heterogeneous mixture is T_i and is a fixed point at P_1 with $F = 0$, as three phases, two liquids, and a gas are in coexistence.

The figure shows that at P_1, lle can exist at $T < T_i$; at $T > T_i$, lle cannot exist, but is replaced by gle until $T = T_g$. Three phases can coexist at T_i for mixtures with total composition in the range $x_B > x > x_A$. At $T > T_g$, only gas can be found. For the phase behavior of this mixture at higher pressures, the L+G area of P_2 is evolved from the combination of L_A+G and L_B+G areas at P_1. The

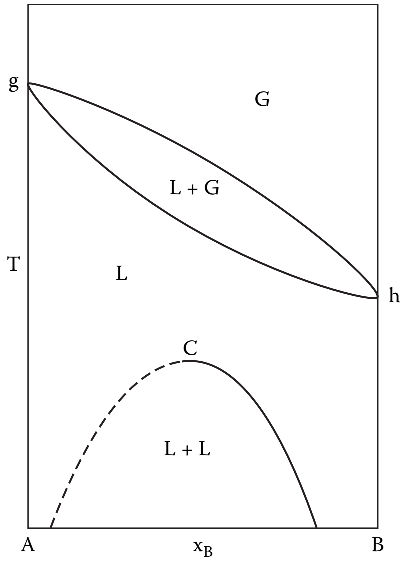

FIGURE 4.12 T–X diagram of an lle and gle system at a low pressure.

L+L area at P_2 is evolved from the L_A+L_B area at P_1. While the L+G areas and the L+L area are contiguous in P_1, the L+G and L+L areas are separated at P_2. Since the L+G area at P_2 touches both coordinates $x = 0$ and $x = 1$, P_2 is below the critical pressures of both A and B. At P_2, T_g is the boiling point of A and T_h is that of B. A liquid-liquid critical point appears at P_2, located at the peak of the L+L region. Since the two-phase region is located below it, this critical temperature is called an upper critical solution temperature, UCST. This temperature changes with T, p, and x to form a curve similar to the gl critical loci. The vapor pressure curves of A and B are similar to the gl critical loci. These curves terminate at the critical points at high p and T; the gle space is bounded by the critical loci. For some systems, even solidification of the heavier component occurs. As an example, Figure 4.13 shows such solidification and the formation of a quaternary point for mixtures of methane and n-heptane at high pressures.

4.2.4.3 Gas-Gas Equilibrium

Gas-gas equilibrium refers to the fluid-phase equilibrium that exists at high temperature and very high pressures above the critical points of the components and that persists to ever higher temperature and pressure apparently without limit. The occurrence of gge in mixtures follows the breakup of the gle critical locus and the merging of one branch of the broken gle critical loci with the UCST. The other branch of the critical locus, unhinged from the critical point of the light component, becomes free to move up to ever higher temperature and pressure. As an example, helium-nitrogen mixtures show such behavior. These are two branches of the saturation loop that intersect on the vapor-pressure curve of nitrogen. Above the T_c of helium, there is no intersection on the other composition axis. At a higher temperature T_2, the loop develops a pinch, indicating a maximum mutual solubility at the pinch pressure. The pinch tightens with increasing temperature until at T_3 the pinch is complete, and the saturation loop divides into two branches with a critical state located on each. The locus of critical states at the lower branches is connected to the critical point of nitrogen. The upper branch with its critical state proceeds to ever higher temperatures. The saturation loops of the upper branch are all open-ended at the top and remain open to the highest pressures explored. The openness is displayed by many systems of weak interaction between the unlike components, notably water + hydrocarbons.

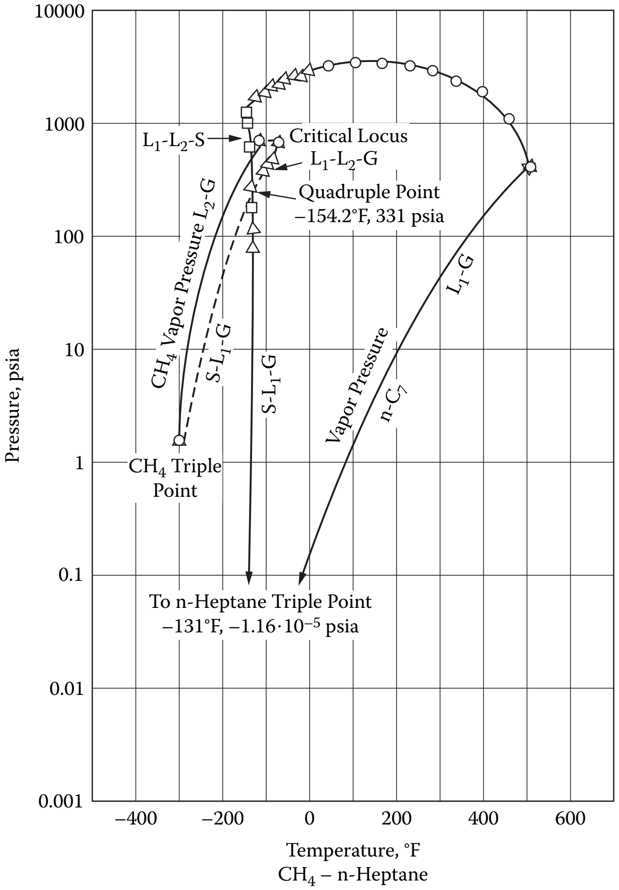

FIGURE 4.13 *pT* diagram of methane + n-heptane system. (From Chang, H. L., Hurt, L. J., and Kobayashi, R. *AIChE J.* 12: 1212,1966. With permission.)

4.2.5 Equations of State

An equation of state (eos) is an algebraic expression of the pressure-volume-temperature relationship of a substance. A good equation of state faithfully represents the isotherms, the isochores, and the generalized correlation previously presented. The algebraic form makes it convenient to derive formulas for the energy functions and other thermodynamic properties. The derived formulas together with the equation of state are useful for calculating properties of pure fluids and mixtures, for example, density of gas or liquid, vapor pressure, vapor-liquid equilibrium (vle), liquid-liquid equilibrium (lle), enthalpy, and entropy. Here we review some of the more important eos's. A more extensive review of equations of state can be found in Walas [3] and Sandler et al. [4]. Most belong to one of three types:

1. Van der Waals equations
2. Perturbation equations
3. Virial and extended virial equations

4.2.5.1 Van der Waals-Type Equations

The van der Waals (vdW) equation of state (eos) is as follows:

$$p = \frac{RT}{v-b} - \frac{a}{v^2} \tag{4.148}$$

Pressure is expressed as the difference between a repulsive pressure (the first term on the right-hand side) and an attractive pressure (the second term). The repulsive pressure is due to the forces of molecules that resist overlapping of volumes of different molecules. The volume open and free for molecular motion, called free volume, is reduced from the bulk fluid volume. In the vdW eos, the free volume is expressed by $(v - b)$, where b is the "excluded volume" representing the volume that is unavailable to molecular motion due to the molecular hard cores. For the collision between two molecules assumed to be spherical, the excluded volume is a sphere at the center of either of the colliding molecules and of a radius equal to the sum of the radii of both molecules in contact, i.e., the diameter of the molecules D. There being only one excluded spherical volume for each two molecules in collision, the total excluded volume of a fluid of N molecules is $(N/2)(4/3)(\pi D)^3$. The volume of the hard cores of the molecules v_b is $N(4/3)\pi R^3$, where R is the radius of a molecule. Therefore, the excluded volume is four times the hard core volume of the molecules:

$$b = 4v_b \tag{4.149}$$

In the vdW eos, the excluded volume is a constant independent of density. Taking out the excluded volume as being unavailable for molecular motion, the volume in the ideal-gas equation is replaced by the free volume to form the repulsive pressure $RT/(v - b)$ of Equation (4.148). The attractive pressure $-a/v^2$ in the vdW eos arises from the attraction between molecules in proximity. Since the frequency of encounter of molecules in pairs is proportional to the concentration of molecules squared, the attractive pressure is given by the inverse of the volume squared. The negative sign indicates that the attractive force contributes to a reduction of pressure.

In the vdW eos, two parameters a and b are specific for each substance. These are determined by fitting the equation to experimental data, including the critical state. Upon applying the critical conditions, Equation (4.134) and Equation (4.135), to the eos and solving for a and b from the two resulting equations, we obtain

$$a = 27R^2T_c^2/(64p_c) \tag{4.150}$$

$$b = RT_c/(8p_c) \tag{4.151}$$

The vdW eos is reducible to a dimensionless form when Equation (4.150) and Equation (4.151) are substituted into Equation (4.149). The reduction gives

$$p_r = \frac{8T_r}{3v_r - 1} - \frac{3}{v_r^2} \tag{4.152}$$

The vdW eos is the first to describe the phenomena of condensation/vaporization, vapor pressure, and critical state. Although only qualitative, it often gives more reliable answers than many complex equations.

With mixtures, the parameters a and b need to represent the effect of molecular encounters, two molecules at a time. For pure fluids, encounters are between molecules of the same kind. In a mixture, the probability of finding a molecule i at a position is x_i; the probability of finding a molecule j at the proximity is x_j. The probability of finding both i and j in the proximity is the product of the two independent probabilities, x_ix_j, assuming no correlation. This is the probability

of an encounter of species i and j, which is the probability of a_{ij} being produced, where a_{ij} is the a of ij interaction. The a of the mixture is the sum of the a_{ij}'s produced by binary encounters of all species,

$$a = \sum_i \sum_j x_i x_j a_{ij} \tag{4.153}$$

where the summation is over all molecular specifics in the mixture. Similarly, we have for b of the mixture,

$$b = \sum_i \sum_j x_i x_j b_{ij} \tag{4.154}$$

A parameter with indices that are identical is just the pure-component parameter, i.e., $a_{ii} \equiv a_i$ and $b_{ii} \equiv b_i$. The a_{ij} with $i \neq j$ is a cross-interaction parameter, and is found only in mixtures containing i and j, but never in a pure substance. Since a expresses the effect of intermolecular attractive energy, for similar molecules i and j, a_{ij} is approximated by the geometric mean of a_{ii} and a_{jj} in analogy to the London dispersion energy. But the geometric mean becomes worse as the i and j molecules become more dissimilar. It is generally useful to represent a_{ij} by

$$a_{ij} = (1 - k_{ij})\sqrt{a_i a_j} \tag{4.155}$$

where k_{ij} is an adjustable mixture parameter that is nearly vanishing for similar substances i and j but becomes significantly different from zero for highly dissimilar molecules. Values of k_{ij} can be determined by referring to mixture data and have been reported for many pairs of substances [5].

Assuming molecular hard cores to be spheres, we obtain the cross-interaction parameter b_{ij} of Equation (4.154),

$$b_{ij}^{1/3} = (b_i^{1/3} + b_j^{1/3})/2 \tag{4.156}$$

But the simpler formula is widely adopted as an approximation:

$$b_{ij} = (b_i + b_j)/2 \tag{4.157}$$

Substituting Equation (4.157) into Equation (4.154) leads to the linear mixing rule for b:

$$b = \sum_i x_i b_i \tag{4.158}$$

The mixing rules described above for vdW eos's, known as van der Waals one-fluid mixing rules, or simply van der Waals mixing rules, apply as well to the *vdW-type* cubic equations described next.

The van der Waals one-fluid mixing rules work well, yielding good results for most mixtures of nonpolar and weakly polar substances. However, for strongly polar molecules, associating molecules, and molecules with specific interaction, the vdW mixing rules are unreliable. The free-energy-matching mixing rules have been developed from theory of solutions for molecules that strongly correlate. Refer to Section 4.3.5 for discussion.

The fundamental assumption of the vdW eos is that the intermolecular force is separated into repulsive and attractive pressures. The separate representation of the repulsive and attractive forces is maintained in the vdW-type eos and the perturbation equations, but is dropped in the virial equations and the extended virial equations.

Redlich and Kwong (RK) [6] changed the vdW eos as follows:

$$p = \frac{RT}{v-b} - \frac{a}{T^{0.5} v(v+b)} \tag{4.159}$$

When the constants a and b are fitted to the critical temperature and pressure, they are given by

$$a = 0.42747R\ \ 2T_c^{2.5} / p_c \tag{4.160}$$

$$b = 0.08664\, RT_c / p_c \tag{4.161}$$

One change made by RK is to introduce the factor $1/T^{0.5}$ into the attractive pressure, in essence making the vdW attractive-pressure parameter α a decreasing function of temperature. The second change is to replace the v^2 with $v(v + b)$, opening the possibility of replacing v^2 with a second-degree polynomial of v. The repulsive pressure is left unchanged. Thus the RK equation gives improved representation of the gas state, including the second virial coefficient, the fugacity of vapors up to the vapor pressure, and fugacity of gases up to high pressures. But it is of no help for liquid states.

Wilson [7] correlated the vapor pressure of normal fluids to obtain a modified RK eos as follows:

$$p = \frac{RT}{v-b} - \alpha \frac{a_c}{v(v+b)} \tag{4.162}$$

where a_c and b are constants determined at the critical state. The new factor is introduced as a function of reduced temperature,

$$a = T_r[1 - (1.57 + 1.62\omega)(1/T_r - 1)] \tag{4.163}$$

where ω is Pitzer's acentric factor, as defined in Equation (4.143). Equation (4.163) is obtained by fitting α to vapor pressure of various substances at various temperatures and correlating the fitted values. Although Wilson's equation does not accurately fit vapor pressure, it is the key to the success of eos for the accurate representation of the chemical potential of liquids and, in consequence, other energy functions of liquids and vapor-liquid equilibrium.

Soave [8] retained the form of the Wilson eos, Equation (4.162), but developed a new function to fit vapor pressure,

$$\alpha = [1 + (0.480 + 1.574\omega - 0.176\omega^2)(1 - T_r^{0.5})]^2 \tag{4.164}$$

The equation, referred as the SRK eos, gives quantitative fitting of vapor pressure, good representation of the fugacity of liquid, and improved representation of the energy functions of liquid for normal fluids, although liquid density is not well represented. The equation was the first to be widely used for both the gas and liquid phases and, hence, for gas-liquid equilibrium in engineering calculations.

In the Peng and Robinson (PR) [9] eos, the volume dependence of the attractive pressure is changed as follows:

$$p = \frac{RT}{v-b} - \alpha \frac{a_c}{v(v+b) = b(v+b)} \quad (4.165)$$

The a and b are fitted to critical temperature and pressure to give

$$a_c = 0.45724\, R^2 T_c^2 / p_c \quad (4.166)$$

$$b = 0.07780\, RT_c / p_c \quad (4.167)$$

The functional form of Soave's α is retained, but the fitting coefficients of the terms are adjusted,

$$\alpha = [1 + (0.37464 + 1.54226\omega - 0.26992\omega^2)(1 - T_r^{0.5})]^2 \quad (4.168)$$

These changes result in improvement in the liquid molar volume while retaining the good representation of fugacity and energy functions of the liquid state for normal fluids.

The SRK and PR equations follow the principle of corresponding states in the three-parameter form; only the commonly available critical properties T_c, p_c, and ω are required to apply the equation to a substance. The simple vdW mixing rules work well with these equations. Hence they are widely used for the calculation of vapor-liquid equilibrium in mixtures.

The PR eos has been extended by Stryjek and Vera [10] to polar substances by introducing a substance-specific parameter. The modification also gives improved fitting of the vapor pressure of normal fluids. The function of the PRSV equation is given by

$$\alpha = [1 + \kappa(1 - T_r^{0.5})]^2 \quad (4.169)$$

with

$$\kappa = \kappa_0 + \kappa_1(1 + T_r^{0.5})(0.7 - T_r) \quad (4.170)$$

$$\kappa_0 = 0.378893 + 1.4897153\omega - 0.17131848\omega^2 + 0.0196554\omega^3 \quad (4.171)$$

with κ_1 being an adjustable parameter characteristic of each substance. Table 4.1 reports the value of κ_1 for 26 substances of common interest. For water and alcohols, the value of κ_1 applies from low temperatures up to the critical point. For all other compounds, slightly better results are obtained using $\kappa_1 = 0$ for reduced temperatures above 0.7. This table also shows the low deviation of the predicted vapor pressures.

4.2.5.2 Perturbation Equations

Equations of state developed from perturbation theory are composed of a reference fluid equation to which are added perturbation terms. The reference fluid expresses the high repulsive energy that determines the molecular correlation and hence the structure of the fluid. The attractive energies that are relatively weak are treated as perturbations. Perturbation theory opens the door to the separate development of statistical theories for various intermolecular energies: hard-sphere-fluid

pressure, hard-sphere-chain pressure, pressures of fluids of various hard bodies, square-well attractive pressure, Lennard-Jones attractive pressure, intramolecular pressure, rotational pressure, association pressure, etc. The appropriate pressures are summed to form the equation of state of the fluid.

A commonly used reference fluid is the hard-sphere fluid expressed by the Carnahan-Starling (CS) equation of state:

$$z = \frac{1+\eta+\eta^2-\eta^3}{(1-\eta)^3} \tag{4.172}$$

where z denotes the compressibility factor pv/RT; $\eta = \pi\rho\sigma^3/6$ is a reduced dimensionless density, also referred to as the packing fraction, expressing the fraction of volume that is packed by the spheres; ρ is the density of molecules n/v; and σ is the diameter of the hard sphere. This equation is based on the fluid structure derived from correlation theory and is verified by molecular simulation. It takes the place of the repulsive pressure $RT/(v - b)$ of the vdW eos, which is an oversimplification in counting excluded volume as due to all molecules in binary collisions. In

liquids and dense gases, clusters of more than two molecules are abundant, and the excluded volumes of the pairs in the clusters overlap; the excluded volume in vdW eos is an overcount; and the vdW repulsive pressure is excessively high.

The double-series attractive pressure due to Alder et al. [13] is in common use. The attractive energy of square-well molecules is simulated with the method of molecular dynamics and fitted to a double series in T and ρ. Integration of U/T^2 gives A, and differentiation with v gives the attractive pressure, here expressed as a compressibility factor,

$$z_{att} = \sum_{n=1}^{4}\sum_{m=1}^{9} mD_{nm}(u/kT)^n/(v^0/v)^m \tag{4.173}$$

where u denotes the depth of the energy well, v^0 is the close-packed volume of the hard core spheres equal to $N\sigma^3/\sqrt{2}$, and σ is the diameter of the hard sphere.

Chen and Kreglewski [11] developed a perturbation equation based on Boublik's [12] hard-convex-body equation as the reference fluid equation. The repulsive pressure is Alder et al.'s double-series polynomial with modified coefficients fitted to experimental argon data. The Boublik–Alder–Chen–Kreglewski (BACK) eos is

$$z = z_{rep} + z_{att} \tag{4.174}$$

$$z_{rep} = 1 + \frac{(3\alpha+1)y + (3\alpha^2 - 3\alpha - 2)y^2 + (1-\alpha^2)y^3}{(1-y)^3} \tag{4.175}$$

where z_{att} is given by Equation (4.173) with Chen arid Kreglewski's [11] polynomial coefficients. The variables of the equation are: $y = 0.74048\ v^0/v$ is the packing fraction; α is a nonsphericity parameter; v^0 is the close-packed volume; and u is an interaction energy parameter. Both v^0 and u are temperature dependent:

$$v^0 = v^{00}[1 - C\exp(-3u^0/kT)] \tag{4.176}$$

$$u = u^0(1 + \eta/kT) \tag{4.177}$$

The five substance-specific parameters—u^0/k, v^{00}, α, η/k, C—and the attractive-pressure polynomial coefficients can be looked up in the literature [11]. The BACK eos is capable of high-accuracy representation of pVT and was used to prepare American Petroleum Institute Project 44 tables of thermodynamic properties.

In the perturbed hard-chain theory (PHCT) of Beret and Prausnitz [14] and Donohue and Prausnitz [15], the reference fluid is modeled as chains of tangential hard spheres. Since the fluid is still composed of hard spheres, albeit bonded, the CS eos is applied with modification to account for the bonding. The hard-sphere-chain equation is

$$z = \frac{1 + (4c-3)r\eta + (3-2c)(r\eta)^2 - (r\eta)^3}{(1-r\eta)^3} \tag{4.178}$$

One modification is to replace the packing fraction η of Equation (4.172) with $r\eta$ to account for the r spheres in one chain molecule. The other modification is to revise the terms in the numerator

of Equation (4.172) in light of the increased degrees of freedom of the chain of spheres from that of the single sphere. Let the number of external degrees of freedom of a chain molecule be denoted by $3c$. These are transformed from the $3r$ degrees of translational motion of the r spheres that make up the chain. In general, $3c$ is smaller than $3r$ but larger than 3 and consists in the three translational modes and some rotational modes. Any vibrational modes are of high energy and independent of the density of the fluid; they are not included in the $3c$ degrees of external motion. The rotational modes are of lower energy. Though not fully free, some are density dependent. They need to be addressed in equations of state of polyatomic molecular fluids. Prigogine [16] expressed these rotational modes as equivalent translational degrees of freedom. Flory et al. [17] constructed a cell theory for the equivalent translational modes that is widely used in polymer equations of state and polymer solution theory. Beret and Prausnitz [14] and Donohue and Prausnitz [15] reinterpreted the terms in the numerator of the CS equation in light of the added equivalent translational degrees of freedom of the chain molecule. The result is the new terms in the numerator of Equation (4.178). These terms revert to their forms in Equation (4.172) upon setting $3c = 3$.

The attractive pressure of the chain-of-spheres model is the sum of the double-series attractive pressures of the c external degrees of freedom,

$$z = -c\sum_n \sum_m \frac{mA_{nm}}{\tilde{v}^m \tau^n} \tag{4.179}$$

where the reduced variables are $\tau = ckT/(q)$ and $\tilde{v} = v\sqrt{2}/(Nr\sigma^3)$ and the variable ε is the characteristic intermolecular potential energy of a molecule per unit surface area, εq is the surface area of a molecule, and q is the characteristic attractive energy of a molecule. The constants A_{nm} have been adjusted to fit data for alkanes.

The PHCT pressure is the sum of the hard-sphere-chain pressure of Equation (4.172) and the attractive pressure of the chain of spheres of Equation (4.179),

$$z_{\text{PHCT}} = z_{\text{R}} + z_{\text{att}} \tag{4.180}$$

Three adjustable parameters are specific for each substance: εq, $r\sigma^3$, and c. The parameters are fitted to pVT and vapor pressure data. The PHCT is applicable to a very wide domain: for simple molecules where $c \to 1$, it reduces to the perturbed Carnahan-Starling eos; at low density, it gives a reasonable second virial coefficient and approaches ideal gas at very low density; for high densities, PHCT is essentially equal to the Prigogine–Flory–Patterson theory of polymer liquids.

In the chain-of-rotators (COR) equation proposed by Chien, Greenkorn, and Chao [17], a chain molecule is modeled as joined spheres in which adjacent covalent bonds can rotate. Rotation takes place because the chain is not straight; any two adjacent bonds are joined at an angle like the radials from the center of a pyramid to the four corners. Chien et al. found the pressure of rotation by comparing the pressure of Boublik and Nezbeda's hard dumbbell fluid [18] with the pressure of Carnahan and Starling's hard spheres. The rotational pressure found is

$$z_{rot} = c\left(\frac{e-1}{2}\right)\left(\frac{3\eta + 3e\eta^2 - (e+1)\eta^3}{(1-\eta)^3}\right) \tag{4.181}$$

where η is a reduced density defined to be v_{h}/v, also referred to as the packing fraction; v_{h} is the hard core volume; c is the rotational degrees of freedom of a molecule; and e is the eccentricity parameter of the model dumbbell rotator, defined by

$$e = \frac{(1+L)(2+L)}{2+3L-L^3} \quad \text{for } L \leq 1 \tag{4.182}$$

where $L = l/\sigma$, with l being the center-to-center distance and σ representing the diameter of the spheres. Chien et al. [17] took a two-carbon segment as the model rotor. Substituting for ethane gives a value of 1.078 for e. The probability of rotation-caused collision is significant in liquids and dense gases, and the rotational pressure is significant. The probability of collision is small in dilute gas, and the rotational pressure drops rapidly with decreasing density down to z values much lower than the values that the CS hard spheres would ever attain. The z of rotation approaches 0 instead of 1 at zero density. There can be any number of rotators in a molecule without affecting the fluid from approaching ideal-gas behavior at zero density.

The COR eos is made up of three terms: the CS hard-sphere eos, the rotational pressure of Equation (4.181), and Alder et al.'s double-series attractive pressure modified for nonspherical molecules,

$$\begin{aligned} z = {} & \frac{1+\eta+\eta^2-\eta^3}{(1-\eta)^3} + c\left(\frac{3-1}{2}\right)\left(\frac{3\eta+3e\eta^2-(e+1)\eta^3}{(1-\eta)^3}\right) \\ & + \left[1+\frac{c}{2}(B_0+B_1/\tilde{T}+B_2\tilde{T})\right]\sum_n\sum_m \frac{mA_{nm}}{\tilde{T}^n\tilde{v}^m} \end{aligned} \tag{4.183}$$

where the reduced temperature $\tilde{T} = T/T^*$ (T^* being a substance-specific characteristic temperature) and the reduced volume $\tilde{v} = v / v_0$ (v_0 being the closest packed volume and also a substance-specific value). Since $\eta = v_h/v$ and $v_h = (\pi\sqrt{2/6})v_0 = 0.740478$ (the value of v_0 based on the assumption of hard spheres), $\eta = 0.74048/\tilde{v}$. Table 4.2 presents parameters for several common substances, comparisons of predicted values versus experimental vapor pressure, and density of saturated liquid data.

The usefulness of equations of state can be extended with the method of group contribution. By this method, the eos parameters of molecules are synthesized from those of the constituent

groups of the molecule. Once the group parameters are determined, properties of the molecular fluids can be calculated. Since many molecules are composed of a relatively small number of groups, the group contribution method can be used for many molecular fluids.

To make it suitable for group contribution, Pults et al. [19] simplified the COR eos by replacing the double-series attractive pressure with the Redlich-Kwong attractive pressure in Equation (4.159). The COR group contribution (CORGC) eos is

$$z=\frac{1+\eta+\eta^2-\eta^3}{(1-\eta)^3}+c\left(\frac{e-1}{2}\right)\left(\frac{3\eta+3e\eta^2-(e+1)\eta^3}{(1-\eta)^3}\right)-\frac{a(T)}{RT[v+b(T)]} \tag{4.184}$$

where y is the reduced density equal to $b(T)/(4v)$; $b(T)$ is the covolume, a function of T; c is the degree of rotational freedom; e is a constant = 1.078; and $a(T)$ is a T-dependent attractive-pressure parameter.

The eos parameters a, b, and c are made up of group contributions according to the following equations:

$$a(T)=\sum_i^{N_c}\sum_j^{N_c}x_ix_j\sum_m^{N_i}\sum_n^{N_j}v_{im}v_{jn}q_mq_nq_{mn}(T) \tag{4.185}$$

$$b_i(T)=\sum_m^{N_i}v_{im}b_m(T) \tag{4.186}$$

$$b(T)=\sum_i^{N_c}x_ib_i(T) \tag{4.187}$$

$$c_i=\sum_m^{N_i}v_{im}c_m \tag{4.188}$$

$$c=\sum_i^{N_c}x_ic_i \tag{4.189}$$

In these equations, ν_{im} is the number of groups m in molecule i. The index N_i is the number of group species in molecule i, and N_c represents the number of components in the mixture. The coordination number q_m is a normalized surface area of group m based on a value of q_m = 10 for methane.

Equation (4.185) combines the interactions of groups to give the total interaction of the fluid. It is a generalization of the van der Waals mixing rule to include groups (or atoms) as well as molecules as entities that interact. To count the interaction of groups is in accord with the nature of polyatomic molecules. Equations (4.185) to (4.189) are given in their general forms for pure fluids and mixtures. For pure fluids, set $i = j = 1$, $N_i = N_j = 1$, and $x_i = x_j = 1$. The equations simplify to van der Waals mixing rule for a mixture of monatomic molecules, with $\nu_{im} = 1$ for all i and all n.

Equation (4.186) sums up the excluded volume of the constituent groups to form the excluded volume of the molecule. The linear sum is justified because the excluded volume of a group is defined as $(4v_h)$, where v_h stands for the hard core volume. Equation (4.187) linearly combines the

[a] Value in a five-membered naphthenic ring.
[b] Value in a six-membered naphthenic ring
$(\ )_{ar}$ member of an aromatic ring; $(\ )_{cyc}$ member of a naphthenic ring; -al attached to an aliphatic group; -ar attached to an aromatic ring; -ri attached to a ring group (either aromatic or naphthenic).

excluded volumes of the molecules to form the excluded volume of the mixture by the van der Waals mixing rule. Similarly, the summing of the constituent number of rotors of the groups to form the number of rotors of the molecule and the linear combination of the number of rotors of the molecules to form the total number of rotors of the mixture are carried out in Equation (4.188) and Equation (4.189).

The group properties a and b are functions of temperature as follows:

$$a_{mn} = \hat{a}_{mn}\left(\frac{T}{\hat{T}_{mn}}\right)^{-0.18135} \exp\left(\frac{-T}{\hat{T}_{mn}}\right) \tag{4.190}$$

$$b_m = b_m^* \exp(-T / T_m^*) \tag{4.191}$$

Six parameters describe the contributions of a group m, and these are $\hat{a}_{mm}, \hat{T}_{mm}, b_m^*, T_m^*, c_m$, and q_m. Table 4.3 presents the values for 21 groups, including small molecules: hydrogen, methane, ethane, H_2S, and CO_2 are counted as independent groups.

The interaction between unlike groups m and n, appearing as a_{mn}, requires two additional parameters, $\hat{a}_{mm}$ and $\hat{T}_{mm}$, for its description. Unlike interaction parameters have been reported by Pults [20].

To apply to high polymers, Sy-Siong-Kiao, Caruthers, and Chao [21] extend the COR eos to obtain the polymer chain-of-rotator (PCOR) equation,

$$\frac{pv_m}{RT} = c_m\left(\frac{e-1}{2}\right)\frac{3\eta + 3e\eta^2 - (e+1)\eta^3}{(1-\eta)^3} - \frac{a_{mm}}{RT(v_m + b_m)} \tag{4.192}$$

The equation addresses the molar volume of a segment of the polymer v_m, the subscript m indicating a segmental molar quantity. The parameters of the equation are segmental parameters: thus b_m is the excluded volume of a segment; $\eta = b_m/(4v_m)$ is the density of the fluid expressed in a reduced dimensionless form, also called the packing fraction; and a_{mm} is the attractive-pressure parameter of the segment. The eccentricity parameter of the rotators is e, equal to 1.078 for the model rotator. Results of data reduction indicate the attractive parameter a_{mm} to vary weakly and linearly with temperature,

$$a_m = a_{m0} + a_{m1}T \tag{4.193}$$

The parameter b_m does not change with temperature, being a constant value for each polymer. The temperature independence of b_m in the range of temperature of the data indicates low kinetic energy of the giant polymer molecules.

Comparing the PCOR with the COR eos, Equation (4.183), the translational pressure in the COR eos is missing in the PCOR eos. The long-chain polymer molecules are so entangled and entwined that the molecules make only translational rotations.

The PCOR eos describes only a liquid state. In agreement with experimental observation, a high polymer does not vaporize or exert a vapor pressure as pressure approaches zero. The equation does give an accurate quantitative representation of the pVT relationship of high-polymer melts. Average absolute deviation of the equation from the experimental specific volumes is 0.1% or less for the complete range of the experimental data covering a pressure range of 0 to 100 or 200 MPa for all polymers studied.

By generalizing Flory's dimer theory, Hall and coworkers [22, 23] obtained the GF-D equation of state, which is as follows:

$$Z_m = Z_1 + \frac{v_{e,m} - v_{e,1}}{v_{e,2} - v_{e,1}}(Z_2 - Z_1) \tag{4.194}$$

where the compressibility factor of the chain molecule is expressed as an extrapolation of the monomer and dimer values linearly with respect to the excluded volume. The chain molecule is modeled as an m-mer of tangential hard spheres with an attractive potential. The incremental compressibility factor with the addition of a sphere to the chain is a constant equal to the increment at the formation of the dimer from the monomer. The compressibility factor for the monomer or dimer fluid is given by

$$Z_i = Z_i^{rep} + Z_i^{att} \quad i = 1 \text{ or } 2 \tag{4.195}$$

For the hard core reference fluids, the following monomer and dimer equations apply:

$$Z_1^{rep} = \frac{1 + \eta + \eta^2 - \eta^3}{(1-\eta)^3} \tag{4.196}$$

$$Z_2^{rep} = \frac{1 + 2.45696\eta + 4.10386\eta^2 - 3.75503\eta^3}{(1-\eta)^3} \tag{4.197}$$

The attractive pressures of the monomer and dimer are, respectively,

$$Z_1^{att} = \frac{-288.15745}{(T^*)^2}\eta^2 \frac{1 - 5.4019\eta}{(1 + 6.75237\eta)^4} \tag{4.198}$$

$$+\frac{-9.5}{T^*}\eta \frac{1 - 1.3086\eta - 5.72921\eta^2 + 9.50043\eta^3 - 2.3751\eta^4}{(1-\eta)^4} \tag{4.199}$$

with

$$\begin{aligned} Z_2^{att} &= \frac{-492.36296}{(T^*)^2}\eta^2 \frac{2 - 12.31907\eta}{(1 + 8.26765\eta)^4} \\ &+\frac{-12.00332}{T^*}\eta \frac{1 + 1.56564\eta - 15.12892\eta^2 + 19.14672\eta^3 - 4.78668\eta^4}{(1-\eta)^4} \end{aligned} \tag{4.200}$$

$$\begin{aligned} \eta &= mv_h / v \\ T^* &= kT / \varepsilon \end{aligned} \tag{4.201}$$

where m is the number of segments per molecule, v_{h} is the molar volume of the hard spheres, and ε is the energy of interaction. These three factors are the pure-component properties in the GF-D eos that can be regressed from experimental pure-component saturated properties.

The excluded volumes of a monomer, dimer, and trimer are given, respectively, by

$$v_{e,1} = (4/3)\pi\sigma^3 \tag{4.202}$$

$$v_{e,2} = (9/4)\pi\sigma^3 \tag{4.203}$$

$$v_{e,3} = 9.82605\sigma^3 \tag{4.204}$$

where σ is the hard-sphere diameter. For interpolation at m between 1 and 2, the formula below is used,

$$v_{e,m} = (1.064343 + 3.246773m - 0.122327m^2)\sigma^3 \tag{4.205}$$

For $m > 2$, the excluded volume is given by the following:

$$v_{e,m} = v_{e,2} + (m-2)(v_{e,3} - v_{e,2}) \tag{4.206}$$

The GF-D has been fitted with high accuracy to over 100 substances by Wu and Chen [24]. The parameters v^0 and $/k$ are temperature dependent:

$$v^0 = v^{00} + 0.005T \tag{4.207}$$

$$\varepsilon / k = \varepsilon^0 / k - 0.004T \tag{4.208}$$

The temperature dependences of v^0 and ε/k do not apply to alkanols and water; these quantities are kept constant independent of T.

The statistical-associated fluid theory (SAFT) of Chapman et al. [25, 26] is based on the perturbation theory of Wertheim [27]. The model molecule is a chain of hard spheres that is perturbed with a dispersion attractive potential and association potential. The residual Helmholtz energy a^R of the fluid is given by the sum of the Helmholtz energies of: the initially free hard spheres; bonding the hard spheres to form a chain; the dispersion attractive potential; and the association potential,

$$a^R = a_{hs} + a_{chain} + a_{disp} + a_{assoc} \tag{4.209}$$

Wertheim found a_{chain} and a_{assoc} in his perturbation theory. Upon differentiating the Helmholtz energy with respect to volume, the equation of state is obtained,

$$z = z^{id} + z_{hs} + z_{chain} + z_{disp} + z_{assoc} \tag{4.210}$$

where the ideal-gas $z^{id} = 1$, and

$$z_{hs} = r\frac{4\eta - 2\eta^2}{(1-\eta)^3} \tag{4.211}$$

$$z_{chain} = (1-r)\frac{5\eta - 2\eta^2}{(1-\eta)(2-\eta)} \tag{4.212}$$

$$z_{disp} = r\sum_n \sum_m mD_{nm}\left(\frac{u}{kT}\right)^n \left(\frac{\eta}{\eta_{cp}}\right)^m \tag{4.213}$$

$$z_{assoc} = \rho \sum_S \left(\frac{1}{X^S} - \frac{1}{2}\right)\left(\frac{\partial X^S}{\partial \rho}\right) \tag{4.214}$$

where r is the number of spheres in a chain; η is the packing fraction = $r\rho_A(\pi/6)d^3$; ρ is the molar density of the chain molecules; d is the temperature-dependent diameter of the spheres given by Equation (4.176) in terms of the 0°K value σ, which is related to the eos parameter v_0, the closest packed volume of the spheres at 0°K, $N_A\sigma^3 = \sqrt{2}\, v_0$; and $\eta_{cp} = \pi\sqrt{2}/6$. By Chen and Kreglewski, the energy well depth u is temperature dependent and is given by Equation (4.177).

Associating molecules are bonded at association sites. There can be a number of association sites on a molecule. In Equation (4.214), X^S denotes the mole fraction of site S that is not bonded and is given by

$$X^S = \left\{1 + N_A \sum_Y \rho X^Y \frac{2-\eta}{2(1-\eta)^3}\left[\exp\left(\frac{\varepsilon^{SY}}{kT}\right) - 1\right]\right\}^{-1} \tag{4.215}$$

Here the summation with respect to Y is over all different kinds of sites in the fluid, and ε^{SY} and κ^{SY} are the characteristic energy and volume, respectively, for association between sites S and Y.

Three adjustable parameters characterize the chain of spheres of the molecule: r, the number of spheres making up a chain; v_0, the molar volume of the spheres at closest packing; and ε, the temperature-independent depth of the energy well of sphere-to-sphere interaction. To characterize the association, two more parameters are required for each pair of association: ε^{SY} and κ^{SY}. Huang and Radosz [28] reported SAFT parameter values for many substances.

The SAFT eos has been applied successfully to pure fluids and fluid mixtures of small, large, nonassociating, and associating molecules. The representation of *pVT* is generally quite good. The strength of the SAFT is in phase equilibrium of associating substances. Liquid-liquid equilibrium is found predominantly in mixtures of associating substances, and SAFT is superior for liquid-liquid equilibrium.

4.2.5.3 The Virial and Extended Virial Equations

A virial equation is a power-series expansion of the compressibility factor isotherm in molar density from the zero-density ideal gas, $z = 1$ at $\rho = 0$, which is the common point of intersection of all z isotherms,

$$z = 1 + B\rho + C\rho^2 + D\rho^3 + \ldots \tag{4.216}$$

The coefficients B, C, D,—known as the second, third, and fourth virial coefficients—are functions of temperature that are specific for a substance. The equation was originally used by Kammerlingh-Onnes and coworkers for fitting experimental *pVT* data on compressed gases. By adding terms to the equation as needed, the fitting can be extended to higher densities. It was later discovered that the virial coefficients are given by molecular theory as integrals of intermolecular potential in molecular clusters of various sizes: the second virial coefficient by clusters of two molecules, the third virial coefficient by triplets, and so on. Molecular theory teaches that the virial equation applies to mixtures in the same form as Equation (4.216) and that the mixture virial coefficients are combinations of the pure-component coefficients and cross-interaction coefficients,

$$B = \sum_i \sum_j x_i x_j B_{ij} \tag{4.217}$$

$$C = \sum_i \sum_j \sum_k x_i x_j x_k X_{ijk} \tag{4.218}$$

where the subscript denotes molecular species; x_i denotes mole fraction of species i; $B_{ii} \equiv B_i$ of pure i; and B_{ij} denotes the cross interaction of i and j interaction. Similarly, $C_{iii} \equiv C_i$ of pure i, and C_{ijk} denotes the C of the ijk interaction. A cross-interaction coefficient is also a function of temperature specific to the indicated species.

The virial equation is truncated in application. Figure 4.14 shows the comparison of B-virial equation and B + C virial equation with generalized correlation of Pitzer [1] at $T_r = 0.8$, 1.0, and 1.5. The uppermost curve at each temperature is the generalized z. The virial equation curves are based on virial coefficients from the same source. Close approximation of real gas behavior is obtained by the B-virial equation at pressures up to the vapor pressure at $T_r = 0.8$. At lower temperatures approximation is as good or better, as the existent pressure range of the gas phase is reduced. On the higher temperature side, at $T_r = 1$, we see the B equation holds up till p_r reaches to about 0.5; and at $T_r = 1.5$, the B equation stays close to the generalized correlation up to about

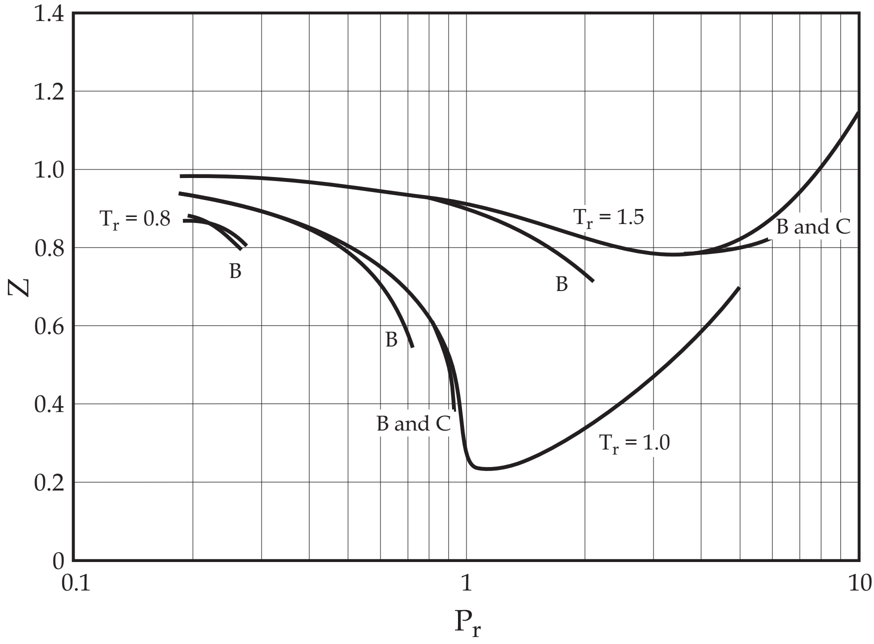

FIGURE 4.14 Comparison of virial equation with a generalized correlation.

the critical pressure. Enhanced by its simple form, and availability of the second virial coefficient, the B-virial equation is convenient and widely used for the vapor phase in low pressure and medium pressure vapor-liquid equilibrium work.

For vapor-liquid equilibrium calculations up to moderate pressures, the *B* equation is suitable and convenient for the vapor phase for its applicability and simple form. Formulas have been derived from statistical theory for the calculation of virial coefficients, including *B*, from intermolecular potential energy functions, but intermolecular energy functions are hardly known quantitatively for real molecules. *B* is found for practical calculations by correlating experimental *B* values. Pitzer [1] correlated *B* of normal fluids in a generalized form with acentric factor ω as the third parameter,

$$\frac{Bp_c}{RT_c} = B_0[T_r] + \omega B_1[T_r] \tag{4.219}$$

where $T_r \equiv T/T_c$ and where B_0 (of simple fluids) and B_1 generalize the correlation to normal fluids. Tsonopoulos [29] revised Pitzer's correlation and extended the correlation to polar and hydrogen-bonded fluids using B_0 and B_1 functions as follows:

$$\frac{Bp_c}{RT_c} = B_0[T_r] + \bar{\omega} B_1[T_r] + B_2[T_r] \tag{4.220}$$

$$B_0 = 0.1445 - 0.330/T_r - 0.1385/T_r^2 - 0.0121/T_r^3 - 0.000607/T_r^8 \tag{4.221}$$

$$B_1 = 0.0637 + 0.331/T_r^2 - 0.423/T_r^3 - 0.008/T_r^8 \tag{4.222}$$

$$B_2 = a / T_r^6 - b / T_r^8 \tag{4.223}$$

The B_2 function expresses the polarity and hydrogen-bond contributions. The coefficient a in the last equation above is a function of the reduced dipole moment μ_R:

$$a = -2.140 \times 10^{-4} \mu_R - 4.308 \times 10^{-21} \mu_R^8 \tag{4.224}$$

The reduced dipole moment is defined by

$$\mu_R = \frac{10^5 \mu^2 p_c}{T_c^2} 0.9869 \tag{4.225}$$

The units in the equation are: debye for μ, bar for p_c, and K for T_c. Equation (4.224) applies to a variety of nonhydrogen-bonded polar fluids, including ketones, acetaldehyde, acetonitrile, and ethers. Better results are obtained with specific equations. For ketones use

$$a = -2.0483 * 10^{-4} \mu_R \tag{4.226}$$

For ethers use

$$a = -\exp[-12.63147 + 2.09681 \ln \mu_R] \tag{4.227}$$

For water, a = 0.0279, and for aliphatic alcohols, a = 0.0878.

The coefficient b in Equation (4.223) is zero for nonhydrogen-bonded polar fluids. For hydrogen-bonded fluids,

$$b = 9.08 \times 10^{-3} + 6.957 \times 10^{-4} \mu_R \tag{4.228}$$

For water, b = 0.0229.

For strongly associated fluids, the virial equation is not useful for the description of nonideal-gas behavior. The theory of association is a more suitable approach; see Equation (4.214).

Combining rules are needed to estimate the cross second virial coefficients B_{ij} that are required in applying the virial equation to mixtures. Equation (4.220) is used for this purpose by treating the cross-interaction quantities as though they are properties of a real substance that follow the principle of corresponding states:

$$T_{cij} = (T_{ci} T_{cj})^{1/2} - \Delta T_{cij} \tag{4.229}$$

$$\omega_{ij} = (\omega_{ii} + \omega_{jj}) / 2 \tag{4.230}$$

$$z_{cij} = 0.291 - 0.08 \omega_{ij} \tag{4.231}$$

$$v_{cij} = \frac{1}{8} (v_{cii}^{1/3} + v_{cjj}^{1/3})^3 \tag{4.232}$$

$$p_{cij} = z_{cij} R T_{cij} / v_{cij} \tag{4.233}$$

For the polar and hydrogen-bond interaction terms, the following rules are suggested: polar-polar interaction can be approximated with the geometric mean; two hydrogen bonds interact with full force; hydrogen bond interacts with dipoles with reduced force; and nonpolar molecules do not interact with poles or hydrogen bonds.

4.2.5.4 Extended Virial Equations

The extended virial equations are made up of a truncated virial series followed by a closure term or terms. In the Benedict-Webb-Rubin (BWR) Equation (4.177), the closure term is an exponential,

$$\begin{aligned} P = RT\rho + (B_0RT - A_0 - C_0/T^2)\rho^2 + (bRT - a)\rho^3 + \alpha a\rho^6 \\ + c\rho^3(1+\gamma\rho^2)(1/T^2)\exp(-\gamma\rho^2) \end{aligned} \tag{4.234}$$

The eight constants required have been reported for numerous hydrocarbons.

The Lee-Kesler eos [2] is an extended BWR equation in reduced variables, as follows:

$$z = 1 + \frac{B}{v_r} + \frac{C}{v_r^2} + \frac{D}{v_r^5} + \left(\frac{c_4}{T_r^3 v_r^2}\right)(\beta + \tilde{a}/v_r^2)\exp(-\tilde{a}/v_r^2) \tag{4.235}$$

$$B = b_1 - \frac{b_2}{T_r} - \frac{b_3}{T_r^2} - \frac{b_4}{T_r^3} \tag{4.236}$$

$$C = c_1 - \frac{c_2}{T_r} + \frac{c_3}{T_r^3} \tag{4.237}$$

$$D = d_1 + \frac{d_2}{T_r} \tag{4.238}$$

where $v_r = p_c v/(RT_c)$ and $T_r = T/T_c$.

Using this equation, Lee and Kesler developed a generalized correlation of the pVT relationship of normal fluids in the following form:

$$z = z_0 + (\omega/\omega_r)(z_0 - z_r) \tag{4.239}$$

The subscript 0 denotes simple fluids with acentric factor $\omega = 0$, and subscript r denotes a reference fluid with acentric factor $\omega_r = 0.3978$ from its origin in n-octane. The Lee-Kesler equation constants for z_0 and z_r are presented in Table 4.4. The compressibility factors in Equation (4.239)—z, z_0, z_r—are at the same $[T_r, p_r]$. This correlation is a three-parameter generalized correlation that improves the Pitzer correlation to a wider range of states. The lower temperature bound of the correlation is extended from $T_r = 0.8$ to 0.3.

Extended virial equations of many terms and constants have been developed for the highly accurate representation of experimental data. Some are developed specifically for standard tables of density and derived thermodynamic functions such as entropy and enthalpy. Bender [31] extended the virial equation to a 20-constant equation to represent argon, oxygen, methane, hydrogen, ethene,

TABLE 4.4
Lee-Kesler Equation of State Constants

Constant	Simple fluids	Reference fluids
b_1	0.1181193	0.2026579

γ	0.060167	0.03754

and propene. Jacobsen and Stewart [32] further extended the virial equation to 32 constants to fit nitrogen. The steam table equation of Keenan, Keyes, Hill, and Moore employs 54 constants [33].

4.2.6 Energy Functions of Ideal Gases and Mixtures

A useful way to find the value of energy functions of real fluids is to calculate it from a suitable equation of state. The calculation gives the deviation of the desired property from its ideal-gas value, called the residual function or deviation function. The energy function is obtained upon adding the residual function and the ideal-gas function. In this subsection we develop the ideal-gas energy functions; in the next subsection we derive the residual functions and sum up with the ideal-gas value.

The ideal gas is defined by

$$p = nRT/V \tag{4.240}$$

and the internal energy, being independent of volume or pressure, is then a function of temperature only,

$$U^* = U^*[T] \tag{4.241}$$

The asterisk (*) indicates an ideal-gas quantity, and the square brackets denote the independent variable or variables. The ideal gas U is given in standard references for a large number of chemical substances.

The enthalpy is defined by

$$H = U + pV \tag{4.242}$$

Forming the pV product from Equation (4.240) and substituting into Equation (4.242),

$$H^* = U^* + nRT \tag{4.243}$$

which shows that H is also independent of p or V, but varies with T,

$$H^* = H^*[T] \tag{4.244}$$

The ideal-gas enthalpy can be found in standard references for a large number of chemical substances.

Ideal-gas free energies A and G are, however, p or V dependent. Consider Helmholtz energy first. From the fundamental differential Equation (4.79),

$$dA = -SdT - pdV \tag{4.245}$$

At constant T, $dT = 0$, we substitute Equation (4.240) into Equation (4.245) and integrate from the volume V^0 at the standard pressure p^0 of either 1 atm or 1 bar to the system volume V,

$$A^* - A_0 = nRT \ln(V_0/V) \tag{4.246}$$

Replacing the standard-state volume in Equation (4.246) with (RT/1) we obtain

$$A^* = A^0 + nRT \ln \frac{RT}{V(1)} \tag{4.247}$$

The factor 1 standing for the standard pressure is often left out of the equation, but is kept here as a reminder that the units of the other factors in RT/V must be consistent with the units of the standard pressure. The ideal-gas A^0 or G^0 is tabulated in standard references.

To find the Gibbs energy of an ideal gas, start from the fundamental differential Equation (4.88):

$$dG = -SdT + Vdp \tag{4.248}$$

At constant $T(dT = 0)$, substitute Equation (4.240) into Equation (4.248) and integrate from a standard pressure $p^0 = 1$ atm or 1 bar to p to obtain

$$G^* - G_0 = nRT \ln(p/p_0) \tag{4.249}$$

If pressure is in units of atmospheres or bars in Equation (4.249), to agree with the units of the standard state, p^0 can be omitted from the equation, leaving

$$G^* = G_0 + nRT \ln p \tag{4.250}$$

The ideal-gas standard-state G^0 can be looked up from standard references for a large number of substances.

To find the entropy of an ideal gas, we combine the enthalpy of Equation (4.244) with the Gibbs energy of Equation (4.250),

$$S^* = (H^* - G^*)/T \tag{4.251}$$

$$= S^0 - nR \ln p \tag{4.252}$$

To find the energy functions of ideal-gas mixtures, we start with the ideal-gas equation of state, Equation (4.240), recognizing that the number of moles n in the equation includes the moles of all species in the mixture, i.e., $n = n_1 + n_2 + \cdots$. To show the mole numbers of the various species, we write the ideal-gas eos as follows:

$$p = (n_1 + n_2 + \cdots)RT/V \tag{4.253}$$

Expanding into several terms,

$$p = n_1RT/V + n_2RT/V + \cdots \tag{4.254}$$

where n_1RT/V is just the pressure of the n_1 moles of species 1 at the V and T of the mixture. It is the partial pressure p_1 of species 1,

$$p_1 = n_1RT/V \tag{4.255}$$

$$= (n_1/n)(nRT/V) \tag{4.256}$$

$$= y_1p \tag{4.257}$$

Equation (4.257) shows that the partial pressure of species 1 is also given by y_1p. Similar equations hold for each component. Equation (4.253) becomes

$$p = p_1 + p_2 + \cdots \tag{4.258}$$

The pressure of an ideal-gas mixture is the sum of the pressures of the components, each being pure at state $[n_i,T,V]$ or $[T,p_i]$.

Since the molecules of an ideal gas do not appreciably attract one another and do not take up any appreciable volume, each component in a mixture behaves like it is existing by itself, leading to the additive partial-pressure phenomenon. J. W. Gibbs stated the principle of independent action: The energy function of an ideal-gas mixture at $[T,p]$ is the sum of the energy functions of the components, each in its pure state at $[T,p_i]$,

$$w^*[T,p] = \sum y_i w_i^*[T,p_i] \tag{4.259}$$

where w^* denotes an energy function per mole of mixture, and w_i^* is the molar value of pure i.

Accordingly, the internal energy of an ideal-gas mixture is made up of the pure-component internal energies,

$$u^*[T,p] = \sum y_i u_i^*[T,p_i] \tag{4.260}$$

Since the U of an ideal gas is independent of pressure, the pressure in the brackets [] can be dropped,

$$u^*[T] = \sum y_i u_i^*[T] \tag{4.261}$$

Similarly, the molar enthalpy of an ideal-gas mixture can be obtained by summing the pure-component enthalpies,

$$h^*[T] = \sum y_i h_i^*[T] \tag{4.262}$$

The Helmholtz energy of an ideal-gas mixture is, following the principle of independent action,

$$a^*[T,p] = \sum y_i a_i^*[T,p_i] \tag{4.263}$$

It is often useful to relate the mixture a^* to the standard value a_i^0 of the components at the standard pressure of 1 atm or 1 bar so it can be looked up in standard references. By substituting $p_i = py_i$ and making use of Equation (4.247), we obtain

$$a_i^*[T,p_i] = a_i^0 + RT \ln y_i + RT \ln p \tag{4.264}$$

Substituting into Equation (4.263) gives

$$a^*[T,p] = \sum y_i a_i^0 + RT \sum y_i \ln y_i + RT \ln p \tag{4.265}$$

Relating the mixture to the pure components all at the same p, we rewrite Equation (4.265) as follows:

$$a^*[T,p] = \sum y_i a_i^*[T,p] + RT \sum y_i \ln y_i \tag{4.266}$$

The Gibbs energy of an ideal-gas mixture is obtained by adding RT to the Helmholtz energy equations. Employing standard values of the pure components and Equation (4.265),

$$g^*[T,p] = \sum y_i g_i^0 + RT \ln p + RT \sum y_i \ln y_i \tag{4.267}$$

To relate the mixture g to the pure-component values at the same pressure, we have from Equation (4.266)

$$g^*[T,p] = \sum y_i g_i^0[T,p] + RT \sum y_i \ln y_i \tag{4.268}$$

The entropy of an ideal-gas mixture is obtained by combining the internal energy of Equation (4.261) and the Helmholtz energy of Equation (4.265):

$$s^* = (u^* - a^*)/T \tag{4.269}$$

$$= \sum y_i s_i^0 - R \ln p - R \sum y_i \ln y_i \tag{4.270}$$

Equation (4.270) is rewritten upon referring to Equation (4.252) to relate the mixture entropy to the pure gases at the same pressure,

$$s^* = \sum y_i s_i^* - R \sum y_i \ln y_i \tag{4.271}$$

4.2.7 Residual Functions and Energy Functions from Equations of State

A residual function is defined to be the difference between the property of a real fluid and that of the fluid as an ideal gas at the same state. The real-fluid property is obtained by adding the residual function to the ideal-gas property. The calculation of residual function from an equation of state follows the identity

$$W - W^* = \int_{\infty}^{V} \left[\left(\frac{\partial W}{\partial V} \right)_T - \left(\frac{\partial W^*}{\partial V} \right)_T \right] dV \tag{4.272}$$

where W denotes the thermodynamic function and the asterisk (*) denotes the ideal gas. The derivative $(\partial W/\partial V)_T$ is obtained from the equation of state, while the ideal gas $(\partial W^*/\partial V)_T$ is obtained from the formulas presented earlier for the four energy functions and entropy. Other thermodynamic functions, when needed, can be derived from the formulas for the energy functions and entropy presented here.

4.2.7.1 Helmholtz Energy

We will begin the derivation with Helmholtz energy, as it is the natural energy function for the independent variables T and V of equations of state. By the fundamental differential equation for A, Equation (4.81)

$$\left(\frac{\partial a}{\partial v} \right)_T = -p \tag{4.273}$$

The p in this equation is the equation of state. For an ideal gas,

$$\left(\frac{\partial a^*}{\partial v} \right)_T = -\frac{RT}{v} \tag{4.274}$$

By Equation (4.272), we obtain the residual Helmholtz energy

$$a - a^* = \int_{\infty}^{v} \left(-p + \frac{RT}{v} \right) dv \tag{4.275}$$

Using Equation (4.247) for a^*, we obtain

$$a^0 = \int_{\infty}^{v} \left(-p + \frac{RT}{v} \right) dv + RT \ln \frac{RT}{v} + a^0 \tag{4.276}$$

The standard state a^0 for a mixture is combined from the components according to

$$a^0 = \sum y_i a_i^0 + RT \sum y_i \ln y_i \tag{4.277}$$

Example 4.11

Find the Helmholtz Energy of Peng-Robinson eos

Solution

The PR eos is Equation (4.165),

$$p = \frac{RT}{v-b} - \frac{\alpha a_c}{v(v+b)+b(v-b)} \tag{4.278}$$

where α is a function of T, and a_c and b are constants.

Substituting Equation (4.278) into Equation (4.275) and then integrating gives the residual Helmholtz energy by the PR eos,

$$a - a^* = RT \ln\frac{v}{v-b} + \frac{\alpha a_c}{2\sqrt{2}b}\ln\frac{v+(1-\sqrt{2})b}{v+(1+\sqrt{2})b} \tag{4.279}$$

Replacing a^* with a^0 by using Equation (4.276), we obtain the Helmholtz energy,

$$a = RT \ln\frac{RT}{v-b} + \frac{\alpha a_c}{2\sqrt{2}b}\ln\frac{v+(1-\sqrt{2})b}{v+(1+\sqrt{2})b} + a^0 \tag{4.280}$$

4.2.7.2 Gibbs Energy

To obtain Gibbs energy from eos, we begin by forming the residual function

$$g - g^* = (a - a^*) + pv - RT \tag{4.281}$$

Expressing $(a - a^*)$ in terms of an eos by Equation (4.275), we obtain

$$g - g^* = \int_\infty^v \left(-p + \frac{RT}{v}\right)dv + pv - RT \tag{4.282}$$

Using Equation (4.250) to replace g^* with g^0,

$$g = \int_\infty^v \left(-p + \frac{RT}{v}\right)dv + pv - RT + RT\ln + \frac{RT}{v} + g^0 \tag{4.283}$$

Example 4.12: Gibbs Energy by PR eos

The integral in Equation (4.282) for the PR eos will be taken from Equation (4.279). The pv term in Equation (4.282) will be formed by using the PR eos presented in Equation (4.278). It follows that

$$g - g^* = RT \ln\frac{v}{v-b} + \frac{\alpha a_c}{2\sqrt{2}b}\ln\frac{v+(1-\sqrt{2})b}{v+(1+\sqrt{2})b} + \frac{RT_v}{v-b} - \frac{\alpha a_c v}{v(v+b)+b(v-b)} - RT \tag{4.284}$$

To obtain g, the terms of Equation (4.284) are used in Equation (4.283),

$$g = RT\ln\frac{v}{v-b} + \frac{\alpha a_c}{2\sqrt{2}b}\ln\frac{v+(1-\sqrt{2})b}{v+(1+\sqrt{2})b} + \frac{RT_v}{v-b} - \frac{\alpha a_c v}{v(v+b)+b(v-b)} - RT + RT\ln\frac{RT}{v} + g^0 \quad (4.285)$$

4.2.7.3 Entropy

The fundamental differential form of dU shows

$$s = -\left(\frac{\partial a}{\partial T}\right)_v \quad (4.286)$$

Accordingly, by differentiating Equation (4.275), we have the residual entropy in terms of eos,

$$s - s^* = \int_\infty^v \left[\left(\frac{\partial p}{\partial T}\right)_v - \frac{R}{v}\right] dv \quad (4.287)$$

To obtain the entropy relative to the standard state, we substitute Equation (4.252) into Equation (4.287),

$$s = \int_\infty^v \left[\left(\frac{\partial p}{\partial T}\right)_v - \frac{R}{v}\right] dv + R\ln\frac{v}{RT} + s^0 \quad (4.288)$$

4.2.7.4 Internal Energy

To obtain internal energy from an eos, we first obtain its residual function by combining the residual Helmholtz energy and residual entropy,

$$u - u^* = (a - a^*) + T(s - s^*) \quad (4.289)$$

Substituting Equation (4.275) for $(a - a^*)$ and Equation (4.287) for $(s - s^*)$ in Equation (4.289),

$$u - u^* = \int_\infty^v \left[T\left(\frac{\partial p}{\partial T}\right)_v - p\right] dv \quad (4.290)$$

In the ideal-gas state, $u^* = u^0$. We rewrite Equation (4.290) to give the value of u itself,

$$u = \int_\infty^v \left[T\left(\frac{\partial p}{\partial T}\right)_v - p\right] dv + u^0 \quad (4.291)$$

Example 4.13: Internal Energy by Peng-Robinson eos

The PR eos is differentiated to give

$$\left(\frac{\partial p}{\partial T}\right)_v = \frac{R}{v-b} - \frac{a_c\alpha'}{v^2+2bv-b^2} \tag{4.292}$$

where α' stands for $\alpha d/dT$ obtained from Equation (4.162),

$$\begin{gathered}\alpha' = -2[1+(0.37465+1.5422\omega-0.26992\omega)(1-T_r^{0.5})] \\ (0.37464+1.5422\omega-0.26992\omega^2)/(T_r^{0.5}T_c)\end{gathered} \tag{4.293}$$

Substituting p of Equation (4.159) and its derivative Equation (4.292) into Equation (4.291) and integrating, we obtain internal energy by PR eos,

$$u = \frac{a_c(\alpha - T\alpha')}{2\sqrt{2}b}\ln\frac{v+(1-\sqrt{2})b}{v+(1+\sqrt{2})b} + u^0 \tag{4.294}$$

The internal energy deviation from ideal gas ($u - u^0$) given in this equation is entirely due to the attractive-force term of the eos. The hard core makes no contribution to the internal energy, as the hard core pressure vanishes in the combination $T(\partial p/\partial T)_v - p$. The hard core in a van der Waals-type eos does not contribute to internal energy. However, in some van der Waals-type eos's, the hard core has a slight temperature dependence, and that does make a weak contribution to internal energy.

4.2.7.5 Enthalpy

To obtain enthalpy from eos we add pv to the internal energy. From Equation (4.290), we obtain the general formula for residual enthalpy from eos,

$$h - h^* = \int_\infty^v \left[T\left(\frac{\partial p}{\partial T}\right)_v - p\right]dv + pv - RT \tag{4.295}$$

For an ideal gas, enthalpy is independent of v but is a function of T only, and $h^* = h^0$. Equation (4.295) is rewritten to give h itself,

$$h = \int_\infty^v \left[T\left(\frac{\partial p}{\partial T}\right)_v - p\right]dv + pv - RT + h^0 \tag{4.296}$$

Example 4.14: Enthalpy by Peng-Robinson eos

By adding ($pv - RT$) to Equation (4.294), we obtain enthalpy by PR eos,

$$h = \frac{a_c(\alpha - T\alpha')}{2\sqrt{2}b}\ln\frac{v+(1-\sqrt{2})b}{v+(1+\sqrt{2})b} + \frac{RTb}{v-b} - \frac{v\alpha a_c}{v^2+2bv-b^2} + h^0 \tag{4.297}$$

4.2.7.6 Some General Comments

The independent variables in the formulas for thermodynamic functions derived from eos are $[T,v]$. To use the formula for a state specified in $[T,p]$, the volume at the given state must first be found

by solving the eos. The formula is equally useful for a pure fluid or a fluid mixture. However, the equation-of-state parameters and standard-state quantities for a mixture, though no different in symbols from those of a pure fluid, are combinations of the pure-component values and are functions of composition. In spite of this difference, they are used the same way in the formulas of this section.

The formulas presented here are valid for fluids at a homogeneous one-phase equilibrium state. They are not to be directly applied to a fluid at an unstable state, for ordinary interest is not on the unstable fluid as a homogeneous phase, but on the saturated phases that separate from the unstable fluid. Separate calculations on the separated phases need to be performed with the eos-derived formulas for the individual saturated phases, and summed if desired. The calculations to find the saturated equilibrium phases are the subject of Section 4.4.

For isothermal processes, the change in enthalpy is equal to the change in residual enthalpy, for the only difference between enthalpy and residual enthalpy is h^0, which is canceled when forming the isothermal change. Similarly, an isothermal change in internal energy is equal to the change in residual internal energy. It is more convenient to use the residual quantity in both instances.

For nonisothermal processes, the change of energy functions contains a change of standard state. The standard-state values need to be known. The ideal-gas standard-state values are given in standard tables. These have to be looked up or, alternatively, heat capacity data are employed instead of the standard-state values. Consider the change of enthalpy; the difference is found by integrating the heat capcity,

$$h_2^0 - h_1^0 = \int_1^2 c_p^0 dT \tag{4.298}$$

Similarly for internal energy and entropy,

$$u_2^0 - u_1^0 = \int_1^2 (c_p^0 - R) dT \tag{4.299}$$

$$s_2^0 - s_1^0 = \int_1^2 \left(\frac{c_p^0}{T} \right) dt \tag{4.300}$$

4.2.8 Fugacity

Fugacity is a transformation of chemical potential for convenient use in place of chemical potential for both phase and chemical equilibrium. The transformation is suggested from observing the chemical potential in an ideal-gas mixture,

$$\mu_i^* = g_i^0 + RT \ln(p_i / 1) \tag{4.301}$$

which is obtained by differentiation of Equation (4.267). By this equation, the chemical potential varies monotonously with p_i at a given temperature, going up or down as p_i goes up or down. Specifying a value for μ_i^* gives a value of p_i. Partial pressure can be used in place of chemical potential as the driving force for chemical reaction or phase change for ideal gases.

Fugacity, f, in general is defined by the transformation equation,

$$RT \ln(f_i / 1) = \mu_i - g_i^0 \tag{4.302}$$

The factor 1 in the equation is the standard-state pressure of 1 atm or 1 bar, and will be left out in subsequent equations for simplicity, with the understanding that f has the dimension of pressure in units of either atmospheres or bars, depending on the convention for g_i^0. It follows from the two equations above that, for an ideal-gas mixture, $f_i = p_i$, reducing for a pure ideal gas to $f = p$.

Upon substitution of μ_i from the defining equation of fugacity, Equation (4.302), in the phase-equilibrium equation, Equation (4.111) et seq., canceling out g_i^0 and RT, and exponentiating, we obtain the fugacity equality condition of heterogeneous phase equilibrium,

$$f_{\alpha i} = f_{\beta i} \tag{4.303}$$

for all components i and all phases α and β. The fugacity of any component must assume the same value in all phases in a heterogeneous system at equilibrium. These equations will be used in calculations in place of the chemical potential equality conditions of Equation (4.111) et seq. in the following sections of this chapter.

Why is fugacity so convenient that it is to be used in place of chemical potential in calculations? The reasons are:

1. Fugacity is freed from the ideal-gas standard state g^0. It is completely determined by the properties of the fluid at the temperature of interest.
2. Low-pressure gas states can be conveniently represented by f, for $f_i = p_i$, for an ideal gas. It follows for a real gas at a low or moderate pressure that $f_i \approx p_i$. The fugacity of a dilute component in a liquid is equal to the fugacity of the component at a small partial pressure in a gas mixture at equilibrium with the liquid, again $f_i \approx p_i$. Since the partial pressure of a gas is a well-behaved mathematical quantity, the fugacity is also well behaved at small partial pressures in a gas or at a small concentration in liquids. In contrast, for a dilute component, as its $p_i \to 0$ in an ideal-gas mixture, $\mu_i \to -\infty$ by Equation (4.301). It follows that $\mu_i \to -\infty$ for a dilute component in a real gas or in a liquid. The limit of $-\infty$ is ill-behaved and is avoided with the replacement of μ_i by f_i, which simply approaches zero.

To obtain a formula to calculate fugacity from an equation of state, we appeal to A, as its natural variables, T and V, are the independent variables of eos. We start with Equation (4.106) and carry out the indicated partial differentiation on Equation (4.276) to obtain

$$\mu_i = \int_{\infty}^{v} \left[\frac{RT}{v} - \left(\frac{\partial p}{\partial n_i} \right)_{T,V,nj} \right] dv + RT \ln \frac{RT/1}{v} + RT \ln y_i + g_i^0 \tag{4.304}$$

Substitution of this μ_i into Equation (4.302) gives

$$RT \ln(f_i/1) = \int_{\infty}^{v} \left[\frac{RT}{v} - \left(\frac{\partial p}{\partial n_i} \right)_{T,V,nj} \right] dv + RT \ln \frac{y_i RT}{v} \tag{4.305}$$

The ratio of fugacity to partial pressure, $f_i/(y_i p)$, called the *fugacity coefficient*, ϕ_i, is in common use as a measure of departure of a real fluid f_i from its ideal-gas value. For a pure fluid, the fugacity coefficient is simply $\phi \equiv f/p$. For an ideal-gas mixture, $\phi_i = 1$ for all i; for a pure ideal gas, $\phi = 1$. For a real fluid, by rearranging Equation (4.305),

$$RT\ln\phi_i = \int_{\infty}^{v}\left[\frac{RT}{v} - \left(\frac{\partial p}{\partial n_i}\right)_{T,V,nj}\right]dv - RT\ln z \tag{4.306}$$

Equation (4.306) is well behaved even as $p_i \to 0$; it is the preferred equation for calculating fugacity. For a pure fluid, the equation reduces to

$$RT\ln\phi = \int_{\infty}^{v}\left(\frac{RT}{v} - p\right)dv - RT\ln z + RT(z-1) \tag{4.307}$$

Although generally used for pure fluids, Equation (4.307) is sometimes also used to find the fugacity of a mixture, $\phi_m \equiv f_m/p$. The fugacity of a mixture is just an altered representation of the Gibbs energy of a mixture, $RT\ln f_m = g - g^0$.

Example 4.15: Fugacity Equation from the Redlich-Kwong (RK) eos

The RK eos, Equation (4.159), will be slightly altered as follows:

$$p = RT/(v-b) - a/[v(v+b)] \tag{4.308}$$

where the parameter a is a function of temperature. The temperature dependence will not show itself explicitly in this example because fugacity is completely determined by the property at the temperature of interest. Since the Wilson and the Soave eos's differ from the RK only in the temperature dependence of a, the fugacity equation is obtained for the other two eos's with the proper selection of the temperature function for a.

The parameters a and b in Equation (4.308) for mixtures are functions of composition. For the present example, we adopt the vdW one-fluid mixing rules,

$$a = \sum_i \sum_j y_i y_j a_{ij} \tag{4.309}$$

$$b = \sum_i y_i b_i \tag{4.310}$$

where y_i denotes the mole fraction of component i.

Substituting the a and b combination rules in Equation (4.308) and replacing y_i with the mole numbers n_i, we obtain

$$p = \frac{nRT}{V - \sum n_i b_i} - \frac{n^2 \sum_i \sum_j n_i n_j a_{ij}}{V\left(V + \sum n_i b_i\right)} \tag{4.311}$$

where $n = \Sigma n_i$, $n_i = ny_i$, and $V = nv$.

Taking the partial derivative $(\partial p/\partial n_i)_{T,p,nj}$, converting the n's back to the y's, and performing the integration indicated in Equation (4.306), we obtain the fugacity coefficient,

$$\ln \phi_k = \ln \frac{v}{v-b} + \frac{b_k}{v-b} - \frac{2\sum_i y_i a_{ik}}{RTb} \ln \frac{v}{v-b} + \frac{ab_k}{RTb^2}\left(\ln \frac{v}{v+b} - \frac{v}{v+b} \right) - \ln z \tag{4.312}$$

4.3 LIQUID SOLUTIONS

4.3.1 Ideal and Real Solutions

The fugacity of liquid solutions is basic to phase equilibrium and chemical equilibrium of liquids. Raoult observed that the equilibrium partial pressure of a component of a liquid solution with like substances is given by

$$p_i = x_i p_i^{\mathrm{S}} \quad \text{for } i = 1, 2, \ldots, v \tag{4.313}$$

where v denotes the number of components in the solution; p_i denotes the partial pressure of i in the coexisting equilibrium vapor mixture, py_i; x_i is the mole fraction of i in solution; and p_i^{S} is the vapor pressure of i at the temperature of the solution. Raoult's law is useful for its simplicity and generality. One needs to know only the vapor pressure. As pure liquid i is diluted to form the solution, its equilibrium partial pressure is reduced from the vapor pressure by a factor equal to the mole fraction x_i, reflecting a purely dilution effect, while molecular interaction remains unchanged given that all solutes are highly alike. Though very useful, Raoult's law is restricted to low pressures. The essence of the law does not find full expression in the form of Raoult's law.

The ideal-solution law is a more general statement of Raoult's law in terms of fugacity. In solution of highly alike substances,

$$f_i = x_i f_i^{\mathrm{P}} \tag{4.314}$$

where f_i is the fugacity of component i in solution, and f_i^{P} is the fugacity of pure liquid i at the T and p of the solution, called the standard state of the component. The standard-state fugacity is the vapor pressure, p_i^{S}, transformed by

$$f_i^{\mathrm{P}} = p_i^{\mathrm{S}} \varphi_i^{\mathrm{S}} \exp[v_{\mathrm{L}}^{\mathrm{S}}(p - p_i^{\mathrm{S}}) / RT\} \tag{4.315}$$

where φ_i^{S} is the fugacity coefficient of the saturated vapor; $v_{\mathrm{L}}^{\mathrm{S}}$ is the molar volume of saturated liquid i; and the exponential factor, called the Poynting correction factor, expresses the incremental fugacity due to compression from pressure p_i^{S} to the pressure of the solution. The standard-state fugacity is also given in the form of a generalized correlation of fugacity of pure liquids.

The ideal-solution law, Equation (4.314), reduces to Raoult's law, Equation (4.313), under the simplifying conditions:

1. Saturated vapor of i being highly dilute, $\varphi_i^{\mathrm{S}} = 1$
2. The Poynting correction factor being nearly equal to 1
3. The equilibrium vapor behaves as an ideal-gas mixture, so the fugacity coefficient φ_i of component i in the equilibrium vapor equals 1.

Expressed in fugacity, the ideal-solution law is not restricted to low pressure, as it is in Raoult's law.

A solution is ideal if it satisfies the ideal-solution law. No real solution is rigorously ideal, but solutions of similar substances approach ideal-solution behavior as the similarity increases. Solutions of xylene isomers, for example, deviate from ideal-solution law by about 1% at the maximum. Close members of the same homologous series are often assumed to be ideal. It is not unusual to calculate mixtures of paraffin hydrocarbons with the ideal-solution equation. Ideal-solution law is the basis for ideal K values often used in industry. However, ideal-solution law is of great value in another way, and that is to provide a basis for introducing a correction factor, known as the activity coefficient.

The activity coefficient is the ratio of the fugacity of a component in a real solution to its ideal-solution value,

$$\gamma_i = \frac{f_i}{x_i f_i^p} \tag{4.316}$$

For ideal solutions, $\gamma_i = 1$ for all i at all compositions. The more different γ is from 1, the more nonideal is the solution. According to Equation (4.316), the fugacity of a component in a real solution is given by

$$f_i = \gamma_i x_i f_i^p \tag{4.317}$$

The activity coefficient expresses the nonideal-solution behavior of fugacity. The formal development of models for the activity coefficient in solution thermodynamics follows.

Both the ideal-solution Equation (4.314) and the real-solution Equation (4.317) reveal the motivation to use vapor pressure as the basis to find fugacity of components in liquids. This method of using vapor pressure and activity coefficient was practically the sole method for the quantitative calculation of fugacities of liquid solutions until the 1970s. Then, van der Waals-type equations of state were employed to calculate liquid fugacities with good accuracy using Equation (4.307) to perform the integration across the condensation range. Subsequently, some extended virial equations and the perturbation equations were used. Different methods are suitable for various classes of solutions or in different pressure ranges. The activity-coefficient method is suitable for highly nonideal solutions at low pressure and is also suitable for high pressure when the activity coefficient is incorporated in an equation of state. The activity-coefficient method is not readily applied to liquid solutions of light gases.

The fugacities f_i or activity coefficients γ_i of a liquid solution are measured in vapor-liquid equilibrium experiments. In commonly employed methods, the liquid solution is brought in contact and kept in contact with a vapor mixture of the same components until equilibrium is attained between the phases. A sample of the vapor is then withdrawn and analyzed to determine its mole fractions y_i, $i = 1,2,\ldots$. Similarly for the liquid sample, the mole fractions $x_i = 1,2,\ldots$ are determined. Together with the measured p, an experimental point of vapor-liquid equilibrium is given by

$$T,\ p,\ x_i\ (i = 1,2,\ldots) \quad \text{and} \quad y_i\ (i = 1,2,\ldots)$$

The fugacities in the gas mixtures are obtained from the gas-phase data: using an equation of state, one can calculate the fugacity coefficient φ_i from the experimental y_i and p and then form the product to give

$$f_{iv} = p y_i \phi_i \tag{4.318}$$

A simple equation of state is sufficient to find ϕ_i for the present purposes because the gas phase is usually at a low pressure. The virial equation truncated after B is useful, and correlation of B is found in Section 4.2.5.

By Equation (4.303), the fugacity of a component in the liquid is equal to that of the component in the equilibrium vapor. In light of Equation (4.318), the experimental fugacities of the components in the liquid are determined as

$$f_{iL} = p y_i \phi_i \tag{4.319}$$

From the liquid fugacities thus obtained, the experimental activity coefficients follow from Equation (4.315),

$$\gamma_i = \frac{py_i\phi_i}{x_i f_i^P} \tag{4.320}$$

Experimental activity-coefficient data are required for the equations to be made useful. To determine the mixture-specific parameters in the activity-coefficient equations, the equation is fitted to the experimental data. A large volume of data and many parameter values for various activity-coefficient equations have been reported. Chapter 1 ("Physical and Chemical Properties") gives sources for this information. The Dechema Chemistry Data Series also presents experimental data and correlations by activity-coefficient equations in many volumes published over several decades.

For mixtures of ethanol + water, the activity coefficient of either component approaches 1 as its mole fraction approaches 1. In this solution, and generally for positively deviating solutions, the activity coefficient of a component steadily increases as its mole fraction decreases. The activity coefficient attains the highest value at infinite dilution. In this mixture, the infinite dilution value often reaches approximately 6 to 8. The activity coefficient rises to much higher values in solutions of a polar/associated substance + a nonpolar one; coefficients of hundreds or higher are encountered in a phase-separated liquid-liquid system, such as water plus hydrocarbons. On the other hand, in solutions of nonpolar substances, such as hydrocarbons, a 20% deviation from the ideal solution earns the designation of definitely nonideal; however, mixtures of homologues like the aliphatics are more ideal. Long-chain molecules make a different class. When small molecules are mixed with these giants, their activity coefficients are as low as 0.01. But mixing one polymer with another polymer often does not result in a homogeneous solution.

The activity coefficients of the various components in a solution are related by the Gibbs-Duhem equation. Converting μ_i to f_i in Equation (4.128) gives the Gibbs-Duhem equation for fugacity at constant $[T,p]$,

$$\sum_k n_k d \ln f_k = 0 \tag{4.321}$$

Substituting Equation (4.315) for f_i results in the Gibbs-Duhem equation for activity coefficient at constant $[T,p]$,

$$\sum_k n_k d \ln \gamma_k = 0 \tag{4.322}$$

For a binary solution, the interdependence of the activity coefficients is determined by rearranging Equation (4.322) as follows:

$$x_A \frac{\partial \ln \gamma_A}{\partial x_A} = x_B \frac{\partial \ln \gamma_B}{\partial x_B} \tag{4.323}$$

The ratio of the slopes of the ln γ curves is equal to the inverse of the ratio of the x's, and the slope of a ln γ_i curve approaches zero as x_i approaches 1. The departure from ideal-solution behavior for a component occurs when it is diluted; the predominant component behaves as if it were in an

ideal solution. In a dilute solution, where the solute follows Henry's law, the solvent follows the ideal-solution law.

4.3.2 Ideal and Excess Solution Properties

Activity coefficient is a function of the state of a mixture. An activity-coefficient equation is required to calculate the fugacities of real solutions. The interrelationship of the activity coefficients through the Gibbs-Duhem equation implies that the activity-coefficient equations of all components are derivatives of a common thermodynamic function. Since the activity coefficient is an expression of the nonideal behavior of a component, a thermodynamic function is needed to express the nonideality of the total solution and then to obtain from it the activity-coefficient equation.

With the fugacity equation of a real solution, Equation (4.317), taking the logarithm of the equation and multiplying by RT gives

$$RT \ln f_i = RT \ln f_i^{\mathrm{P}} + RT \ln x_i + RT \ln \gamma_i \tag{4.324}$$

Transforming the fugacities f_i, and f_i^{P} into chemical potentials by using Equation (4.302) gives

$$\mu_i = g_i^{\mathrm{P}} + RT \ln x_i + RT \ln \gamma_i \tag{4.325}$$

where g_i^{P} is the molar Gibbs energy of pure liquid i at the $[T,p]$ of the solution.

Forming the molar Gibbs energy from the partial values of Equation (4.325),

$$g = \sum_i x_i g_i^{\mathrm{P}} + RT \sum_i x_i \ln x_i + RT \sum_i x_i \ln \gamma_i \tag{4.326}$$

The molar Gibbs energy of an ideal solution is obtained by setting $\gamma_i = 1$ for all i in Equation (4.326),

$$g^{\mathrm{Id}} = \sum_i x_i g_i^{\mathrm{P}} + RT \sum_i x_i \ln x_i \tag{4.327}$$

Even for an ideal solution, the Gibbs energy is not equal to the sum of the pure-liquid constituents.

The change of Gibbs energy upon mixing is the difference between the Gibbs energy of solution and the sum of its pure-liquid constituents at the same $[T,p]$. For 1 mole of solution,

$$g^{\mathrm{M}} \equiv g - \sum_i x_i g_i^{\mathrm{P}} \tag{4.328}$$

Thus, according to Equation (4.326),

$$g^{\mathrm{M}} = RT \sum_i x_i \ln x_i + RT \sum_i x_i \ln \gamma_i \tag{4.329}$$

This is the change in Gibbs energy when the pure liquids are mixed to form 1 mole of solution. For the formation of 1 mole of ideal solution with $\gamma_i = 1$, Equation (4.329) simplifies to

$$g^{\mathrm{M,Id}} = RT\sum_i x_i \ln x_i \tag{4.330}$$

Since $\ln x_i$ is always < 0, $g^{\mathrm{M,Id}} < 0$, and Gibbs energy is decreased in forming an ideal solution.

The excess Gibbs energy of mixing is defined as the excess of g^{M} of a real solution above that of the ideal solution,

$$g^{\mathrm{E}} = g^{\mathrm{M}} - g^{\mathrm{M,Id}} \tag{4.331}$$

In view of Equation (4.329) and Equation (4.330), for 1 mole of solution,

$$g^{\mathrm{E}} = RT\sum_i x_i \ln\gamma_i \tag{4.332}$$

The excess Gibbs energy is the sum of the nonidealities of the components and is the measure of the departure of the total solution from ideal-solution behavior. Hence it is the focal point for theoretical formulation. To facilitate the formulation, g^{E} is conveniently separated into parts,

$$g^{\mathrm{E}} = u^{\mathrm{E}} - Ts^{E} + pv^{\mathrm{E}} \tag{4.333}$$

The excess internal energy, u^{E}, reflects the varied interaction energies of the different molecules of a solution. The excess entropy reflects the orderliness/randomness of the molecular structure. The excess volume is usually left out as being negligible.

The activity-coefficient equation is obtained from g^{E} by taking the partial molar derivative of (ng^{E}) and setting to zero the sum of the derivatives of $\ln \gamma_{\mathrm{k}}$ on account of the Gibbs-Duhem equation, leaving

$$g_i^{\mathrm{E}} = RT\ln\gamma_i \quad i = 1,2,\ldots,v \tag{4.334}$$

where g_i^{E} stands for partial molar excess Gibbs energy and v is the number of components.

Activity coefficients of all components in a solution are obtained from one formulation of g.

4.3.3 Activity-Coefficient Models

Some commonly used activity coefficient equations are presented here. The equations contain parameters that reflect molecular interaction and must be known to use the equation. The parameters are determined by fitting the equation to experimental activity coefficient data. For multi-component mixtures, which are the main interest in engineering applications, the number of equation parameters can be large. The required experimental data to determine the parameters can be excessive.

Simplification of the equation and reduction of data requirement have been achieved in newer equations by addressing binary molecular interactions only. Interactions of clusters of greater than two molecules are not explicitly addressed, but their constituent molecular pairs are included as binary interactions. In this way only binary interaction parameters appear in all activity coefficient equations—for binary solutions as well as for multi-component solutions. By fitting binary solution data all solution parameters can be obtained, for multi-component solutions as well. The need for experimental data on multi-component solutions is eliminated, as all required parameters can be determined by fitting binary solution data.

Experience has shown that the binary interaction equations are at least as good as any larger cluster interaction equation in fitting data; usually they are superior. Their convenience and economy can be over-riding. The binary interaction equations have become the preferred equations to use. The other types of equations are included in this section only because they are still in the literature.

4.3.3.1 Redlich–Kister Equation

Redlich and Kister (RK) [1] employ a parabola $B_{12}x_1x_2$ as the basic form for the g^E of a binary solution. A power series in $(x_1 - x_2)$ is added to to express the asymmetry, if any, of the g^E function,

$$\frac{g_{12}^E}{RT} = x_1x_2[B_{12} + C_{12}(x_1 - x_2) + D_{12}(x_1 - x_2)^2] \tag{4.335}$$

Binary parameters B, C, and D are to be determined by fitting activity-coefficient data. Progressively more parameters are used, depending on the complexity of the function, but D is generally the highest employed. Differentiation of Equation (4.335) gives the activity coefficients

$$\begin{aligned} \ln\gamma_1 &= (B + 3C + 5D)x_2^2 - 4(C + 4D)x_2^3 + 12Dx_2^4 \\ \ln\gamma_2 &= (B - 3C + 5D)x_1^2 + 4(C - 4D)x_1^3 + 12Dx_1^4 \end{aligned} \tag{4.336}$$

The RK equation is strictly data fitting with a power series. The judiciously selected function gives a good representation of experimental data for many nonpolar, polar, and associated systems with activity coefficients either greater than or smaller than 1. It is easy to use. But for three-component and higher solutions, the RK equation becomes complex and unwieldy; they are not presented here.

4.3.3.2 Van Laar Equation

Van Laar [2] developed an activity-coefficient equation for liquid solutions based on the vdW eos. This equation has found wide use. Based on the observation that strongly nonideal solutions were associated with large heats of mixing, it was conjectured that nonideality was due to heat of mixing only. Neglecting s^E,

$$g^E = h^E \tag{4.337}$$

For liquids, pv^E is small, and excess enthalpy is assumed equal to u^E,

$$g^E = u^E \tag{4.338}$$

Van Laar [2] modified the van der Waals (vdW) equation to reduce the internal energy by Equation (4.291):

$$u = -\frac{a}{v} + u^0 \tag{4.339}$$

Forming u^E from the energies of the liquids, and setting the u^E to be g^E,

$$g^{\mathrm{E}} = -\frac{a_{\mathrm{m}}}{v_{\mathrm{m}}} + \sum x_i \frac{a_i}{v_i} \tag{4.340}$$

where the subscript m denotes the mixture and subscripts $i, j, \ldots$ are the pure liquids. The energies of the ideal gases, u^0, disappear from Equation (4.340) because $u^{\mathrm{M}} = 0$ for the ideal gases.

Van Laar set the liquid molar volumes v in Equation (4.340) to be b as an estimate:

$$g^{\mathrm{E}} = -\frac{a_{\mathrm{m}}}{b_{\mathrm{m}}} + \sum x_i \frac{a_i}{b_i} \tag{4.341}$$

To set v to be equal to b is highly unrealistic. However, the b as well as a will be treated as adjusted parameters in van Laar's activity-coefficient equation to fit experimental data. Van Laar also followed van der Waals mixing rules for a_{m} and b_{m} (cf. Equation (4.180) and Equation (4.181)):

$$a_{\mathrm{m}} = \sum_i x_i x_j a_{ij} \tag{4.342}$$

$$b_{\mathrm{m}} = \sum_i x_i b_i \tag{4.343}$$

with $a_{ii} = a_i$ and $a_{ij} = \sqrt{\mathrm{a_i a_j}}$.

Substitution of Equation (4.342) and Equation (4.343) into Equation (4.341) and algebraic rearrangement gives, for binary solutions,

$$g^{\mathrm{E}} = \frac{x_1 x_2 b_1 b_2}{x_1 b_1 + x_2 b_2}\left(\frac{\sqrt{a_1}}{b_1} - \frac{\sqrt{a_2}}{b_2}\right)^2 \tag{4.344}$$

Taking the partial molar derivatives gives

$$RT \ln \gamma_1 = \frac{A_{12}}{\left(1 + \frac{A_{12}}{A_{21}}\frac{x_1}{x_2}\right)^2} \tag{4.345}$$

$$RT \ln \gamma_2 = \frac{A_{21}}{\left(1 + \frac{A_{21}}{A_{12}}\frac{x_2}{x_1}\right)^2} \tag{4.346}$$

where

$$A_{12} = b_1\left(\frac{\sqrt{a_1}}{b_1} - \frac{\sqrt{a_2}}{b_2}\right)^2 \tag{4.347}$$

$$A_{21} = b_2\left(\frac{\sqrt{a_2}}{b_2} - \frac{\sqrt{a_1}}{b_1}\right)^2 \tag{4.348}$$

Equations (4.345) and (4.346) are the van Laar activity-coefficient equations that are used for fitting data by adjusting the parameters A_{21} and A_{12}. Although these parameters are derived from pure-component parameters, as shown in Equations (4.347) and (4.348), they are, nevertheless, considered mixture-specific binary interaction parameters and are thus indicated with subscripts because they are determined by fitting binary mixture data. Equations (4.347) and (4.348), while showing the source of derivation of the parameters, are not used for their determination.

From the assumed $s^E = 0$, the van Laar equation gives ($RT \ln \gamma$) as a constant, independent of temperature. The van Laar equation gives a good representation of the activity coefficient of many mixtures, including highly nonideal solutions. However, because it always gives activity coefficient greater than 1, it is not to be used for negatively deviating solutions with $g^E < 0$ and $\gamma < 1$.

By following the same procedure, the activity coefficient in a ternary solution is obtained,

$$RT\ln\gamma_1 = \left[x_2^2 A_{12}\left(\frac{A_{21}}{A_{12}}\right)^2 + x_3^2 A_{13}\left(\frac{A_{31}}{A_{13}}\right)^2 + x_2 x_3 \frac{A_{21}A_{31}}{A_{12}A_{13}}\left(A_{12} + A_{13} - A_{32}\frac{A_{13}}{A_{31}}\right)\right] \Bigg/ \left(x_1 x_2 \frac{A_{21}}{A_{12}} + x_3 \frac{A_{31}}{A_{13}}\right)^2 \tag{4.349}$$

To obtain the activity coefficient of component 2 or 3, the subscripts are shifted in the order 1-2-3-1.

The three-component equation is complex, and the complexity increases rapidly with the number of components of the solution. Hence, the van Laar equation is rarely used for solutions containing more than two components.

4.3.3.3 Regular Solutions

Hildebrand et al. [3] define a regular solution as one with negligible excess entropy that is composed of nonpolar or slightly polar compounds that do not chemically associate or hydrogen bond. Like van Laar's solutions, the nonideality of regular solutions is an energy effect. Study of solubility data led to the observation that the energy effect is more precisely an energy density effect. The energy density is defined for a pure liquid by

$$a = \frac{u^* - u}{v} \tag{4.350}$$

The residual energy or the molecular interaction energy ($u^* - u$) is obtained from the heat of vaporization minus RT and plus any vapor nonideality correction.

Scatchard [4] suggests that the molar energy of a solution be given by

$$(u^* - u)_m = v_m \sum_{i>} \sum_{j} \phi_i \phi_j a_{ij} \tag{4.351}$$

where ϕ denotes a volume fraction defined by

$$\phi_i = \frac{x_i v_i^{\text{P}}}{\sum_k x_k v_k^{\text{P}}} \tag{4.352}$$

The superscript P denotes a pure liquid. The molar volume of the solution v_{m} is given by

$$v_{\text{m}} = \sum_i x_i v_i^{\text{P}} \tag{4.353}$$

ignoring any change of volume with mixing.

The excess energy of the solution is obtained by combining the energy of the solution from Equation (4.351) and the energies of the pure liquids from Equation (4.350), and canceling the ideal-gas energies,

$$u^{\text{E}} = \sum_i \phi_i v_i a_i - \sum_{i>} \sum_j v_{\text{m}} \phi_i \phi_j a_{ij} \tag{4.354}$$

With the assumed zero s^{E} and neglecting v^{E}, the u^{E} of Equation (4.354) is set to be g^{E}. Combining terms of the summation gives

$$g^{\text{E}} = v_{\text{m}} \sum_{i>} \sum_j \phi_i \phi_j (a_i - a_{ij}) \tag{4.355}$$

Taking partial molar derivative of g^{E} gives

$$RT \ln \gamma_k = v_k \left(a_k - 2\sum_j \phi_j a_{kj} + \sum_i \sum_j \phi_i f_j a_{ij} \right) \tag{4.356}$$

Introducing the assumption $a_{ij} = (a_i a_j)^{1/2}$ simplifies Equation (4.356) to

$$RT \ln \gamma_k = v_k (\delta_k - \delta_{\text{m}})^2 \tag{4.357}$$

where δ is the solubility parameter defined to be the square root of the energy density,

$$\delta_k = a_k^{1/2} \tag{4.358}$$

For a solution,

$$\delta_m = \sum_i \phi_i \delta_i \tag{4.359}$$

For a binary solution, Equation (4.357) reduces to

$$RT \ln \gamma_A = v_A \phi_B^2 (\delta_B - \delta_A)^2 \tag{4.360}$$

$$RT \ln \gamma_B = v_B \phi_A^2 (\delta_A - \delta_B)^2 \tag{4.361}$$

The v and δ are pure-component properties. There are no mixture parameters to adjust for data fitting in Equation (4.357), Equation (4.360), and Equation (4.361). The regular solution equation is predictive based on pure-component liquid properties. It is generally useful for a first-order estimate for nonpolar, nonassociating, nonhydrogen bonding solutions. $RT \ln \gamma_k$ of a regular solution by Equation (4.357) is not dependent on T,

$$\left(\frac{\partial g^E}{\partial T}\right)_{p,x} = -s^E = 0 \tag{4.362}$$

The regular solution equation is useful for solutions of normal fluids encountered in the petroleum and gas industries up to high pressure. The regular solution equation is useful for the calculation of solubility of gases. Since the temperature of usual interest is greatly above the critical temperature of the light gases, a hypothetical standard state has to be determined for the regular solution equation to be useful for the light gases. This and other topics related to gas solubility will be found in Section 4.4.

4.3.3.4 Flory–Huggins Equation

The dissolution of polymers into a solvent produces little heat effect for polymers and solvent of similar chemical structure. However, the solvents in these solutions are much less volatile than in an ideal solution with activity coefficients much lower than 1.

Solutions with no heat of mixing are called athermal, and $h^E = 0$. The nonideality of an athermal solution is due to excess entropy. Flory and Huggins independently found the excess entropy of polymer solutions by counting the number of ways by which space is occupied by molecules of different sizes. The more ways to occupy space, the greater is the entropy. According to statistical mechanics, entropy is determined by the number of micromolecular states, $S = k \ln \Omega$, where k is the Boltzmann constant equal to the universal ideal-gas constant per molecule R/N_A; and for molecular solutions, Ω is the number of states for the molecules to occupy space. For the purpose of counting the states, the elemental segments of the polymer molecular chain are assumed to be located on a regular lattice structure like that of a crystal, with each segment taking up one lattice point. Suppose the polymer molecules are placed on the lattice structure one at a time so that the elemental segments of the molecule take up contiguous sites. The number of ways to place the ith polymer molecule on the lattice, ω_i, is $(M_0 - M_{i-1})[z(1 - M_{i-1}/M_0]^{m-1}$, where the factors are:

- $(M_0 - M_{i-1})$ is the number of ways to place the first segment of the ith molecule on the lattice, with M_0 being the total number of lattice sites and M_{i-1} being the number of lattice sites that are occupied after $i - 1$ molecules have been placed.
- z is the coordination number of the lattice, i.e., the number of closest neighbors of a site. For face-centered and hexagonal close-packed lattices, $z = 12$, and for body-centered packing, $z = 8$. Thus a number from 8 to 10 would be a reasonable value to assign to the hypothetical lattice of a liquid. Although used in the counting, the value of z does not make a difference to the entropy.

$(1 - M_{i-1}/M_0)$ represents the fraction of unoccupied sites. Upon being multiplied by z, the product represents the average number of vacant neighbor sites available for the placement of a segment of the ith molecule.

m is the number of segments of a polymer molecule.

The number of ways the molecules occupy space, Ω, is the continuous product of the ω_i's of all the polymer molecules. Substituting Ω in the entropy equation and converting the lattice sites into molecular core volumes, the entropy of mixing of a polymer solution is found to be

$$s^{\mathrm{M}} = -R\sum_i x_i \ln\phi_i \tag{4.363}$$

where ϕ_i is the volume fraction of component i in solution given by

$$\phi_i = \frac{x_i v_i}{\sum_j x_j v_j} \tag{4.364}$$

and v_i is the molar hard core volume of the linear molecule.

The excess entropy following from Equation (4.363) is

$$s^{\mathrm{E}} = -R\sum x_i \ln(\phi_i / x_i) \tag{4.365}$$

For a solution of molecules of the same size—$\phi_i = x_i$ by Equation (4.364), and $s^{\mathrm{E}} = 0$—the solution reverts to an ideal solution.

There being no difference in the interaction energy of the molecules under consideration, $u^{\mathrm{E}} = 0$, and $g^{\mathrm{E}} = -Ts^{\mathrm{E}}$,

$$g^{\mathrm{E}} = -RT\sum x_i \ln(\phi_i / x_i) \tag{4.366}$$

Taking the partial molar derivatives gives

$$\ln\gamma_i = \ln\frac{\phi_i}{x_i} + 1 - \frac{\phi_i}{x_i} \tag{4.367}$$

This is the Flory-Huggins (FH) equation for athermal solutions [5, 6]. The equation formally appears symmetric to all components of a mixture, but in fact it describes the great asymmetry between the polymer and the small solvent in solution. Consider the solution of a small solvent and a polymer that is r times the volume of the solvent. The solvent may well be the monomer, here designated as component 1, and the polymer may be an r-mer as component 2. Setting v_2/v_1 in Equation (4.367) gives

$$\ln a_1 = \ln\phi_1 + \left(1 - \frac{1}{r}\right)\phi_2 \tag{4.368}$$

$$\ln a_2 = \ln \phi_2 + (1-r)\phi_1 \tag{4.369}$$

where a_i is the activity $\equiv x_i\gamma_i \equiv f_i / f_i^{\mathrm{P}}$. The equations are, in fact, asymmetric with respect to solvent and polymer.

It is remarkable that no empirical mixture parameters and no experimental data are required to use the equation. The only parameters in the Flory-Huggins equation are the hard core volumes v_i, which are a pure-component property, and the atomic or group contribution values are found in standard compilations. Since the v_i's are significant in the FH equation only in terms of their ratios, pure-liquid molar volumes are often used for v_i in place of hard core volumes. For solutions of polymers of the same chemical formula, molecular masses are legitimate substitutes for v_i, for the same reason. Thus the volume fractions ϕ_i can be substituted by mass fractions w_i. Either volume fraction or mass fraction is directly related to laboratory data. To avoid mole fractions, the activity a_i from Equations (4.368) and (4.369) can be used to calculate f_i by $f_i \equiv a_i f_i^{\mathrm{P}}$.

A surprisingly simple but elegant statistical mechanical result is represented by Equations (4.367), (4.368), and (4.369). Though originally developed for polymer solutions, it is also applicable to solutions of small molecules to account for molecular size differences. It has been made part of some activity-coefficient equations, as will be discussed in the following.

Polymer solutions are not athermal when the solvent and the polymer are of different chemical structure. To account for the effect of energy of mixing, Flory suggested, from counting the change of contacts of the different molecular species upon mixing, an explanation for the excess energy as follows:

$$u^{\mathrm{E}} = RT\frac{v_{\mathrm{m}}}{v_1}\chi\phi_1\phi_2 \tag{4.370}$$

where v is molar liquid volume and (v_m/v_1) is a measure of the total molecular contacts. The exchange energy, $\chi \equiv \chi_{12} - (\chi_{11}+\chi_{22})/2$, expressing the energy of formation of a 1–2 contact at the expense of a 1–1 contact and a 2–2 contact, is a mixture-energy parameter for each solvent-polymer combination at a fixed temperature, and is a constant independent of molecular mass for homopolymers. This constant is zero for solutions of a polymer in its monomer.

By adding the u^{E} of Equation (4.370) with the s^{E} of Equation (4.365) to form g^{E}, and by differentiating the g^{E}, the activity coefficient is obtained,

$$\ln a_1 = \chi\phi_2^2 + \ln\phi_1 + \left(1-\frac{1}{r}\right)\phi_2 \tag{4.371}$$

$$\ln a_2 = \div\chi_1^2 + \ln\phi_2 + (1-r)\phi_1 \tag{4.372}$$

where subscript 1 denotes solvent and 2 is a polymer. These are Flory's χ equations, in which the χ parameter is adjusted for data fitting. Although supposed to be constant, χ has been found to vary with concentration and with polymer molecular mass to varying extent, depending on the mixture system. The χ equation is not as generally useful as the Flory-Huggins equation.

4.3.3.5 Wilson's Local-Composition Equation

Wilson [7] postulated that the nonideality of a solution is caused by a realignment of molecules at the microscopic neighborhood due to the different attractive energies of the various species. Certain molecules are strongly attracted to the central molecule preferentially. The local composition about

the central molecule becomes altered from the bulk composition of the solution. Wilson postulates the local composition to determine the entropy of the central molecule.

The probability of a molecule *j* being at the immediate neighborhood of a central molecule *i* is x_j, if there is no correlation between the *i* and *j* molecules. In case the two are correlated, the probability is x_j times the total correlation. The total correlation can be found by solving an integral equation, given the interaction potential energy function. It is, however, impractical to build the total correlation into a theory of excess functions. Wilson replaced the total correlation with the simpler direct correlation, which is part of the total correlation, to express the probability of finding a *j* molecule in the microscopic neighborhood of a central *i* molecule by $x_j \exp(-g_{ji}/RT)$, where g_{ji} is the energy of the *i-j* interaction and the Boltzmann exponential factor is the direct correlation.

The local mole fraction of *j* about *i* is obtained upon normalization,

$$x_{ji} = \frac{x_j \exp(-g_{ji}/RT)}{\sum_k x_k \exp(-g_{ki}/RT)} \tag{4.373}$$

where x_j denotes the bulk mole fraction of *j* and x_{ji} represents the mole fraction of *j* in the neighborhood of *i*.

The local mole fraction is converted to the local volume fraction as follows:

$$\phi_{ji} = \frac{x_j v_j \exp(-g_{ji}/RT)}{\sum_k x_k v_k \exp(-g_{ki}/RT)} \tag{4.374}$$

where v_i is the volume of *i*. Wilson postulated that the local volume fraction of *i* in its own neighborhood determines its entropy in the same way that volume fraction determines the entropy in the Flory-Huggins theory of solution of molecules of different sizes (cf. Equation (4.363)). The entropy of mixing of the solution is therefore given by

$$s^{\mathrm{M}} = -R\sum_i x_i \ln \phi_{ii} \tag{4.375}$$

Ignoring any excess energy contribution, Wilson's excess Gibbs energy is $-Ts^{\mathrm{E}}$ as follows:

$$\mathrm{g}^E = RT\sum_i x_i \ln(\phi_{ii}/x_i) \tag{4.376}$$

Substitution of ϕ_{ii} by Equation (4.374) into Equation (4.376) and rearrangement gives

$$g^{\mathrm{E}} = -RT\sum_i x_i \ln\left(\sum_i x_k \Lambda_{ik}\right) \tag{4.377}$$

where we have defined the interaction parameter

$$\Lambda_{ik} \equiv \frac{v_k}{v_i}\exp\frac{-(g_{ik} - g_{ii})}{RT} \tag{4.378}$$

In general, $g_{ik} = g_{ki}$, $\Lambda_{12} \neq \Lambda_{21}$, and $\Lambda_{ii} = 1$.

The activity coefficient is obtained by taking partial molar derivatives of g^E,

$$\ln \gamma_i = 1 - \ln\left(\sum_j x_j \ln \Lambda_{ij}\right) - \sum_k \left(\frac{x_k \Lambda_{ki}}{\sum_j x_j \Lambda_{kj}}\right) \tag{4.379}$$

For a binary solution, Equation (4.379) reduces to

$$\ln \gamma_1 = -\ln(x_1 + \Lambda_{12} x_2) + x_2 \left(\frac{\Lambda_{12}}{x_1 + \Lambda_{12} x_2} - \frac{\Lambda_{21}}{\Lambda_{21} x_1 + x_2}\right) \tag{4.380}$$

$$\ln \gamma_2 = -\ln(x_2 + \Lambda_{21} x_1) - x_1 \left(\frac{\Lambda_{12}}{x_1 + \Lambda_{12} x_2} - \frac{\Lambda_{21}}{\Lambda_{21} x_1 + x_2}\right) \tag{4.381}$$

Two adjustable parameters, Λ_{12} and Λ_{21}, need to be determined by fitting binary-solution data to Equation (4.380) and Equation (4.381). Parameters obtained from binary solutions are useful and sufficient in Equation (4.379) for multicomponent solutions, since no higher interaction parameters are required in the multicomponent equation.

The Wilson equation is widely used for many nonpolar, polar, and associated solutions in vapor-liquid equilibrium systems. It is often best for hydrogen-bonded substances. For multicomponent solutions, it makes effective use of binary-solution parameters to give good results, but it cannot predict the liquid immiscibility phenomena.

4.3.3.6 Nonrandom Two-Liquids (NRTL) Equation

To extend the activity-coefficient equation to partially miscible solutions, Renon and Prausnitz [8] introduced a factor to the exponential energy term in Wilson's equation. With $\alpha < 1$, the effect is to suppress the preferential attraction of molecules to the central molecule. The local mole fraction of component 2 about component 1 in a binary solution is given by

$$x_{21} = \frac{x_2 \exp[-\alpha_{12}(g_{21} - g_{11})/RT]}{x_1 + x_2 \exp[-\alpha_{12}(g_{21} - g_{11})/RT]} \tag{4.382}$$

and the local mole fraction of 1 about 1 is

$$x_{11} = \frac{x_1}{x_1 + x_2 \exp[-\alpha_{12}(g_{21} - g_{11})/RT]} \tag{4.383}$$

The factor α is assumed to be a constant for a binary system, $\alpha_{11} = \alpha_{22} = \alpha_{12} = \alpha_{21}$. The partial contribution of component 1 to the excess Gibbs energy of the solution is assumed to be $g^{(1)} - g_p^1$, where

$$g^{(1)} = x_{11} g_{11} + x_{21} g_{21} \tag{4.384}$$

and g_p^1 is the g of 1 in the pure-liquid state, set to be g_{11}. Renon and Prausnitz [8] changed Wilson's g, which is energy to Gibbs energy. Summing the contributions of both 1 and 2,

$$g^{\mathrm{E}} = x_1(g^{(1)} - g_{11}) + x_2(g^{(2)} - g_{22}) \quad (4.385)$$

The activity coefficient obtained from Equation (4.385) is

$$\ln\gamma_1 = x_2^2\left[\tau_{21}\frac{\exp(-2\alpha_{12}\tau_{21})}{[x_1 + x_2\exp(-\alpha_{12}\tau_{21})]^2} + \tau_{12}\frac{\exp(-\alpha_{12}\tau_{12})}{[x_2 + x_1\exp(-\alpha_{12}\tau_{21})]^2}\right] \quad (4.386)$$

$$\ln\gamma_2 = x_1^2\left[\tau_{12}\frac{\exp(-2\alpha_{12}\tau_{12})}{[x_2 + x_1\exp(-\alpha_{12}\tau_{12})]^2} + \tau_{21}\frac{\exp(-\alpha_{12}\tau_{21})}{[x_1 + x_2\exp(-\alpha_{12}\tau_{21})]^2}\right] \quad (4.387)$$

where

$$\tau_{12} = \frac{g_{12} - g_{22}}{RT} \quad (4.388)$$

$$\tau_{21} = \frac{g_{21} - g_{11}}{RT} \quad (4.389)$$

with

$$g_{12} = g_{21} \quad (4.390)$$

The general equation for a multicomponent solution is

$$\ln\gamma_i = \frac{\sum_j x_j\tau_{ji}G_{ji}}{\sum_k x_kG_{ki}} + \sum_j \frac{x_jG_{ij}}{\sum_k G_{kj}x_k}\left(\tau_{ij} - \frac{\sum_m x_m\tau_{mj}G_{mj}}{\sum_k G_{kj}x_j}\right) \quad (4.391)$$

where $G_{ij} = \exp(-\alpha_{ij}\tau_{ij})$.

The NRTL equations—Equation (4.386), Equation (4.387), and Equation (4.391)—contain three parameters for each binary system that are adjusted to fit data. Experience indicates that α varies in the range 0.20 to 0.47. Where experimental data are scarce, the value of α can be set by referring to known values of similar mixtures. Renon and Prausnitz [8] recommended values for broad classes of mixtures. A typical value of α is 0.3. The NRTL equation offers advantages over the Wilson equation for strongly nonideal mixtures, and especially for partially miscible systems.

4.3.3.7 The Complete Local-Composition Equation

Wilson's account for nonideality is all entropic. Only s^{E} contributes to g^{E}, while u^{E} is ignored. Hence Wilson's local-composition equation is incapable of describing immiscibility phenomena. Wang and Chao [9] modify the Wilson equation by restoring the missing u^{E} to g^{E}, thus completing the formation of g^{E}. By counting the contacts between the various molecular species based on the local mole fractions, they expressed the excess energy as follows:

$$u^{\mathrm{E}} = \frac{1}{2}\sum_i x_i \sum_j z x_{ji}(g_{ji} - g_{ii}) \tag{4.392}$$

where g is energy as in Wilson's equation, and z is the coordination number, i.e., the number of closest neighbor molecules.

Adding Equation (4.392) to Wilson's $-Ts^{\mathrm{E}}$ gives the complete g^{E},

$$g^{\mathrm{E}} = \frac{z}{2}\sum_i x_i \sum_j x_{ji}(g_{ji} - g_{ii}) + RT\sum_i x_i \ln(\phi_{ii}/x_i) \tag{4.393}$$

The activity coefficient obtained from Equation (4.393) is

$$\ln\gamma_i = \frac{1}{RT}\left(\frac{z}{2}\right)\left[\sum_j x_{ji}(g_{ji} - g_{ii}) + \sum_j x_j \sum_k x_{kj}\left(\frac{x_{ij}}{x_i}\right)(g_{ij} - g_{kj})\right]$$
$$+1 - \ln\left(\sum_j x_j\Lambda_{ij}\right) - \sum_k\left(\frac{x_k\Lambda_{ki}}{\sum_j x_j\Lambda_{kj}}\right) \tag{4.394}$$

where Λ_{ij} is defined as

$$\Lambda_{ij} = \frac{v_j}{v_i}\exp\frac{-(g_{ji} - g_{ii})}{RT} \tag{4.395}$$

For binary mixtures, Equation (4.394) simplifies to

$$\ln\gamma_1 = \frac{1}{RT}\left(\frac{z}{2}\right)\left[x_{21}^2(g_{21} - g_{11}) + x_2 x_{22}\frac{x_{12}}{x_1}(g_{21} - g_{22})\right]$$
$$-\ln(x_1 + \Lambda_{12}x_2) + x_2\left(\frac{\Lambda_{12}}{x_1 + x_2\Lambda_{12}} - \frac{\Lambda_{21}}{x_2 + x_1\Lambda_{21}}\right) \tag{4.396}$$

$$\ln\gamma_2 = \frac{1}{RT}\left(\frac{z}{2}\right)\left[x_{21}^2(g_{12} - g_{22}) + x_1 x_{11}\frac{x_{21}}{x_2}(g_{21} - g_{11})\right]$$
$$-\ln\left(x_2 + \Lambda_{21}x_1\right) + x_1\left(\frac{\Lambda_{12}}{x_1 + x_2\Lambda_{12}} - \frac{\Lambda_{21}}{x_2 + x_1\Lambda_{21}}\right) \tag{4.397}$$

The effective volume v is generally set to be the pure-liquid molar volume. The coordination number z has been found to be 6 by fitting the equation to a number of solutions. Two adjustable parameters (g_{21}-g_{11}) and (g_{12}-g_{22}) are to be determined by fitting experimental data on the binary solution. The binary-solution parameters are useful for multicomponent solutions in Equation (4.394).

Comparison with experimental data shows that the complete local-composition equation preserves the quality of Wilson's equation in describing vapor-liquid equilibrium of completely miscible systems. There are no more than slight differences between the complete equation and Wilson's equation in the fitting of data. But the complete local-composition (CLC) equation extends Wilson's local-composition equation to partially miscible solutions. Good predictions of the coexistent liquid compositions of ternary mixtures based on the binary parameters have been found for water + ethyl acetate + ethanol, for water + methyl acetate + acetone, and for water + acrylonitrile + acetonitrile.

4.3.3.8 UNIQUAC Equation

In the UNIQUAC equation (UNIversal QUAsi Chemical), Abrams and Prausnitz [10] and Maurer and Prausnitz [11] account for the congregation of molecules toward the strongly attractive by using the quasichemical equilibrium theory of Guggenheim, in which two interacting molecules are compared with a quasimolecule. The quasimolecule AB formed from unlike molecules A and B is postulated as being at association/dissociation equilibrium with the quasimolecules AA and BB,

$$\mathrm{AA} + \mathrm{BB} \leftrightarrow 2\mathrm{AB} \tag{4.398}$$

The numbers of quasimolecules, i.e., the numbers of interacting pairs, are governed by the equilibrium equation

$$\frac{N_{\mathrm{AB}}^2}{N_{\mathrm{AA}}N_{\mathrm{BB}}} = \frac{1}{4}\exp\left(-\frac{2w_{\mathrm{AB}}}{RT}\right) \tag{4.399}$$

where the exchange energy, w_{AB}, defined by $\varepsilon_{\mathrm{AB}} - (\varepsilon_{\mathrm{AA}} + \varepsilon_{\mathrm{BB}})/2$, is the energy of "dissociation/association." There is one equilibrium equation for each unlike pair like AB.

To satisfy the equilibrium equations, the number of contacts AB is given by

$$N_{\mathrm{AB}} = x_{\mathrm{A}}x_{\mathrm{B}}\exp\left(\frac{-\varepsilon_{\mathrm{AB}}}{RT}\right) \tag{4.400}$$

and similarly for all unlike and like pairs, i.e., for A = 1,2,…,v; B = 1,2,…,v. Thus the local contact numbers in Wilson's local-composition equation are recovered similarly to correlation. However, in UNIQUAC, Equation (4.400) is used to form the excess energy without normalization.

An extended Flory and Huggins equation is added in the UNIQUAC equation to account for the entropy effects of molecular size differences. The UNIQUAC g^{E} is made up of two parts,

$$g^{\mathrm{E}} = g^{\mathrm{E}}_{\mathrm{combinatorial}} + g^{\mathrm{E}}_{\mathrm{residual}} \tag{4.401}$$

The component parts are given by

$$\frac{g^{\mathrm{E}}_{\mathrm{combinatorial}}}{RT} = \sum_i x_i \ln\frac{\phi_i^*}{x_i} + \frac{z}{2}\sum_i q_i x_i \ln\frac{\theta_i}{\phi_i^*} \tag{4.402}$$

$$\frac{g^{\mathrm{E}}_{\mathrm{residual}}}{RT} = \sum_i q_i' x_i \ln\left(\sum_j \theta_j' \tau_{ji}\right) \tag{4.403}$$

where z, the coordination number, is set equal to 10. The segment fraction ϕ^* and area fractions θ and θ' are given by

$$\phi_i^* = \frac{r_i x_i}{\sum_j r_j x_j} \tag{4.404}$$

$$\theta_i = \frac{q_i x_i}{\sum_j q_j x_j} \tag{4.405}$$

$$\theta_i' = \frac{q_i' x_i}{\sum_j q_j' x_j} \tag{4.406}$$

Parameter r measures the number of segments of a molecule for the term v in the Flory-Huggins equation. Parameters q_i and q' are surface areas that are interchangeable for all except strongly hydrogen-bonded water and alcohols. Parameters r, q, and q' are pure-component molecular structure parameters. The combinatorial g^E is dependent only on pure-component parameters. The residual g^E depends additionally on binary interaction parameters τ_{ij} and τ_{ji},

$$\tau_{ij} = \exp\left(-\frac{a_{ij}}{T}\right) \tag{4.407}$$

$$\tau_{ji} = \exp\left(-\frac{a_{ji}}{T}\right) \tag{4.408}$$

where $a_{ij} = \Delta u_{ij}/R$ is an energy of interaction expressed in Kelvins. The terms a_{ij} and a_{ji} are the adjustable parameters for fitting binary-solution data.

The UNIQUAC activity-coefficient equation is given by

$$\begin{aligned} \ln\gamma_i = {} & \ln\frac{\phi_i^*}{x_i} + \frac{z}{2} q_i \ln\frac{\theta_i}{\phi_i^*} + \ell_i - \frac{\phi_i^*}{x_i}\sum_j x_j \ell_j - q_i' \ln\left(\sum_j \theta_j' \tau_{ji}\right) \\ & + q_i' - q_i' \sum_j \frac{\theta_i' \tau_{ij}}{\sum_k \theta_k' \tau_{kj}} \end{aligned} \tag{4.409}$$

where

$$\ell_j = \frac{z}{2}(r_j - q_j) - (r_j - 1) \tag{4.410}$$

For a binary solution, the equations are simplified to the following:

$$\ln\gamma_1 = \ln\frac{\Phi_1^*}{x_1} + \frac{2}{z}q_1\ln\frac{q_1}{\Phi_1^*} + \Phi_2^*\left(\ell_1 - \frac{r_1}{r_2}\right)$$
$$- q_1'\ln\left(\theta_1' + \theta_2' q_1'\right) + \theta_2' q_1'\left(\frac{\tau_{21}}{\theta_1' + \theta_1'\tau_{21}'} - \frac{\tau_{12}}{\theta_2' + \theta_1'\tau_{12}}\right) \tag{4.411}$$

$$\ln\gamma_2 = \ln\frac{\Phi_2^*}{x_2} + \frac{z}{2}q_2\ln\frac{\theta_2}{\Phi_2^*}\left(\ell_2 - \frac{r_2}{r_1}\ell_1\right)$$
$$- q_2'\ln(\theta_2' + \theta_1'\tau_{12}) + \theta_1' q_2'\left(\frac{\tau_{12}}{\theta_2' + \theta_1'\tau_{12}} - \frac{\tau_{21}}{\theta_1' + \theta_2'\tau_{21}}\right) \tag{4.412}$$

The UNIQUAC equation, based on the name UNIversal QUAsi Chemical, is applicable to liquid solutions of hydrocarbons, alcohols, nitriles, ketones, aldehydes, organic acids, and water. Partially miscible solutions are represented. The two interaction parameters are determined by fitting binary-solution data, and the equations are useful for binary as well as multicomponent solutions.

An important advantage of the UNIQUAC equation is its applicability to the solution of groups. A group is a structural part of a molecule, such as the methyl group, the methylene, the hydroxyl, the nitrile, etc. By viewing a solution of molecules as a solution of the existent groups, many molecular solutions can be described with a relatively small number of adjustable parameters. The descriptive power of the equation becomes greatly magnified. The UNIQUAC equation is renamed the UNIFAC (universal functional activity coefficient) equation when applied to solutions of groups, as discussed next.

4.3.4 Group Contribution Methods

A small number of groups make up a great variety of molecules. This fact has motivated studies of group contribution to excess properties of solutions. By viewing a solution of molecules as a solution of the groups, many solutions can be described.

To be useful as the basis for conceptually reducing solutions of molecules to solutions of groups, a group must have a distinct chemical structure, a distinct geometric configuration, and a distinct force field. It must possess all of these qualities independent of the molecule in which it finds itself. Take the methylene group. It has a distinctive chemical structure, $–CH_2$, and a distinctive geometric configuration, with the two hydrogen atoms occupying two apexes of the C-tetrahedron and with the two bonds extending toward the remaining two apexes. Methylene groups in many molecules satisfy these two conditions. The force field is determined by the electronic configuration. An indication of the electronic configuration is the localized electric charges within the group. From *ab initio* quantum mechanical calculation of whole molecules, Wu and Sandler [12] found the charge on a methylene in paraffin molecules to be +0.002e, which is practically neutral; but in a methylene adjacent to a hydroxyl group in an ethanol molecule, the charge is 0.333e. The two methylenes are different and require different interaction parameter values. Using quantum calculations, they have identified a large number of distinct groups.

4.3.4.1 Four Postulates of Group Solution

Wilson and Deal [13] suggest four postulates to describe a solution of groups for the representation of molecular solutions as follows:

1. The partial molar G^E, or simply ln γ_i, of a molecular species is made up of two parts: one due to the size differences, called ln γ_i^s, and the other due to interaction of the groups, called ln γ_i^g,

$$\ln\gamma_i = \ln\gamma_i^s + \ln\gamma_i^g \tag{4.413}$$

The subscript i denotes a molecule.

2. The contribution due to size differences of the molecules is given by the Flory-Huggins athermal solution equation. The constituent atoms (other than hydrogen) m_i are used as a measure of molecular size:

$$\ln\gamma_i^s = \ln\frac{m_i}{\sum_j x_j m_j} + 1 - \frac{m_i}{\sum_j x_j m_j} \tag{4.414}$$

3. A group i has an activity coefficient Γ_i that is a function of group fractions X_k, $k = 1, 2,\ldots,v$, and temperature. The group fraction is the mole fraction of the group in the group solution that is converted from the mole fraction x of the molecules that make up the solution:

$$X_k = \frac{\sum_j \nu_{kj} x_j}{\sum_l \sum_j \nu_{lj} x_j} \tag{4.415}$$

where X_k is the group fraction of group k, x_j is the mole fraction of molecules j, and v_{kj} is the number of k groups in a j molecule. The activity of a group can be represented by a function F:

$$\ln\Gamma_k = F_k(X_1, X_2, X_3, \ldots;\ T) \tag{4.416}$$

where F can be one of the activity-coefficient equations such as the Wilson equation or the UNIQUAC equation.

4. The group interaction contribution to the activity coefficient of molecule j, ln γ_j^g, is the sum of $\ln(\Gamma_k / \Gamma_{kj}^*)$ of all groups k in molecule j,

$$\ln\gamma_j^g = \sum_k \nu_{kj}(\ln\Gamma_k - \ln\Gamma_{kj}^*) \tag{4.417}$$

where Γ_k is given by Equation (4.416) and Γ_{kj}^* is the activity coefficient of group k in pure liquid j, and is given by the same function F of Equation (4.416):

$$\ln\Gamma_{kj}^* = F_k(X_{1,j}^*, X_{2,j}^*, \ldots;\ T) \tag{4.418}$$

The group fraction $X_{1,j}^*$ is that of group 1 in pure liquid j, and similarly for the other groups. The subtraction of $\Gamma_{1,j}^*$ in Equation (4.417) ensures that the standard state of the pure liquid is satisfied; γ_j^g always approaches 1 as $x_j \rightarrow 1$ in any solution.

4.3.4.2 Analytical Solution of Groups

In the analytical solution of groups (ASOG) method of Derr and Deal [14], the four postulates of Wilson and Deal are implemented. The activity coefficient due to molecular size differences is given by the Flory-Huggins equation, Equation (4.414), and the group activity coefficient is given by the Wilson equation,

$$\ln \Gamma_i = 1 - \ln \sum_j X_j a_{ij} - \sum_k \frac{X_k a_{ki}}{\sum_j X_j a_{kj}} \tag{4.419}$$

Equation (4.419) is identical to Equation (4.379) except for the replacement of mole fraction x by group fraction X, and molecular-interaction parameters Λ by group-interaction parameters a.

Kojima and Tochigi [15] have reported 143 sets of group-group interaction parameters a_{ij} for Equation (4.419) for 31 groups. In their work, the group count n_{kj}, the number of k groups in a j molecule, is adjusted from the molecular formula for use in Equation (4.415) and Equation (4.417):

1. Methyl and methylene are assumed to be the same and are lumped together as methylene.
2. Methyne, CH, is assumed to be CH = 0.8 CH_2.
3. Similarly, carbonium C in alkanes is C = 0.5 CH_2.
4. Water is counted as 1.6 OH groups; v H_2O = 1.6.

The count of groups in the Flory-Huggins equation is, however, not altered. In Equation (4.414), m_i remains the number of nonhydrogen atoms of molecule i.

Benzene and n-hexane have activity coefficients up to about 1.5 in the dilute range. For hydrocarbon mixtures, this is a rather large activity coefficient. Ethanol and n-heptane, however, have activity coefficients up to about 10 in the dilute range. Large activity coefficients occur for mixtures of very different components, ethanol being highly polar and n-heptane being nonpolar. The activity coefficients of acetone + methanol are only as high as about 2, which is a moderate value for these highly polar substances if compared with their activity coefficients in solutions with nonpolar substances. Comparison with experimental data shows that all three mixtures are well represented by the ASOG model with Kojima and Tochigi's parameters.

The UNIFAC (universal functional activity coefficient) method [16] is similar to the ASOG method and is based on the four postulates of Wilson and Deal [13] regarding solution of groups. In UNIFAC, the activity coefficient is made of two parts,

$$\ln \gamma_i = \ln \gamma_i^{c} + \ln \gamma_i^{R} \tag{4.420}$$

The superscripts c and R denote, respectively, the combinatorial and residual contributions. The term γ_i^c is given by

$$\ln \gamma_i^{c} = (\ln \Phi_i / x_i + 1 - \Phi_i / x_i) - \frac{1}{2} z q_i (\ln \Phi_i / \theta_i + 1 - \Phi_i / \theta_i) \tag{4.421}$$

where x is the mole fraction and z the coordination number, or the number of closest neighbors assumed to be 10:

$$\Phi_i = x_i r_i \Big/ \sum_j x_j r_j \tag{4.422}$$

The core volume r_i is given by

$$r_i = \sum_k v_{ki} R_k \tag{4.423}$$

with v_{ki} being the number of group k in molecule i, and R_k being the volume of group k.

The surface area θ_i is given by

$$\theta_i = x_i q_i \Big/ \sum_j x_j q_j \tag{4.424}$$

The surface area fraction q_i is the sum of the group values:

$$q_i = \sum_k v_{ki} Q_k \tag{4.425}$$

where Q_k is the surface area of group k.

The residual activity coefficient is the sum of group activity coefficients Γ_k,

$$\ln \gamma_i^{\mathrm{R}} = \sum_k v_{ki} \ln \Gamma_k - \ln \Gamma_k^{(i)} \tag{4.426}$$

where the summation of all groups in molecule i and $\Gamma_k^{(i)}$ is the Γ_k in a group solution that is purely molecules of i.

The group Γ_k is given by the UNIQUAC equation applied to the groups,

$$\ln \Gamma_k = Q_k \left[1 - \ln\left(\sum_m \theta_m \Psi_{mk} \right) - \sum_m \left(\theta_m \Psi_{mk} \Big/ \sum_n \theta_n \Psi_{nm} \right) \right] \tag{4.427}$$

$$\Psi_{nm} = \exp(-a_{nm} / T) \tag{4.428}$$

$$\theta_m = Q_m X_m \Big/ \sum_n Q_n X_n \tag{4.429}$$

The group fraction X is given by

$$X_m = \frac{\sum_j v_{mj} x_j}{\sum_j \sum_n v_{nj} x_j} \tag{4.430}$$

The $\Gamma_k^{(i)}$ in Equation (4.426) is determined from Equation (4.427) at group fractions $X_k^{(i)}$ of the group solution that is purely molecules of i.

Group volume R and surface area Q are presented for 50 groups by Hansen et al. [17]. While the group volume R and surface area Q are obtained from analysis of pure substance data, the group-interaction parameters are obtained from correlation of mixture vapor-liquid equilibrium data.

4.3.5 Gibbs Energy Models of Liquid Solutions

One begins by forming excess Gibbs energy, g^E, from the equation of state, according to Equation (4.283):

$$g = \int_{\infty}^{v}\left(-p + \frac{RT}{v}\right)dv + pv - RT + RT\ln\frac{RT}{v} + g^0 \quad (4.431)$$

where p stands for the equation of state. Excess Gibbs energy, g^E, is formed by substituting the eos of the mixture in this equation, followed by substituting the eos of the pure components and then combining the results at the same $[T,p]$ according to

$$g^E = g - \sum_i x_i g_i^P - RT\sum_i x_i \ln x_i \quad (4.432)$$

where g denotes the molar Gibbs energy of the mixture, and g_i^P is the molar Gibbs energy of pure i.

Using the Peng-Robinson eos, Equation (4.159), for illustration, we obtain from Equation (4.431) and Equation (4.432)

$$\frac{g^E_{eos}}{RT} = \ln\left(\frac{v}{v-b}\right) - \sum_i x_i \ln\left(\frac{v_i^P}{v_i^P - b_i}\right) + \frac{a}{2\sqrt{2}bRT}\times$$
$$\ln\left[\frac{v+b(1-\sqrt{2})}{v+b(1+\sqrt{2})}\right] - \frac{1}{2\sqrt{2}RT}\sum_i x_i(a_i/b_i)\ln\left[\frac{v_i^P + b_i(1-\sqrt{2})}{v_i^P + b_i(1+\sqrt{2})}\right] \quad (4.433)$$
$$+\frac{p}{RT}\left(v - \sum_i x_i v_i^P\right) - \ln v + \sum_i x_i \ln v_i^P$$

where the superscript P indicates a pure component, and v is the molar volume of the mixture.

The eos parameters a and b for the mixture, so far unspecified by any mixing rules, make their appearance in Equation (4.433). By setting the g^E_{eos} equal to the g^E_{sm} of a solution model, one could solve for a to make g^E_{sm} part of a, thus specifying its composition dependence and making up a mixing rule. By using the a thus obtained in the eos, the solution model becomes incorporated in the eos. To proceed to solve for a, the v's in Equation (4.433) that are so far undetermined must be specified.

The g^E_{sm} solution models fit low-pressure vapor-liquid equilibrium data for many liquid solutions. These models with fitted parameters are the prime interest to be incorporated into equations of state. To set Equation (4.433) to be equal to these g^E_{sm}'s, the v's in the equation are set to the standard-state pure-liquid volumes of a low-pressure vapor-liquid equilibrium mixture. Novenario et al. [19] calculated the saturated liquid volume for a large number of substances at low pressures with the PR eos and expressed the volume as a multiple of b,

$$v_i^P = kb_i \quad (4.434)$$

The pressure of a saturated Peng-Robinson liquid with $k = 1.15$ is between 0 and 2 atm for all the substances tested. Since Gibbs energy of a liquid is insensitive to pressure at low pressures, $v_i^P = 1.15\, b_i$ is adopted as the standard state in PR eos for pure liquids at low-pressure vapor-liquid equilibrium. Similarly, the volume of the liquid mixture is set to be $v = 1.15\, b$. Substitution of Equation (4.434) into Equation (4.433) leads to

$$\frac{g^{\mathrm{E}}_{\mathrm{eos}}}{RT} = \frac{1}{2\sqrt{2}RT}\ln\left(\frac{k+1-\sqrt{2}}{k+1+\sqrt{2}}\right)\left[\frac{a}{b} - \sum_i x_i\left(\frac{a_i}{b_i}\right)\right] + \frac{pk}{RT}\left(b - \sum_i x_i b_i\right) - \ln b + \sum_i x_i \ln b_i \tag{4.435}$$

where $k = 1.15$ for the PR eos.

Upon adopting the additive mixing rule for b,

$$b = \sum_i x_i b_i \tag{4.436}$$

The middle term of Equation (4.435) can be eliminated, and Equation (4.435) becomes

$$\frac{g^{\mathrm{E}}_{\mathrm{eos}}}{RT} = \frac{1}{2\sqrt{2}RT}\ln\left(\frac{k+1-\sqrt{2}}{k+1+\sqrt{2}}\right)\left[\frac{a}{b} - \sum_i x_i\left(\frac{a_i}{b_i}\right)\right] - \ln b + \sum x_i \ln b_i \tag{4.437}$$

Upon setting the $g^{\mathrm{E}}_{\mathrm{eos}}$ of Equation (4.437) to be equal to $g^{\mathrm{E}}_{\mathrm{sm}}$ of the solution model, we solve for a/b to obtain

$$\frac{a}{b} = \frac{2\sqrt{2}RT}{\ln\left(\frac{k+1-\sqrt{2}}{k+1+\sqrt{2}}\right)}\left(\frac{g^{\mathrm{E}}_{\mathrm{sm}}}{RT} + \ln b - \sum x_i \ln b_i\right) - \sum x_i\left(\frac{a_i}{b_i}\right) \tag{4.438}$$

Equation (4.436) and Equation (4.438) make a set of mixing rules for a and b. The fugacity coefficient obtained from the mixing rules is

$$\ln\phi_i = -\ln\left[\frac{p(v-b)}{RT}\right] + \frac{b_i}{b}(z-1) + \frac{a}{2\sqrt{2}bRT}\left[\frac{1}{na}\left(\frac{\partial n^2 a}{\partial n_i}\right) - \frac{b_i}{b}\right]\ln\left[\frac{v+b(1-\sqrt{2})}{v+b(1+\sqrt{2})}\right] \tag{4.439}$$

with

$$\frac{1}{na}\left(\frac{\partial n^2 a}{\partial n_i}\right) = \frac{b_i}{b} + \frac{b}{a}\left\{K\left[-\ln\gamma_i + \ln\left(\frac{b_i}{b}\right) + 1 - \frac{b_i}{b}\right] + \frac{a_i}{b_i}\right\} \tag{4.440}$$

and

$$K = \frac{-2\sqrt{2}RT}{\ln\left(\frac{k+1-\sqrt{2}}{k+1+\sqrt{2}}\right)} \tag{4.441}$$

The Peng–Robinson–Stryjek–Vera (PRSV) eos with the incorporation of UNIFAC activity-coefficient predicts well experimental data of numerous mixtures, including ethanol-water mixtures at 150–350°C and acetone-with mixtures at 100–250°C.

The free-energy-matching method of incorporating a solution model into an eos is not restricted to a cubic eos. The incorporation of a solution model in a noncubic equation will be illustrated in the following with the chain-of-rotators (COR) eos, Equation (4.183). The excess Gibbs energy is obtained by substituting this equation in Equation (4.431) successively for the mixture and the pure components and combining the results according to Equation (4.432). A lengthy equation is obtained, but this is simplified when the molar volumes are set at the value of the standard state $V_i = kb_i$ and $v = kb$. Novenario et al. [19] found that with $k = 0.6$, the fluids are low-pressure saturated liquids by the COR eos. The equation is further simplified with the adoption of linear mixing rules for b and c,

$$b = \sum x_i b_i \tag{4.442}$$

$$c = \sum x_i c_i \tag{4.443}$$

leading to

$$g^{\mathrm{E}}_{\mathrm{eos}} = \ln(1+1/k)\left[-\left(\frac{a}{b}\right)+\sum_i x_i\left(\frac{a_i}{b_i}\right)\right]+RT\left(\sum_i x_i \ln b_i - \ln b\right) \tag{4.444}$$

Upon setting the g^{E} of the low-pressure COR liquids of Equation (4.444) equal to that of solution model $g^{\mathrm{E}}_{\mathrm{sm}}$, we obtain the mixing rule

$$\frac{a}{b} = \frac{RT}{\ln(1+1/k)}\left(\frac{g^{\mathrm{E}}_{\mathrm{sm}}}{RT}+\sum_i x_i \ln b_i - \ln b\right)+\sum_i x_i\left(\frac{a_i}{b_i}\right) \tag{4.445}$$

where $k = 0.6$. Equation (4.442), Equation (4.443), and Equation (4.445) make up the set of *free-energy-matching mixing rules* for the COR eos. The fugacity coefficient for a mixture component i obtained from the COR eos with the mixing rules is

$$\begin{aligned}\ln\phi_i = {} & \frac{y(4-3y)}{(1-y)^2}+\frac{c_i}{2}(\alpha-1)\left[\frac{(\alpha+4)y-3y^2}{(1-y)^2}+(\alpha+1)\ln(1-y)\right] \\ & +\left(\frac{b_i}{b}\right)(z-1)-\ln z-\frac{\ln(1+4y)}{RT} \\ & \left[\frac{a_i}{b_i}+\frac{RT}{\ln(1+1/k)}\left(-\ln\gamma_i+\ln\left(\frac{b_i}{b}\right)-1-\left(\frac{b_i}{b}\right)\right)\right]\end{aligned} \tag{4.446}$$

Mixing rules based on setting $g^{\mathrm{E}}_{\mathrm{eos}}$ to be equal to $g^{\mathrm{E}}_{\mathrm{sm}}$ are often called free-energy-matching mixing rules. Huron and Vidal [18] pioneered the free-energy-matching method to apply to cubic equations of state. In their method, the molal volumes of fluids that are mixed are set to be equal

to b, so that the mixing state is at infinite pressure. As a result, the eos does not fit experimental low-pressure data, unless the solution-model parameters in the incorporated eos are refitted to the data. Huron-Vidal's method cannot utilize the wealth of correlated low-pressure g^{E}_{sm} and γ, including correlations such as ASOG and UNIFAC. By setting the mixing at a low-pressure liquid state, the method of Novenario et al. [19] succeeded in making use of liquid-solution models with parameters fitted to low-pressure data.

In the method of Wong and Sandler [20, 21], mixing rules are developed for a and b to satisfy two conditions:

1. To equate the excess Helmholtz energy of the eos at infinite pressure to that of a solution model at a low pressure
2. To impart a quadratic composition dependence to the second virial coefficient of the eos

To achieve the first condition, it is found that

$$g^{E}\,(T, p = 1\text{ bar}) \approx a^{E}(T, p = 1\text{ bar}) \approx a^{E}(T, \text{high pressure}) \approx a^{E}(T, p)$$

Using the Peng-Robinson eos for illustration, the excess Helmholtz energy is found by combining the Helmholtz energy given by Equation (4.280). Upon setting $v = b$ in the excess function to attain infinite pressure,

$$a^{E}_{eos} = -\frac{a}{b} + \sum_{i} x_i \frac{a_i}{b_i} \tag{4.447}$$

where the un-subscripted a and b refer to the mixture. Setting this excess function to be equal to the g^{E}_{sm} of a solution model and solving for the a/b of the eos,

$$\frac{a}{b} = -g^{E}_{sm} + \sum_{i} x_i \frac{a_i}{b_i} \tag{3.448}$$

This is one of the two equations that are to be solved to give the combining rules for a and b. We turn to the second virial coefficient to find the other equation to be solved for a and b.

$$b = \frac{\sum_{i}\sum_{j} x_i x_j \left(b - \frac{a}{RT}\right)_{ij}}{1 + \frac{g^{E}_{sm}}{RT} - \sum x_i \left(\frac{a_i}{b_i RT}\right) i} \tag{4.448}$$

Equation (4.447) and Equation (4.448) together make the mixing rules for a and b.

The free-energy-matching method of Wong et al. [20, 21] has been found to have good accuracy with experimental value data for ethanol-water mixtures and for acetone-water mixtures.

4.4 FLUID-PHASE EQUILIBRIA

4.4.1 Vapor-Liquid Equilibrium in a Single-Component Fluid

Vapor pressure is the pressure of a single-component fluid at vapor-liquid equilibrium at a given temperature. Conversely, at constant pressure, temperature remains constant as long as both phases coexist. Vapor pressure is the primary variable in engineering operations of evaporation, condensation, power generation, drying, humidification, and a host of others. Normal boiling point (the temperature at which vapor pressure equals 1 atm) and the critical point at the upper end of the vapor pressure curve are among the most commonly used property constants.

The vapor pressure increases rapidly as temperature is increased; an increase of five orders of magnitude is common from the triple point to the critical point. To find the vapor pressure as a function of T, we begin by finding its differential equation. Since the chemical potential of the vapor and that of the liquid are equal for all states on the vapor pressure curve, differential changes of the chemical potentials with differential changes dT and dp on the vapor pressure curve are also equal,

$$dg_v = dg_L \tag{4.449}$$

For a pure substance, the chemical potential is the molar Gibbs energy. The change of g_v due to dT and dp is given by Equation (4.88):

$$dg_v = -s_v dT + v_v dp \tag{4.450}$$

Similarly, for the equilibrium liquid,

$$dg_L = -s_L dT + v_L dp \tag{4.451}$$

Setting the last two equations to be equal according to Equation (4.449) and rearranging gives

$$\frac{dp}{dT} = \frac{\Delta_v s}{\Delta_v v} \tag{4.452}$$

The symbol Δ_v denotes the change with vaporization. The change of entropy with vaporization is equal to the heat of vaporization divided by T, therefore:

$$\frac{dp}{dT} = \frac{\Delta_v h}{T\Delta_v v} \tag{4.453}$$

This is the Clapeyron equation, the differential equation for vapor pressure as a function of T.

To integrate the equation at low pressure, we assume: the vapor volume to be given by the ideal-gas equation; the liquid volume to be negligible; and the heat of vaporization to be unchanging with T. We obtain from Equation (4.453) the Clausius-Clapeyron equation,

$$d\ln p = \frac{\Delta_v h}{RT^2} dT \tag{4.454}$$

Integration gives

$$\ln p = A - \frac{\Delta_v h}{RT} \tag{4.455}$$

where A is an integration constant. Lumping the parameters, we have the vapor pressure equation

$$\ln p = A - B/T \tag{4.456}$$

which contains two parameters to be adjusted to fit the data. This equation gives good fitting of data in a moderate temperature range, but becomes only approximate when extended to a large temperature range. By fitting the equation to the critical state and the normal boiling point, we obtain a quick approximation at the interpolation range. The deviation grows quite large at extrapolated temperatures below the normal boiling point.

$$\ln p = \frac{\ln p_c - \ln 1.0}{1/T_b - 1/T_c}\left(\frac{1}{T_b} - \frac{1}{T}\right) \tag{4.457}$$

Here pressure is atmospheric, and T is absolute temperature. Subscript b denotes boiling point, and c denotes the critical point.

Another approximate equation is obtained by interpolation between the critical point and T_r = 0.7 by employing the acentric factor,

$$\log P_r = \frac{7}{3}\left(\frac{1}{0.7} - \frac{1}{T_r}\right)(\omega + 2) - (1 - \omega) \tag{4.458}$$

A common logarithm is used in this equation. Both Equation (4.456) and Equation (4.458) are useful for making an initial estimate of either T or p in iterative computer calculations for vapor-liquid equilibrium calculations.

The Antoine equation is an empirical modification of Equation (4.456) as follows:

$$\ln p = A - B/(T + C) \tag{4.459}$$

With an additional parameter C, the Antoine equation is widely used for vapor pressure data up to about 2 bars. Over the entire temperature range, an equation of greater complexity is required. Several have been obtained by integrating Equation (4.454) based on various temperature functions for $\Delta_v h$ and $\Delta_v v$ and empirical observation. The Frost-Karkwarf-Thodos equation [1–3] is widely used with constants reported [4] for a large number of substances. The equation is

$$\ln p = A + B/T + C \ln T + Dp/T^2 \tag{4.460}$$

When or if p appears on both sides of the equation, the equation has to be solved by trial and error to find the vapor pressure.

Vapor pressure of normal fluids has been correlated in a generalized reduced form by Lee and Kessler [5] with the following:

$$\ln P_r = F^{(0)}[T_r] + \omega F^{(1)}[T_r] \tag{4.461}$$

$$F^{(0)} = 5.92714 - 6.09648/T_r - 1.28862 \ln T_r + 0.169347 T_r^6 \tag{4.462}$$

$$F^{(1)} = 15.2518 - 15.6875/T_r - 13.4721 \ln T_r + 0.43577 T_r^6 \tag{4.463}$$

A vapor pressure function $p^S[T]$ is implicit in an equation of state that covers both the gas and the liquid states. The vapor pressure functions of some equations of state are accurate over a wide temperature range, and with the use of a computer program, the implicit function becomes a convenient source of vapor pressure information; some programs can calculate vapor pressure with suitable data or with slightly expanded program code.

To find the vapor pressure using an equation of state (eos), we begin with vapor-liquid equilibrium for a single-component system:

$$f_V = f_L \tag{4.464}$$

The fugacity by an eos is given by Equation (4.307) as follows:

$$\ln(f/p) = \int_{\infty}^{v} \left(\frac{1}{v} - \frac{p}{RT} \right) dv - \ln z + z - 1$$

Taking the difference between the fugacities of the saturated liquid and saturated vapor, we obtain

$$\ln(f_L/f_V) = \frac{1}{RT} \int_{v_L}^{v_V} p\,dv + \frac{p_L v_L - p_V v_V}{RT} \tag{4.465}$$

The subscripts L and V denote the saturated liquid and the saturated vapor, respectively. An isotherm is an S-shaped curve, while an isobar is a horizontal line. At a phase-equilibrium state, $f_L = f_V$ and $p_L = p_V = p^S$, where p^S stands for the vapor pressure. Equation (4.465) rearranges to

$$p^S = \frac{1}{v_V - v_L} \int_{v_L}^{v_V} p dv \tag{4.466}$$

This is the implicit vapor pressure equation. It is solved by repeated substitution. Beginning with an estimated p^S, v_V and v_L are calculated at a given T until they converge adequately.

Example 4.16

Find the implicit vapor pressure equation of the Redlich-Kwong eos. The RK eos, Equation (4.153), will be written in a simplified form,

$$p = \frac{RT}{v-b} - \frac{a_T}{v(v+b)} \tag{4.467}$$

where a_T is a function of T and is given as $a/T^{0.5}$ for the RK eos. Substituting Equation (4.159) into Equation (4.465) and integrating gives

$$p^S = \frac{1}{v_V - v_L}\left[RT \ln\frac{v_V}{v_L} - \frac{a_T}{b}\ln\frac{v_V(v_L+b)}{v_V(v_V+b)}\right] \tag{4.468}$$

The saturated volumes v_V and v_L in Equation (4.468) are solved in the RK eos, Equation (4.467), at the vapor pressure, which makes the equation implicit. The equation can be readily solved for the saturated pressure by repeated substitution. Agreement with vapor pressure is qualitative at best.

Many eos's also provide only a qualitative representation of vapor pressure data due in part to the fact that vapor pressure by eos is determined by the integral $\int pdv$ of the eos in Equation (4.466) in the condensation range from v_L to v_V. The eos is either unstable or metastable in this range. No experimental data exist for the unstable states. Only scarce data exist for some metastable states. It is impossible to fit the eos to the pv isotherm in this range, as the isotherm hardly exists in the range of interest.

Yet it is desired that the eos give an accurate representation of vapor pressure. The key to achieving this goal is in Equation (4.468), which shows that the p^S by the RK eos is dependent on the attractive-pressure parameter a. By solving Equation (4.468) for a and letting p^S be the experimental vapor pressure, we obtain

$$a_T = \frac{RT\dfrac{v_V - b}{v_L - b} - p^S(v_V - v_L)}{\dfrac{1}{b}\ln\dfrac{v_V(v_L+b)}{v_L(v_V+b)}} \tag{4.469}$$

This equation is implicit in a_T, inasmuch as the saturated volumes are dependent on a_T, but the equation can be readily solved, for instance, by the method of repeated substitution. By using the solved value of a_T in the eos, Equation (4.162), the vapor pressure calculated by the eos simply reproduces the experimental vapor pressure data. Wilson correlated the a_T's that are fitted to vapor pressure data of a number of normal fluids to obtain Equation (4.157), the Wilson eos. Vapor pressure calculated by the Wilson eos is improved over that of the RK eos, but the accuracy still leaves something to be desired. Soave correlated the vapor pressure, fitting a_T with Equation (4.164). Even better, the Soave eos is useful for the quantitative calculation of vapor pressure. In addition, the Peng-Robinson and the chain-of-rotators eos's provide quantitative calculations of vapor pressure.

The success of vapor pressure calculation by an eos is a result of the equality of the calculated fugacities of the saturated vapor and the liquid at the true vapor pressure. The vapor fugacity is generally calculated with good accuracy, as the departure from ideal gas is not great for the gas. Hence the liquid fugacity is likewise accurately calculated by such an eos, which is a major triumph for the eos, for the departure from ideal gas is always quite large for the liquid. Since fugacity is transformed Gibbs energy, the Gibbs energy of the liquid is well represented by the eos. Because entropy is equal to the temperature derivative of Gibbs energy, the entropy of saturated liquid is well represented by the eos. By $h = g + Ts$, the eos achieves good representation of enthalpy of the liquid. Thus, by fitting vapor pressure, the eos attains quantitative fitting of the energy functions and entropy of the saturated liquid.

The initial success of the van der Waals eos to describe the existence of both the gas and the liquid marked a milestone in eos development. The more recent achievement of quantitative fitting of fugacity and energy functions of liquids is another milestone. However, the correlation of liquid *pVT* data is not improved by vdW-type equations, since adjustment is made of the integral of *pdv* in the condensation range. Liquid density predictions often deviate; using the Soave eos, detractions are often 10%–20%, depending on the temperature. The lack of fitting of *pVT* of the liquids points to the deteriorating representation of the energy functions at *compressed* liquid states, as the *incremental* changes of the energy functions from the *saturated* liquid state on are dependent on the *pVT* of the liquid. In this regard, it is noteworthy that the perturbation equations provide much better fitting of *pVT* data of liquids. It can be concluded that the vdW-type eos's, in spite of the great success of some of them in the description of vapor-liquid equilibrium (vle), are in general not suitable for high-pressure work: *pVT*, thermodynamic functions, liquid/liquid equilibrium, and so on. The perturbation eos's are the choice for high-pressure work.

4.4.2 Vapor-Liquid Equilibrium of Ideal Mixtures

An ideal mixture is one in which the ideal-solution law is followed in all phases. For the liquid phase in an ideal mixture, by Equation (4.314), the fugacity of a component i is given by

$$f_i^{\mathrm{L}} = x_i f_i^{\mathrm{PL}} \tag{4.470}$$

where the superscript L denotes a liquid, and PL a pure liquid. The fugacity of pure i is taken at the $[T,p]$ of the system. The fugacity of a component in the vapor mixture is similarly given by

$$f_i^{\mathrm{V}} = y_i f_i^{\mathrm{PV}} \tag{4.471}$$

where y_i, is the mole fraction of i in the vapor. This equation is called the *Lewis fugacity rule.*

At vapor-liquid equilibrium, the fugacity of i in the liquid is equal to that in the vapor, and it follows, by setting the two equations above to be equal and rearranging, that

$$y_i / x_i = f_i^{PL} / f_i^{PV} \tag{4.472}$$

The ratio of the mole fractions y_i and x_i at equilibrium is defined to be the K value of i, often called the equilibrium ratio or equilibrium constant,

$$K_i \equiv y_i / x_i \tag{4.473}$$

The definition is general for ideal as well as nonideal mixtures, and is a measure of the volatility of a component. A component with $K > 1$ is referred to as a light component, and one with $K < 1$, a heavy component.

The K values in an ideal mixture are given, according to Equation (4.472), by

$$K_i^{\mathrm{Id}} = f_i^{\mathrm{PL}} \big/ f_i^{\mathrm{PV}} \tag{4.474}$$

The pure-component fugacity is a substance-specific function of $[T,p]$. It follows from Equation (4.474) that ideal K values are substance-specific functions of $[T,p]$, but they are also independent of the composition of the mixture. Ideal K values provide an approximate description of mixtures of isomers, mixtures of near-neighbor homologues, and mixtures of isomers of near-neighbor homologues.

K values are useful for vapor-liquid equilibrium (vle) calculations. Five vle calculations are basic in applications:

1. Bubble-point temperature
   Given: liquid composition and pressure
   To find: vapor composition and temperature
2. Bubble-point pressure
   Given: liquid composition and temperature
   To find: vapor composition and pressure
3. Dew-point temperature
   Given: vapor composition and pressure
   To find: liquid composition temperature
4. Dew-point pressure
   Given: vapor composition and temperature
   To find: liquid composition and pressure
5. Flash
   Given: T, p, and overall composition of feed mixture
   To find: fraction of liquid formed, and composition and fraction of vapor formed and composition

The solution of the bubble- and dew-point problems using K values will be illustrated with the bubble-point temperature determination: Start by making an initial estimate of the bubble-point temperature. Using a chosen K-value chart, read K_i for the components of the mixture at the given pressure and the estimated temperature. Calculate the mole fractions of the incipient vapor by using the K values and the given x_i: $y_i = K_i x_i$ for all i. Sum the y_i's and check if the sum is equal to 1,

$$\sum_i K_i x_i = 1 \tag{4.475}$$

If the equation is not satisfied to within a specified small tolerance, the summation is repeated using a new estimated temperature until convergence is obtained The converged T is the bubble-point temperature. The method is a one-dimensional temperature search.

To find the bubble-point pressure, begin by making an estimate of the bubble pressure and carry out a one-dimensional search for the pressure at which $\Sigma_i K_i x_i = 1$ is satisfied to within a tolerance. Make a new chart reading for new K values at each new pressure. The converged pressure is the sought bubble pressure, and the converged $y_i = K_i x_i$ is the mole fraction of the vapor.

The dew-point problems are similarly one-dimensional searches, but the criterion to satisfy becomes the formation of an incipient dew expressed by the equation

$$\sum y_i / K_i = 1 \tag{4.476}$$

The solution of a flash problem requires the satisfaction of material balances in addition to the equilibrium between the vapor and the liquid. Let us take 1 mole of total feed as a basis and denote the number of moles of liquid formed as n_L and the number of moles of vapor formed as n_V. Overall mass balance requires

$$n_L + n_V = 1 \tag{4.477}$$

The component mass balance requires

$$n_L x_i + n_V y_i = z_i \tag{4.478}$$

where z_i denotes the given mole fraction i in the overall feed mixture. Equilibrium between the vapor and liquid phases requires

$$y_i = K_i x_i \tag{4.479}$$

Upon substituting Equation (4.479) into Equation (4.478) and solving for x_i,

$$x_i = \frac{z_i}{n_L + (1 - n_L)K_i} \tag{4.480}$$

The x_i's must add up to 1,

$$\sum_i \frac{z_i}{n_L + (1 - n_L)K_i} = 1 \tag{4.481}$$

Multiplying Equation (4.480) by K_i we obtain

$$y_i = \frac{K_i z_i}{n_L + (1 - n_L)K_i} \tag{4.482}$$

The y_i's must add up to 1,

$$\sum_i \frac{K_i z_i}{n_L + (1 - n_L)K_i} = 1 \tag{4.483}$$

Either Equation (4.481) or Equation (4.483) can be solved for n_L, with n_V to follow, by searching with a suitable numerical procedure in the interval from 0 to 1. The existence of an extremum within the search interval can be troublesome, though not serious; for example, interval halving will provide a solution. However, a more robust equation for numerical solution is obtained by combining the two equations. Subtracting one equation from the other gives

$$\sum_i \frac{z_i}{n_L + (1-n_L)K_i} - \sum_i \frac{K_i z_i}{n_L + (1-n_L)K_i} = 0 \tag{4.484}$$

The necessary and sufficient condition for the search for an n_L to succeed is that $\Sigma_i K_i z_i > 1$ and $\Sigma_i z_i / K_i > 1$ so as to ascertain that the specified $[T,p]$ is bracketed by the dew point and the bubble point. When the conditions are satisfied, numerous one-dimensional search procedures can be used. Upon finding n_L and n_V, the x_i's follow from Equation (4.480) and the y_i's from Equation (4.482).

Calculation of vapor-liquid equilibrium states using K values is particularly convenient for ideal mixtures for which the K values are independent of composition, changing only with temperature or pressure or both. While convenient, the K-value method does satisfy all the equilibrium conditions: the component fugacities are equal in both phases for all components in the mixture, and temperature and pressure are equal in both phases. It follows that the K-value method can be used in general for nonideal mixtures as well. The composition dependence of the K values of nonideal mixtures is addressed next.

4.4.3 Vapor-Liquid Equilibrium by γ-ϕ Models

Most mixtures are not ideal. An activity coefficient is then introduced in the liquid solution and a fugacity coefficient in the vapor of the mixture. A γ-ϕ model is made up of a selected activity-coefficient equation for the liquid and a selected equation of state for the vapor plus the associated standard-state equations and parameters.

4.4.3.1 Low-Pressure Models

Low pressure is generally meant to be less than 5 bar. The departure of a low-pressure gas mixture from ideal-gas mixture behavior is generally minor, and a simple equation of state is commonly employed to calculate the ϕ_i. The γ-ϕ model primarily counts on the activity-coefficient model to describe the vle phenomenon.

4.4.3.1.1 Fugacities of the Liquid Components

The fugacities in the liquid are given by

$$f_{iL} = x_i \gamma_i f_{iL}^P \quad i = 1, 2 \ldots v \tag{4.485}$$

An activity-coefficient equation is to be selected which, to a large extent, defines the character of the model. Examples will be given later of models of various activity-coefficient equations.

The required standard-state fugacity f_{iL}^P in Equation (4.485) is given by

$$f_L^P = p^S \phi^S \exp\left[\frac{v_L^S (p - p^S)}{RT}\right] \tag{4.486}$$

The subscript i is left out of Equation (4.486) to address the pure component. Of the three factors on the right-hand side of the equation that make up the standard fugacity, the first one, p^S, is the primary factor. For a nonpolar component at a low pressure, a good approximation ignores the other two factors, thereby simplifying the standard fugacity to be just the vapor pressure. Such a simplification may introduce an overestimate of the standard fugacity by ≈1% for a nonpolar liquid at its normal boiling point. The next higher approximation is to ignore only the exponential factor that accounts for the pressure effect on the liquid fugacity. This factor generally does not differ significantly from 1. For the difference $(p - p^S)$ as much as 5 atm, the exponential factor does not

differ more than 2 or 3% from 1. However, the fugacity coefficient of the saturated vapor ϕ^S cannot be ignored for polar components, as it is often significantly smaller than 1. Values as low as ≈0.3 have been reported for some carboxylic acids. The fugacity coefficient can be estimated with the truncated second virial equation. The virial equation is discussed in Section 4.2.5.

For normal fluids, an alternative to the use of vapor pressure to find the standard liquid fugacity f_L, is to use a generalized correlation such as the correlation by the acentric factor method,

$$\log \nu = \log \nu_0 + \omega \log \nu_1 \tag{4.487}$$

where ν is f/p and ω is the acentric factor. The tabulated liquid values of Curl and Pitzer [6] and Lydersen, Greenkorn, and Hougen [7] are fitted by Chao and Seader [8] with the following functions:

$$\begin{aligned}\log v_0 = {} & 5.75748 - 3.01761/T_r - 4.98500T_r + 2.02299T_r^2 \\ & + (0.08427 + 0.26667T_r - 0.31138T_r^2)p_r \\ & + (-0.02655 + 0.02883T_r)\, p_r^2 - \log p_r\end{aligned} \tag{4.488}$$

$$\begin{aligned}\log v_1 = {} & -4.23893 + 8.65808T_r - 1.22060/T_r - 3.15224T_r^8 \\ & - 0.025(p_r - 0.6)\end{aligned} \tag{4.489}$$

Equation (4.488) and Equation (4.489) are valid in the range $1.3 > T_r > 0.5$ and $p_r < 9.0$. Upon obtaining v from the three equations above, f_L is found by

$$f_L = vp \tag{4.490}$$

4.4.3.1.2 Fugacities of the Gas Components

For the gas mixture, the fugacities are given by

$$f_{iV} = y_i \phi_i p \qquad i = 1, 2 \ldots v \tag{4.491}$$

where the fugacity coefficient ϕ_i is to be obtained from a selected eos. Nonpolar mixtures at a low pressure of 1 bar or lower are often assumed to be ideal gas, $\phi_i = 1$ for all i. The ideal-gas assumption is made for even higher pressure gases, depending on the degree of approximation that is acceptable. For nonpolar and polar gases to moderate pressures, the virial eos truncated at the second virial coefficient gives reliable results of ϕ_i. The results may not be as reliable for highly associated substances like carboxylic acids and HF. Using the second virial eos, the fugacity coefficient is given by

$$\ln \phi_i = \frac{2}{v} \sum_j y_j B_{ij} - \ln z \quad i = 1, 2 \ldots, \nu \tag{4.492}$$

The ν and z in this equation are to be solved from the second virial eos,

$$z = 1 + \frac{1}{v}\sum_i \sum_j y_i y_i B_{ij} \tag{4.493}$$

at the specified [*T,p*]. A correlation of second virial coefficient is found in Section 4.2.5

4.4.3.1.3 Equilibrium Equations and Calculations

Equilibrium between the gas and liquid phases requires the fugacities of component *i* in both phases to be equal,

$$x_i \gamma_i f_{iL}^P = p y_i \phi_i, \quad i = 1, 2 \ldots v \tag{4.494}$$

These are the equilibrium equations of the γ-φ model that are to be solved for the unknown variables among *T*, *p*, *x*, *y*, n_L, or n_V from the known variables simultaneously with the mass balances and/or other applicable constraint equations. A common method of solution of the simultaneous equations is to use *K* values. From Equation (4.494) the *K* values are formed,

$$K_i \equiv y_i / x_i = \gamma_i f_{iL}^P / (p\phi_i) \quad i = 1, 2, \ldots \nu \tag{4.495}$$

As described in Section 4.4.2, the *K* values are useful for the calculation of the bubble, dew, or flash states. However, the method of calculation described in Section 4.4.2 needs to be modified because the *K* values formed by Equation (4.495) are not constant at a specified [*T,p*] but change with composition. The method of repeated substitution is suited to the use of composition-dependent *K* values: One begins by making an initial estimate for the variables that are being sought, be it *p*, *T*, x_i, y_i, n_V, or n_L, while using specified values of the specified variables. The K_i's are computed by Equation (4.495). The bubble, dew, or flash calculations are made as described in Section 4.4.2 to obtain values of the sought variables, be it *T*, *p*, x_i, y_i, n_V, or n_L, The calculated variables are generally not the same as the initial estimates. Use the calculated values as the new estimates and repeat the equilibrium calculation until adequate convergence occurs.

The equilibrium calculations are straightforward without iteration if the gas phase is an ideal-gas mixture, as it may be assumed at low pressures for normal fluids. Consider the bubble-point pressure problem: given *T* and x_i, find *p* and y_i. From Equation (4.487),

$$y_i p = x_i \gamma_i f_{iL}^P / \phi_i \tag{4.496}$$

Summing over *i* and setting Σy_i equal to 1 at the bubble pressure, we obtain the bubble pressure

$$p = \sum_i X_i \gamma_i f_{iL}^P / \phi_i \tag{4.497}$$

The vapor composition is obtained by dividing Equation (4.496) by Equation (4.497),

$$y_i = (x_i \gamma_i f_{iL}^P / \phi_i) \Big/ \left(\sum_j x_j \gamma_j f_{jL}^P / \phi_j \right) \tag{4.498}$$

The two equations are the complete solutions of the bubble-point problem, but the equations are implicit because the ϕ_i's are functions of y_i and *p*, and $f_{iL}{}^P$ and $f_{jL}{}^P$ are functions of *p*. Repeated

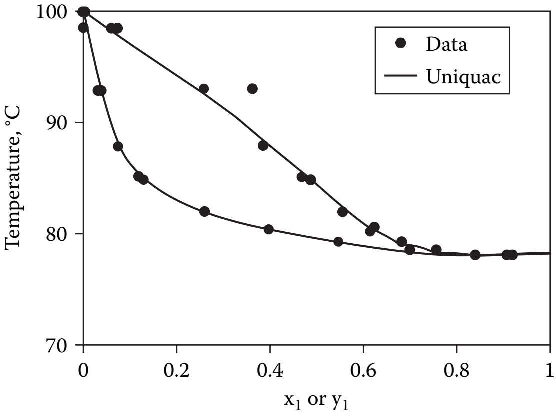

FIGURE 4.15 T-x-y phase diagram for ethanol(1) + water(2) mixtures at 1 atm calculated from UNIQUAC compared with data. (Kojima & Tochigi, New York: Elsevier Scientific Publishing, 1979. With permission.)

substitution leads to solution. The solution of the equations becomes a straightforward matter of substitution for low-pressure mixtures upon assuming ideal gas for the vapor, whereupon $\phi_i = 1$. It is also necessary to leave out the exponential factor from f_{iL}^{P} so that it is simplified to be $\phi_i^S p_i^S$ or, for nonpolar mixtures, to p_i^S.

For the basic vle problems other than the bubble pressure, there is no special advantage to using equations similar to Equation (4.497) and Equation (4.498) in place of the *K*-value method, as they do not afford an explicit straightforward solution, but require an iterative solution.

An extensive compilation of experimental vle data is found in the Dechema Chemistry Data Series, which includes thousands of mixture systems. Several eos's do a fair-to-excellent job of correlating equilibrium data and calculating activity coefficients, including Margules, Van Laar, Wilson, NRTL, UNIFAC, and UNIQUAC, as indicated for data at atmospheric pressure. The examples all have minimum boiling azeotropes. UNIQUAC gave the best agreement of predicted versus experimental data values for the following binary mixtures: ethanol–water (Figure 4.15), benzene–cyclohexane (Figure 4.16), and ethanol-in-heptane. ASOG was also found to do an excellent job of correlating the above-mentioned systems. Figure 4.17 shares the results for the ethanol–n-hexane mixture.

4.4.3.2 A High-Pressure Model

The Chao-Seader correlation [8] is applicable up to high pressures for normal fluids, including hydrocarbons (paraffins, olefins, aromatics, and naphthenes) and inert gases (methane and hydrogen). The correlation is a combination of three parts: (a) pure-liquid fugacity coefficient ν_i, (b) liquid-solution activity coefficient γ_i, and (c) gas mixture fugacity coefficient ϕ_i. From these parts, the liquid fugacities and vapor fugacities are obtained:

Liquid fugacities: $$f_{i\mathrm{L}} = x_i \gamma_i \nu_i p \quad i = 1, 2 \ldots v \tag{4.499}$$

Vapor fugacities: $$f_{i\mathrm{V}} = y_i p \phi_i \quad i = 1, 2 \ldots v \tag{4.500}$$

The vle equations are obtained by setting the liquid and gas fugacities equal for each component,

$$x_i \gamma_i \nu_i p = y_i p \phi_i \quad i = 1, 2 \ldots, v \tag{4.501}$$

Rearranging x_i and y_i, to the left side and the other variables to the right gives

$$y_i / x_i = \nu_i \gamma_i / \phi_i \quad i = 1, 2, \ldots v \tag{4.502}$$

Upon setting $K_i \equiv y_i/x_i$ in Equation (4.502), it follows that

$$K_i = \nu_i \gamma_i / \phi_i \quad i = 1, 2, \ldots, v \tag{4.503}$$

The three factors—ν_i, γ_i, and ϕ_L—that make up the *K* value in Equation (4.503) are described in the following subsections.

4.4.3.2.1 Pure-Liquid Fugacity Coefficient

The liquid fugacity coefficient plays the part of an ideal *K* value. Indeed, it *is* the *K* value if the liquid solution is ideal $\gamma_i = 1$ and the gas phase is an ideal-gas mixture $\phi_i = 1$. Equations (4.487)

to (4.489) give v as a function of T_r and p_r. The valid range of these equations is $1.3 > T_r > 0.5$ and pressure up to $p_r \approx 9$.

For light gases such as methane and hydrogen, states of common engineering interest are at much higher T_r than the valid range of states for Equations (4.487) to (4.489). A special equation is developed for each gas to fit ν values of the hypothetical liquid of the gas. The equation for methane is

$$\begin{aligned} \log v &= 2.43840 - 2.24550/T_r - 0.34084T_r \\ &+ 0.00212T_r^2 - 0.00223T_r^3 \\ &+ (0.10486 - 0.03691T_r)p_r - \log p_r \end{aligned} \tag{4.504}$$

The equation is valid at 530 > > 200 and pressure up to 55 MPa.

For hydrogen,

$$\begin{aligned} \log v &= 0.8669098 + 9.9195929/T_r - 31.4141598/T_r^2 \\ &+ 37.4500656/T_r^3 + (0.0183734 - 0.1460381/T_r \\ &+ 0.8545416/T_r^2 - 1.1687170/T_r^3)p_r \\ &- 0.0000691p_r^2 - \log p_r \end{aligned} \tag{4.505}$$

The hydrogen of Equation (4.505) is an update by Jin, Greenkorn, and Chao [9] from the original Chao and Seader correlation. The upper temperature limit is extended by the update to about 730°K. The lower limit remains at 200°K, with pressure up to 25 MPa.

4.4.3.2.2 Liquid-Solution Activity Coefficient γ_i

The activity coefficients are given by the regular solution equation,

$$RT \ln \gamma_i = v_i(\delta_i - \delta_m)^2 \tag{4.506}$$

The equation is discussed in Section 4.3.3. Two parameters are required for each component: v_i is the pure i liquid molar volume at 298°K, and δ_i is the solubility parameter of component i. The solubility parameter of the mixture δ_m is given by the volumetric average of the components $\delta_m = \Sigma_i x_i v_i \delta_i / \Sigma_i x_i v_i$. Parameters are available for numerous substances. Additional parameters can be readily determined from their definitions, when the need arises, except for light gases.

4.4.3.2.3 Gas Fugacity Coefficient ϕ_i

In the Chao-Seader correlation, the fugacity coefficient in the gas mixture is obtained from the Redlich-Kwong eos and is as follows:

$$\ln \phi_i = \ln \frac{v}{v-b} + \frac{b_i}{v-b} - \frac{2\sum_j y_j a_{ji}}{RTb} \ln \frac{v}{v-b} + \frac{ab_i}{RTb^2}\left(\ln \frac{v}{v+b} - \frac{b}{v+b}\right) - \ln z \tag{4.507}$$

The molar v in this equation is to be solved from the RK eos,

$$p = \frac{RT}{v-b} - \frac{a}{T^{0.5}v(v+b)} \tag{4.508}$$

The resulting Chao-Seader correlation predicts K values of both methane/n-heptane mixtures and propane/isopentane mixtures down to at least $T_r = 0.5$.

4.4.4 Vapor-Liquid Equilibrium by ϕ-ϕ Models

In a ϕ-ϕ model, one equation of state is used to obtain both the gas-phase fugacity coefficients ϕ_{iV} and the liquid-phase fugacity coefficients ϕ_{iL}. Upon setting the gas and liquid fugacities of a component i to be equal and canceling the pressure on both sides of the equation, we obtain

$$\phi_{iV} y_i = \phi_{iL} x_i \tag{4.509}$$

The K value, defined to be the ratio y_i/x_i, is obtained by rearranging Equation (4.509) as the ratio of the fugacity coefficients,

$$K_i = \phi_{iL} / \phi_{iV} \tag{4.510}$$

While the same eos-derived ϕ equation is used for both ϕ_{iL} and ϕ_{iV}, the input variables to the equation are different: for ϕ_{iL}, the liquid mol fractions x_i and liquid molar volume v_L are the input; for ϕ_{iV}, the gas mol fractions y_i and gas molar volume v_V are the input. Find the liquid volume v_L by solving the eos at specified [x_i p,] and pick the small root; find the vapor volume v_V by solving the eos at specified, [y_i p,] and pick the large root. The vapor-liquid equilibrium calculations using K values are much the same as in the use of γ-ϕ K values.

4.4.4.1 ϕ-ϕ Models—ϕ from vdW Mixing Rules

In this subsection, we present examples of ϕ-ϕ models in which ϕ is derived from vdW mixing rules by which the parameters a and b of mixtures are combinations of the parameters of the components according to

$$a = \sum_i \sum j x_i x_j a_{ij} \tag{4.511}$$

$$b = \sum_i \sum j x_i x_j b_{ij} \tag{4.512}$$

The identical double subscripts refer to a pure component, thus $a_{ii} \equiv a_i$ and $a_{ii} \equiv b_i$. The cross interaction a_{ij} is conventionally expressed as an adjusted geometric mean of the pure-component a's:

$$a_{ij} = (1 - k_{ij})\sqrt{a_i a_j} \tag{4.513}$$

The parameter k_{ij} is obtained by fitting experimental data on binary mixtures of i and j. It is common practice to estimate b_{ij} as the arithmetic mean,

$$b_{ij} = b_i + b_j / 2 \tag{4.514}$$

Substituting Equation (4.514) into Equation (4.512) leads to the linear combination rule for b,

$$b = \sum_i x_i b_i \tag{4.515}$$

These rules are useful for normal fluids, including nonpolar and weakly polar substances.

Example 4.17: vle by Soave eos

The Soave eos has been presented as Equation (4.162) and Equation (4.164). Using van der Waals mixing rules, the fugacity equation is obtained and given as Equation (4.312). The vapor/liquid equilibrium values were calculated for methane/n-butane mixtures at 310.9°K. Both dew-point and bubble-point curves were in excellent agreement at all vapor pressures up to the critical point. For the hydrogen/propane mixture at 310.9°K, there is excellent agreement of the calculated dew-point curve with data at all pressures from the vapor pressure of propane to the critical point, but agreement is not as good on the bubble-point curve. It was assumed that $k = 0$ in these calculations. Because of the large difference between hydrogen and propane molecules, adjustment of k may improve the calculated values.

To find out the accuracy of vle calculations, Han et al. [10] compared the Soave eos K values ϕ_{iL}/ϕ_{iV} calculated at the experimental equilibrium states with experimental K values, y_i/x_i. The deviation of the eos K value from the experimental is chosen for the comparison for the reason that the K value is the quantity used in the vle calculations; furthermore, the deviation of the K values is identical to the deviation from equality of the calculated liquid fugacity and the vapor fugacity at the experimental equilibrium state, as shown by

$$\frac{K_{i,cal}}{K_{i,\exp}} = \frac{\phi_{iL}/\phi_{iV}}{y_i/x_i} = \frac{\phi_{iL}x_i}{\phi_{iV}y_i} = \frac{f_{iL}}{f_{iV}} \tag{4.516}$$

A cross-interaction coefficient, k, was determined for each binary system by minimizing the sum of the squared relative deviations for the K values as compared with experimental data points. Numerous mixtures were included, such as symmetrical binary mixtures, binary mixtures containing hydrogen, and binary mixtures containing methane. For the numerous mixtures investigated, the average absolute deviation (AAD) often was in the range of ≤5% but occasionally was slightly over 10%. The cross-iteration coefficient, k, was relatively high for mixtures of hydrogen/heavy solvents, but was in the range of 0.01 to 0.7 for mixtures of methane and hydrocarbons.

Requiring no substance-specific parameters other than the critical properties and acentric factor, and using van der Waals mixing rules, the Soave eos gives quantitative results for vle calculations for normal fluids, including hydrocarbons and nonpolar light gases. However, density calculations with this eos show deviations over a wide range of temperatures of 10%–20%. When the vle results are to be reported in moles and mole fraction, the Soave equation finds wide application.

Example 4.18: vle by Peng-Robinson eos

The Peng-Robinson eos has been presented as Equation (4.165). Using van der Waals mixing rules, the fugacity equation is obtained by substituting the eos in Equation (4.306), leading to the following:

$$\ln\phi_i = \frac{b_i}{b}(z-1)\ln\left[\frac{p}{RT}(v-b)\right] - \frac{a}{2\sqrt{2}bRT}\left(\frac{2\sum_k x_k a_{ki}}{a} - \frac{b_i}{b}\right)\ln\left(\frac{v+2.414b}{v-0.414b}\right) \tag{4.517}$$

The vle phase results for methane and propane mixtures at 213.71°K were calculated using an interaction parameter to 12 of 0.0114; excellent agreement was found with experimental dew points and bubble points at pressures up to the initial point. Similar calculations (with good agreement with experimental data) have also been made for mixtures of methane and haptane and of carbon dioxide and n-butane.

Han et al. [10] made many comparisons of the Peng-Robinson eos K values ϕ_{iL}/ϕ_{iV} calculated with experimental K values y_i/x_i. For the eos K-value calculations, a cross-interaction coefficient k is determined for each binary system. For 20 symmetric binary systems for which the experimental temperature is below the critical of both components, the average absolute deviation (AAD) of the calculated from the experimental was found to be ≈2.5%. The AAD for the individual systems fall in the range from the smallest value of ≈1.0% for ethylene + propylene to the largest value of ≈4.3% for propylene + isobutene.

The PR eos gives excellent quantitative representations of the vle of normal fluids, including hydrocarbons and nonpolar and slightly polar light gases, using van der Waals mixing rules. The representation of liquid density is fairly good, making vle results expressed in volume fractions readily useful. The PR eos is widely used in engineering design applications.

Example 4.19: vle Chain-of-Rotators eos

The chain-of-rotators (COR) eos has been presented in Equation (4.183). For mixtures, using van der Waals mixing rules for a and b and linear additive rule for c,

$$c = \sum_i x_i c_i \tag{4.518}$$

and following the method of Equation (4.306) leads to the fugacity coefficient equation

$$\begin{aligned}\ln\phi_i = {} & \frac{y(4-3y)}{(1-y)^2} + \frac{c_i}{2}(\alpha-1)\left[\frac{(\alpha+4)y-3y^2}{(1-y)^2} + (\alpha+1)\ln(1-y)\right] \\ & -\frac{\ln(1+4y)}{RT}\left[-b_i\left(\frac{a}{b^2}\right) + \frac{2}{b}\left(\sum_j x_j a_{ij}\right)\right] + \frac{b_i}{b}(z-1) - \ln z\end{aligned} \tag{4.519}$$

The parameters a and b in this COR eos are functions of T as follows:

$$a = a_1 \exp(-a_2 T) \tag{4.520}$$

$$b = b_1 \exp(-b_2 T^{1.5}) \tag{4.521}$$

Five parameters—a_1, a_2, b_1, b_2, and c—are required to be known for the eos to apply to a substance. The parameter values have been reported in the literature for numerous substances. For 11 hydrocarbon mixtures, the average AAD was 2.3% (ranging from 0.5 to 5.65%). For 12 methane-containing mixtures, the AAD was 3.92% (ranging from 1.32 to 8.16%). The five parameters required for each substance are a drawback to convenient application. The eos is superior in its representation of density of liquid and compressed fluid states—to within 1% up to the highest pressures.

The chain-of-rotators eos often predicts vle information for ternary systems except near the critical point; a good example is the mixture of methane, n-butane, and decane.

Han et al. [10] compared the COR eos K values ϕ_{iL}/ϕ_{iV} calculated with experimental K values y_i/x_i. For the eos calculations, a cross-interaction coefficient k is determined for each binary by

minimizing the sum of the squared relative deviations for the K values for both components in all the reported experimental data points.

4.4.4.2 Free-Energy-Matching Mixing Rules

By matching the excess free energy of an equation of state to that of a solution model, eos parameters for mixtures are obtained from the solution model. The solution model is thus made part of the eos. Incorporating a suitable solution model, the eos becomes applicable to mixtures of highly nonideal polar and associating substances. As part of an eos, the solution model is extended to apply to high pressure. The method of incorporating a solution model into an eos is described in Section 4.3.5.

Example 4.20: Peng-Robinson-Stryjek-Vera (PRSV) eos + UNIFAC

The PR eos has been modified by Stryjek and Vera to extend to polar substances that do not follow the three-parameter principle of corresponding states. The modified eos is fitted to the vapor pressure of polar substances with additional substance-specific parameters. The PRSV equation has been described in Equation (4.163) et seq. The free-energy-matched mixture eos parameters are given in Equations (4.436) and (4.438); the fugacity coefficients are given in Equation (4.439). PRSV eos using the UNIFAC activity coefficient predicts the vle data for both ethanol/water mixtures at 423–623°K and acetone/water mixtures at 373–523°K from low to high pressure.

Example 4.21: COR eos + UNIFAC

Free-energy-matching mixing rules for COR eos parameters were obtained in Equation (4.442), Equation (4.443), and Equation (4.445). The fugacity coefficient for a mixture component obtained from the COR eos with the mixing rules was given in Equation (4.446). Upon substituting the UNIFAC in these equations, fugacities are calculated for both the liquid and gas mixtures to form the vle phase diagram, for example, the vle diagram of ethanol/water mixture as predicted using UNIFAC or the PRSV eos plus UNIFAC.

4.4.5 Liquid-Liquid Equilibrium Models

When the liquid-liquids are highly nonideal, two immiscible liquid phases form. Then only a few activity-coefficient models and equations of state can be used.

Using activity-coefficient models, the equality of component fugacities of the two liquid phases at equilibrium is expressed by

$$x_{i\alpha}\gamma_{i\alpha}f_i^{\mathrm{P}} = x_{i\beta}\gamma_{i\beta}f_i^{\mathrm{P}} \quad i = 1, 2, \ldots, \nu \tag{4.522}$$

where the subscript α denotes one phase and β the other phase, and superscript P denotes the pure-liquid standard state. Since the standard-state fugacity is the same on both sides of the equation, it cancels out, leaving

$$x_{i\alpha}\gamma_{i\alpha} = x_{i\beta}\gamma_{i\beta} \quad i = 1, 2, \ldots, \nu \tag{4.523}$$

To find the equilibrium-phase compositions, it is convenient to form the distribution coefficient and perform flash calculations similar to the vle calculations described in Section 4.4.2. For liquid-liquid equilibrium (lle), the distribution coefficient is defined as

$$c_i = x_{i\alpha} / x_{i\beta} \tag{4.524}$$

By Equation (4.523), c_i is calculated by

TABLE 4.5
Find Liquid-Liquid Equilibrium Phase Compositions in a Three-Component Mixture

1. Initialization: Assign a value for x_1. Make initial estimate of mol fractions of all components in both phases other than x_1.
2. $x_{2\alpha} = x_{2\beta}\gamma_{2\beta}/\gamma_{2\alpha}$
3. $x_{3\alpha} = x_{3\beta}\gamma_{3\beta}/\gamma_{3\alpha}$
4. $x_{2\alpha} = x_{2\alpha}(1 - x_{1\alpha})/(x_{2\alpha} + x_{3\alpha})$
5. $x_{3\alpha} = x_{3\alpha}(1 - x_{1\alpha})/(x_{2\alpha} + x_{3\alpha})$
6. $x_{1\beta} = x_{1\alpha}\gamma_{1\alpha}/\gamma_{2\beta}$
7. $x_{2\beta} = x_{2\alpha}\gamma_{2\alpha}/\gamma_{2\beta}$
8. $x_{3\beta} = x_{3\alpha}\gamma_{3\alpha}/\gamma_{3\beta}$
9. $x_{1\beta} = x_{1\beta}/(x_{1\beta} + x_{2\beta} + x_{3\beta})$
10. $x_{2\beta} = x_{2\beta}/(x_{1\beta} + x_{2\beta} + x_{3\beta})$
11. $x_{3\beta} = x_{3\beta}/(x_{1\beta} + x_{2\beta} + x_{3\beta})$
12. Check convergence: Are all mol fractions unchanged within a specified tolerance from the preceding iteration values? If unchanged, calculation is successfully completed. If changed, repeat iteration by going to step 2.

Source: Adapted from data provided by Sandler, S. I. *Chemical and Engineering Thermodynamics*, 3rd ed., New York: John Wiley & Sons, 1999.

$$c_i = \gamma_{i\alpha} / \gamma_{i\beta} \tag{4.525}$$

from the chosen activity-coefficient model at the phase compositions of either the initial estimate or the current iteration. Using c_i in place of K_i, perform a flash calculation on an estimated total feed composition in between the estimated equilibrium phase compositions. Since the c_i's are composition dependent, it is necessary to iterate until convergence. The flash calculation is repeated with the obtained phase compositions to recalculate the activity coefficients; by Equation (4.525) obtain c_i; then perform a flash calculation to obtain phase compositions and check convergence. Flash calculation is a relatively robust method for lle calculations, but it is still not as robust as it is for vle calculations. Initial estimated compositions are particularly important for success.

Another method to calculate equilibrium-phase compositions makes use of repeated substitutions in the fugacity equality conditions, Equation (4.523), while disregarding any mass balances required in the flash calculations. Suppose T and p are given. The variables are $2v$ mol fractions. There are v equilibrium equations and two equations expressing the sum of x being equal to 1 in either phase, totaling $(v + 2)$ equations. The degree of freedom is the number of variables $2v$ minus the number of equations $(v + 2)$; $F = v - 2$. The method will be illustrated with a three-component mixture, $v = 3$ and $F = 1$. One degree of freedom must be specified; let it be $x_{1\alpha}$. Table 4.5 shows a flow sheet of the method.

Besides being expressed in terms of activity coefficients, the fugacities of a liquid solution can also be calculated from equations of state in the form of a fugacity coefficient ϕ_i. The equality of fugacities of two liquid phases at equilibrium becomes expressed by

$$\phi_{i\alpha} p x_{i\alpha} / \phi_{i\beta} p x_{i\beta} \tag{4.526}$$

Canceling p from both sides of the equation,

$$\phi_{i\alpha} x_{i\alpha} = \phi_{i\beta} x_{i\beta} \tag{4.527}$$

For the calculation of the equilibrium phase compositions, it is convenient to use the distribution coefficient c_i ($\equiv x_{i\alpha}/x_{i\beta}$) to perform a flash calculation. The distribution coefficient for the flash calculation is now formed according to Equation (4.527) by

$$c_i = \phi_{i\beta} / \phi_{i\alpha} \tag{4.528}$$

Using the c_i's from this equation, the flash method and the method illustrated in Table 4.3 are just as applicable as using c_i from Equation (4.525).

Example 4.22: lle by NRTL

The NRTL activity-coefficient equations have been presented in Section 4.3.3; they are generally preferred in the representation of lle in ternary systems with the use of only binary parameters. With the best estimates of the parameters α_{12}, it is possible to obtain a good ternary lle by using the other two binary parameters fitted to vle data. But a reliable estimate of α_{12} remains elusure. Renon et al. [11] report that reliable representation for ternary systems can only be obtained by fitting all nine binary parameters to extensive ternary data.

Example 4.23: lle by UNIQUAC

For the UNIQUAC equation, there are two adjustable equation parameters for each binary. For the binary that is partially miscible, the best way to determine the two binary parameters is to fit the mutual solubility data. For the completely miscible binaries, useful interaction parameters can be obtained from vle data. However, fitting vle data to within experimental accuracy does not uniquely determine the binary parameters. The choice of a particular set of parameters can have a significant effect on the representation of the ternary lle. For the ternary system of chloroform, water, and acetone at 333°K, for example, the two binary parameters are first determined from mutual solubility data for chloroform and water and then the other binary parameters for the two miscible binaries. Somewhat improved predictions occur by fitting binary parameters to the miscible binaries. Similar predictions have also been found for ternary systems of ethyl acetate, ethanol, and water.

Some predictions have also been obtained with the UNIQUAC equation for termary systems containing two immiscible binaries and one completely miscible binary. The ternary of a mixture of m-hexane, aniline, and methyl cyclopentane is such an example.

Example 4.24: lle by UNIFAC

Less success has been obtained to date in predicting lle as compared with vle data. The absolute mean deviation between experimental and calculated mole fractions for 17 ternary lle test systems is found to be 9.22 mole %. To improve fitting of data, UNIFAC parameters have been redetermined based on lle data, and a new table of interaction parameters has been prepared by Magnussen et al. [12] while keeping the pure-component parameters R and Q unchanged. Using the lle parameters, the fitting of data is improved. The absolute mean deviation between data and calculations is reduced to 1.73 mole % for the same 17 text mixtures.

Table 4.6 is an abridgment of the table showing interaction parameters. Having different tables presents no great difficulty in the storing and using the parameters. But difficulty arises in vlle calculations, such as in extractive distillation where vle and lle coexist. A choice has to be made for either set of parameters.

Example 4.25: lle by UNIQUAC

The UNIQUAC equation has been presented in Section 4.3.3. There are two adjustable equation parameters for each binary. For the binary that is partially miscible, the best way to determine the two binary parameters is to fit the mutual solubility data. For the completely miscible binaries, useful interaction parameters can be obtained from vle data. However, fitting vle data to within experimental accuracy does not uniquely determine the binary parameters. The choice of a particular set of parameters can have a significant effect on the representation of the ternary lle. The following example has been predicted: chloroform-water-acetone at 333°K (using UNIQUAC calculation with binary parameters). Even better results were obtained by fitting the binary parameters of the miscible binaries to ternary lle data. Some examples of good predictions include the following

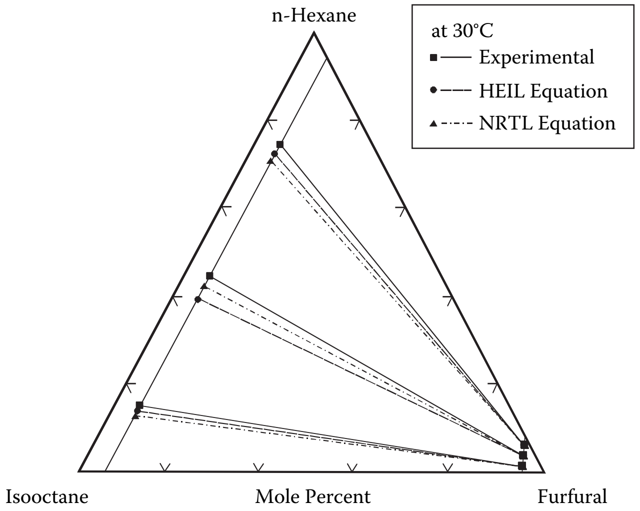

FIGURE 4.18 NRTL-calculated and observed lle in iso-octane (1) + n-hexane (2) + furfural (3) at 30°C. (From J.M. Prausnitz, AIChE J. 14:135, 1968.)

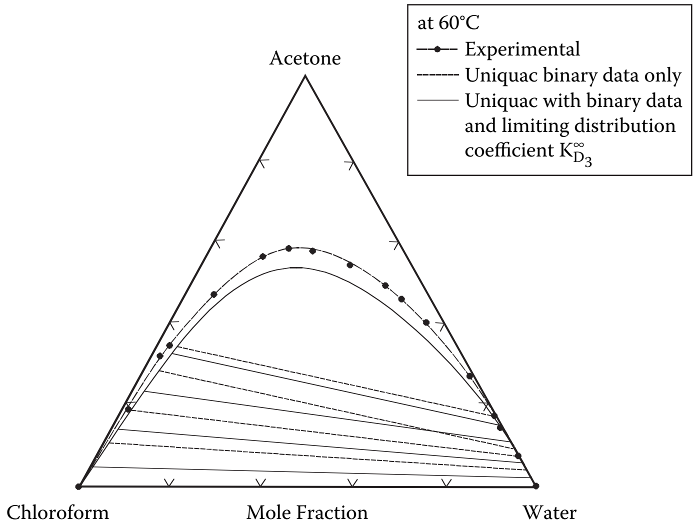

FIGURE 4.19 UNIQUAC-calculated and observed lle in chloroform (1) + water (2) + acetone (3) 60°C. Concentration is mass fractions. (From D. Abrams, J.M. Prausnitz, AIChE J. 21:116, 1975.)

systems: (a) furfural–benzene–isooctane; (b) furfural–n-hexane–isooctone (see Figure 4.18); (c) chloroform-acetone-water (see Figure 4.19); (d) n-hexane–hexane–aniline–methylpentane. An important difference in these systems is the plait point (meeting point of the two immiscible liquid phases); here the activity-coefficient equations are invalid.

Example 4.26: lle by the Complete Local-Composition Model

Addition of an excess energy term to the Hang–Chao–Hilson complete local-composition model, presented earlier, can be used to model liquid-liquid equilibrium. For combinations of water-ethyl acetate-ethanol, predicted values agree well with data at 328°K at low concentrations of ethanol. The predictions are poorer as the ethanol concentration approaches the critical amount. For the combination of water-ethyl acetate-acetonitrile, predictions are better even in the region of critical

concentration. For the combination of benzene–n-heptane–acetonitrile, the model predicts well even at high concentrations. Such predictions can be used in liquid-liquid extractions.

Example 4.27: Comparison of lle by SAFT, Peng-Robinson, and UNIFAC

You and Chen [13] have compared these three eos's for calculating lle. They employed data for 5 binary mixtures of methanol + an aliphatic hydrocarbon, 6 binaries of phenol + an aliphatic hydrocarbon, 12 binaries of water + an aliphatic or a hydrocarbon, 7 binaries of water + an ester, 5 binaries of acetic acid + an aliphatic or a naphthenic hydrocarbon, and 6 binaries of aniline + an aliphatic or a naphthenic hydrocarbon. Temperature was in the range of 273–343°K, with one exception at 236°K.

Predictions of calculated versus experimental data were in the following order of absolute average duration (aad) of X_1: SAFT of 1.90×10^{-2}, PR eos of 3.7×10^{-2}; UNIFAC with Magnussen et al. [12] parameters of 3.5×10^{-2}, and UNIFAC with Larsen parameters of 5.4×10^{-2}. SAFT was also best for extrapolation of both lle and solubility. SAFT also predicted the ternary systems that tested best.

4.4.6 Gas-Solid Equilibrium Models

Gas-solid equilibrium for a single-component system is commonly referred to as sublimation equilibrium. Sublimation pressure, the vapor pressure of a solid, is basic to the modeling of solid-gas equilibrium. Sublimation pressure changes with temperature by an equation similar to that of the vapor pressure of a liquid, Equation (4.453),

$$\frac{dp}{dT} = \frac{\Delta h}{T \Delta v} \tag{4.529}$$

where the Δ sign designates change upon sublimation. Since sublimation pressure is usually not large, the Antoine equation (4.459) gives useful representation for the entire range of temperature of common interest for many solids,

$$\ln p = A - B/(T + C) \tag{4.530}$$

The fugacity of the pure saturated vapor is given by the sublimation pressure times the fugacity coefficient,

$$fv = p^S \phi^S \tag{4.531}$$

The superscript S denotes a saturated state. The fugacity coefficient ϕ can be calculated from an eos or a correlation of a second virial coefficient, but is often assumed to be 1 at the low vapor pressure of many solids.

The fugacity of the solid at sublimation equilibrium is equal to the fugacity of the pure saturated vapor and is therefore also given by Equation (4.531),

$$fs = p^S \phi^S \tag{4.532}$$

Mixture gas-solid equilibrium is basic to supercritical extraction, the extraction of a solid component from a mixture of solids with a compressed gas at a state above and about its critical point. Another example is deposition of solid carbon dioxide, hydrogen sulfide, or heavy

hydrocarbons from natural gas at cryogenic processing conditions. Such deposition often needs to be avoided.

In modeling mixture gas-solid equilibrium, consideration is given to pure solid phase or phases; solid solutions are so rare they will not be considered. The modeling is simplified in two ways: First, modeling the fugacity of a solid is simple; second, there are no equilibrium equations for the components that do not form solids; they remain in the gas phase. Denoting a solid-forming component by *i*, the equilibrium equation is

$$f_{iS} = f_{iG} \tag{4.533}$$

The subscript S denotes the solid phase; G, the gas phase.

To find the fugacity of the solid, Equation (4.532) is modified by the effect of the system pressure *p* being different from p_i^S. Thus,

$$f_{iS} = p_i^S \phi_i^S \exp[v_i (p - p_i^S)/RT] \tag{4.534}$$

where v_i denotes the molar volume of solid *i*. Equation (4.534) is similar to the standard-state fugacity of a liquid-solution component.

The fugacity in the gas phase can be obtained from the fugacity coefficient ϕ_i calculated with a suitable equation of state,

$$f_{iG} = p y_i \phi_i \tag{4.535}$$

The formula for the calculation of ϕ_i with an eos can be found in Section 4.2.8.

The equilibrium equation is obtained by setting Equation (4.534) and Equation (4.535) to be equal,

$$p y_i \phi_i = p_i^S \phi_i^S \exp[v_i (p - p_i^S)/RT] \tag{4.536}$$

The concentration of *i* in the equilibrium gas mixture is usually the objective of interest. Solving for y_i from Equation (4.536) gives the mole fraction of *i* in the gas,

$$y_i = (p_i^S / p)(\phi_i^S / \phi_i) \exp[v_i (p - p_i^S)/RT] \tag{4.537}$$

The first parenthesized factor of the equation is the ideal y_i; it is what y_i would be if the gas mixture were an ideal gas, the pure saturated vapor of *i* were also an ideal gas, and the Poynting pressure effect were negligible. The actual y_i in a compressed gas is often many times greater than the ideal value, since the factor ϕ_i becomes much smaller than 1. Hence the actual solubility increases up to its real value by a factor of 1000 or more.

A common problem in supercritical extraction is as follows: given the *T*, *p*, and *i*-free composition of the gas, calculate the mole fraction of *i* and mole fractions of all other components in the gas at equilibrium with pure solid *i*. The solution is found from Equation (4.537), which gives the required y_i. But there is a snag: y_i must be known to calculate ϕ_i to substitute into Equation (4.537). One makes an initial estimate of y_i and then calculates the *y*'s of other components by normalization, calculates φ_i with an equation of state, and substitutes ϕ_i and all required variables into Equation (4.537) to calculate y_i. One compares the calculated y_i with the initial estimate and continues until suitable convergence.

Example 4.28: Supercritical Extraction

In supercritical extraction, a compressed gas at a temperature above and near its critical temperature is used as a solvent to dissolve a solid component. At near-critical states, molecular clusters are formed in abundance; the formation of clusters of small solvent molecules about a large solute molecule effectively contributes to the solvent power of the compressed gas. The fugacity coefficient ϕ_i is reduced, and the solubility y is raised.

An attractive application is the extraction of heat-sensitive biological materials using light gases such as carbon dioxide, ethane, and ethylene as the solvent gas. Their critical temperatures are 304, 305, and 282°K, respectively. Hence, they are often good solvents for supercritical extractions near room temperature. Expansion of the saturated gas from the extractor precipitates the extract for recovery, and the gas is ready to be recycled by compression to the extractor for reuse. Heating and cooling requirements are minimal. Meanwhile, the extract is not exposed to any high-temperature or low-temperature conditions, a vital consideration for heat-sensitive materials, such as many biological products.

In the food industry, supercritical carbon dioxide is used for the decaffeination of coffee, deodorization of plant oils, and extraction of hops and spices. In the tobacco industry, supercritical carbon dioxide is utilized in denicotinizing tobacco. Studies have also been made for the refining of coal by supercritical extraction.

As a general rule, extraction is best when the density of the compressed gas approaches that of the liquid. Often there is a large increase of solubility as the pressure increases at pressures just above the critical pressure. Further increased pressure then results in little increased solubility.

Haselow [14] has compared predictions made with seven eos's for binary mixtures. The four best sets of predictions as expressed as absolute average deviations of 31 binary mixtures four are as follows: Redlich-Kwong, 34; cubic chain-of-rotators, 37; Hans-Coy-Bono-Kwolz-Harling, 38; and Heyen, 40. The other three showed much larger deviations. It can be concluded that predictions involving supercritical fluids are not easy to make with high accuracy because of the high uncertainity in predicting critical properties. Such properties had to be estimated in several systems by group-contribution methods. Furthermore, several eos's, otherwise considered reliable, are not suitable for predicting supercritical information or for solid solutes.

Some success has, however, been obtained in predicting data involving solid phase, e.g., solubility of solid carbon dioxide in compressed air at 143°K (using a truncated second virial eos at pressures up to 40 atm). Good predictions were also realized for existence of solid carbon dioxide in liquid and gaseous mixtures of methane and carbon dioxide. The Peng-Robinson eos was used with success.

4.5 CHEMICAL REACTION EQUILIBRIA

In Section 4.1.6, the fundamental criterion of chemical reaction equilibrium was derived, yielding a corelationship between the chemical potentials of all the components participating in a given chemical reaction. Given that the chemical potentials of the reactants and products are not all independent, the criterion of chemical reaction equilibrium can be used to determine the equilibrium compositions of the reacting species. The development and use of the chemical equilibrium relations are the focus of this section.

4.5.1 Chemical Reaction Equilibrium

As noted previously, a given chemical reaction can be expressed in the following general form:

$$\sum_i v_i M_i = 0 \tag{4.538}$$

where v_i denotes the stoichiometric coefficient of species i participating in the reaction, and M_i is the molecular formula. By convention, v_i is positive for the products and negative for the reactants. The stoichiometry of the reaction can be expressed by

$$dn_i / v_i = d\xi \quad \text{for all } i \tag{4.539}$$

where ξ is the degree of advancement or extent of the reaction. Since the total number of moles of reactants and products is not necessarily fixed as the reaction proceeds, all mole number changes for each species can be expressed in terms of ξ, for which

$$dn_i = v_i d\xi \quad \text{for all } i \tag{4.540}$$

The following occurs at chemical reaction equilibrium:

$$\sum_i \mu_i v_i = 0 \tag{4.541}$$

where μ_i is the chemical potential of species i in the mixture. The sum of the chemical potentials of all species participating in the reaction weighted by their stoichiometric coefficient is zero.

In arriving at Equation (4.541), the derivation implicitly assumes that independent chemical reactions were occurring in the system. In general, what species may be consumed or generated through chemical reaction may not be known *a priori*. A counterpart to Equation (4.541), called the nonstoichiometric formulation, may then be derived. In this case, all possible (if known) components are included, and the minimization of an appropriate thermodynamic potential proceeds by taking into account an atom balance over the given components. The resulting equilibrium compositions are determined without the need to specify any particular reaction pathways. In general, the minimization requires heavy computational effort. The nonstoichiometric approach is not considered here, but the reader can find additional details in the literature.

Even if the actual chemical reaction pathways are not known, a set of linear independent reactions can be generated from some given set of components, thereby allowing Equation (4.541). This approach is known as the stoichiometric formulation and is considered in some detail in Section 4.5.5. We must emphasize that the independent reactions generated by this method do not necessarily describe the actual chemical reactions that occur in the system. These independent reactions relate the mole changes of each species in each reaction to changes in the extent of reaction via a stoichiometric coefficient, i.e., Equation (4.540). Since the final equilibrium state will be independent of the particular pathway taken, the final equilibrium compositions of the given species will still be correctly described by Equation (4.541).

4.5.2 Equilibrium Constants

To begin with, consider a system in which only one independent reaction occurs. The chemical potential of each species i in the mixture can be represented as follows (see Section 4.2.8):

$$\mu_i = g_i^0 + RT \ln \frac{f_i}{f_i^{P,0}} \tag{4.542}$$

where g_i^0 is the molar Gibbs free energy of pure i in its standard state (denoted by the superscript 0) at the given temperature and reference pressure p^0 (typically chosen to be unity in the units of pressure that are chosen, such as 1 bar), f_i is the fugacity of species i in the mixture at the given temperature and pressure p of the mixture, and $f_i^{\mathrm{P},0}$ is the fugacity of pure i in its standard state at and p^0. Combining Equation (4.541) with Equation (4.541) yields

$$\sum_i \nu_i \left(g_i^0 + RT \ln \frac{f_i}{f_i^{p,0}} \right) = 0 \tag{4.543}$$

or

$$\prod_i \left(\frac{f_i}{f_i^{\mathrm{P},0}} \right)^{\nu_i} = \exp\left[-\left(\sum_i \nu_i g_i^0 \Big/ RT \right) \right] \tag{4.544}$$

The equilibrium compositions of all components participating in the reaction are determined from Equation (4.544).

By convention, the standard-state Gibbs energy change upon reaction, Δg_{rx}^0, is written as

$$\Delta g_{rx}^0 = \sum_i \nu_i g_i^0 \tag{4.545}$$

with all the components being in their respective standard states. The equilibrium constant, K_a, for the reaction is defined as

$$K_a \equiv \prod_i \left(\frac{f_i}{f_i^{P,0}} \right)^{\nu_i} \tag{4.546}$$

so that

$$K_a = \exp[-\Delta g_{rx}^0 / RT] \tag{4.547}$$

Together, Equation (4.545) and Equation (4.546) are equivalent to Equation (4.544). The above procedure can be extended to describe more than one independent reaction. Separate equilibrium constants, along with separate standard-state Gibbs energy changes upon reaction, are introduced for each independent reaction.

Listing Δg_{rx}^0 for all possible reactions is not feasible, but tables are available for a large number of compounds for which the Gibbs energy and enthalpy of formation of the species from their elemental forms have been determined. To obtain Δg_{rx}^0 and the standard-state heat of reaction, Δh_{rx}^0, from these tables at the temperature (and pressure) of interest, one has that

$$\Delta g_{rx}^0 = \sum_i v_i \Delta g_{f,i}^0 \tag{4.548}$$

and

$$\Delta h_{rx}^0 = \sum_i v_i \Delta h_{f,i}^0 \tag{4.549}$$

where $\Delta g_{f,i}^0$ and $\Delta h_{f,i}^0$ are the Gibbs energy and enthalpy of formation of the species in their standard states from their elements, respectively. A table of $\Delta g_{f,i}^0$ and $\Delta h_{f,i}^0$, for some widely used substances, is provided at the end of this chapter, as well as a brief discussion of additional sources that provide data on other compounds not listed.

Typically (and by convention), $\Delta g_{f,i}^0$ and $\Delta h_{f,i}^0$ are provided at 298.15°K and a pressure of 1 bar. Also by convention, $\Delta g_{f,i}^0 = \Delta h_{f,i}^0 = 0$ for elements existing in their naturally occurring state at these conditions. For example, hydrogen exists as H_2 (g).

If the element exists in the solid state, information about the crystal form is also necessary. Carbon, for example, often exists as graphite. Other forms of carbon do not yield zero values of $\Delta g_{f,i}^0$ and $\Delta h_{f,i}^0$. In general, the states of aggregation of the components specified in the reactions of interest and listed in the tables for $\Delta g_{f,i}^0$ and $\Delta h_{f,i}^0$ may not be the same.

If Δg_{rx}^0 and Δh_{rx}^0 are needed at another temperature (besides 298.15°K), then the following sets of relations can be used. Temperature variations of Δg_{rx}^0 are calculated from the following Gibbs-Helmholtz relation:

$$d\left(\frac{\Delta g_{rx}^0 / T}{dT}\right) = -\frac{\Delta h_{rx}^0}{T^2} \tag{4.550}$$

which can be integrated if Δh_{rx}^0 is known as a function of temperature. The value Δh_{rx}^0 itself can be determined from the following expression:

$$\Delta h_{rx}^0(T) = \Delta h_{rx}^0(T_o) + \int_{T_o}^{T} \Delta C_p^0 dT \tag{4.551}$$

where

$$\Delta C_p^0 = \sum_i \nu_i C_{p,i}^0 \tag{4.552}$$

in which $C_{p,i}^0$ is the isobaric heat capacity of pure i in its standard state at the reference pressure p^0.

Equation (4.550) also allows one to determine how the equilibrium constant varies with temperature. With Equation (4.547), Equation (4.550) implies that

$$\frac{d\ln K_a}{dT} = -\frac{d(\Delta g_{rx}^0 / RT)}{dT} = \frac{\Delta h_{rx}^0}{RT^2} \tag{4.553}$$

If the reaction is exothermic, or $\Delta h_{rx}^0 < 0$, then K_a decreases with an increase in temperature. Conversely, K_a increases with an increase in temperature when the reaction is endothermic, or $\Delta h_{rx}^0 < 0$.

Substitution of Equation (4.551) into Equation (4.553) yields, upon an integration by parts, the following expression for the standard-state Gibbs energy change upon reaction:

$$\frac{\Delta g_{rx}^0(T)}{RT} = \frac{\Delta g_{rx}^0(T_0) - \Delta h_{rx}^0(T_0)}{RT_0} + \frac{\Delta h_{rx}^0(T_0)}{RT} + \frac{1^T}{T_{T_0}} \int \frac{\Delta C_p^0}{R} dT - \int_{T_0}^{T} \frac{\Delta C_p^0}{RT} dT \tag{4.554}$$

which then can be used to determine K_a at a given temperature. Often, Δh_{rx}^0 does not vary appreciably with temperature. Thus, Equation (4.551) can be integrated with a constant Δh_{rx}^0 to yield

$$\ln K_a(T) = \ln K_a(T_0) = -\frac{\Delta h_{rx}^0}{R}\left(\frac{1}{T} - \frac{1}{T_0}\right) \tag{4.555}$$

implying that ln K_a is a linear function of $1/T$. Equation (4.555) provides a useful means of correlating equilibrium constants with temperature. In general, over small temperature changes, ln K_a is nearly linear to $1/T$ in plots.

The determination of both Δg_{rx}^0 and Δh_{rx}^0 requires that the reference state, or standard state, be known. In general, the choice of the standard state varies. For gases, both real and ideal, the standard state is chosen as the pure materials in an ideal-gas unit fugacity state (that is, at a pressure p^0, which is unity for whatever choice of pressure units is desired; hence, f_i must also be expressed in the same pressure units). Thus, in this case, Δg_{rx}^0 and Δh_{rx}^0 represent changes for the components if they were ideal gases, and not the corresponding changes for the real gases (likewise, in Equations (4.551 and 4.552), $C_{p,i}^0$ represents the isobaric heat capacity of pure i as an ideal gas). With this choice of standard state, the reference fugacities, $f_i^{p,0}$, are always chosen to be unity fugacities, so that, in effect, Δg_{rx}^0 and Δh_{rx}^0 are functions of temperature only. Consequently, K_a is only a function of temperature.

Some tables list the Gibbs energies of formation for states that are different from the ideal-gas unity fugacity state. For example, for substances that are typically solutes, properties at two or more standard states may be given. One standard state is the solute as a pure solid (in the crystalline state) and the other is for the solute in solution at a specified concentration.

In the cases discussed above, most of the standard states are chosen at a fixed reference pressure. Hence, neither K_a nor Δg_{rx}^0 is a function pressure. Yet, if one or more of the standard states for any of the components were chosen to be at the system pressure, p, then both K_a and Δg_{rx}^0 would become

functions of this pressure. The pressure change of Δg_{rx}^0, and therefore K_a, can be determined from the following relation:

$$\left(\frac{\partial \Delta g_{rx}^0}{\partial p}\right)_T = \sum_i v_i \left(\frac{\partial g_i^0}{p}\right)_T = -RT\left(\frac{d \ln K_a}{dp}\right)_T \tag{4.556}$$

If g_i^0 is not a function of p, then the above derivatives all vanish. If it is a function of p, then $(\partial g_i^0 / p) = v_i^0$ is the molar volume of pure i in the chosen standard state. Choosing a standard state that is independent of pressure is certainly convenient, since the above pressure derivatives do not need to be evaluated.

If all species participating in the reaction are in the gas phase with the standard-state fugacities $f_i^{p,0}$ taken as unit fugacities, Equation (4.546) can be expressed as

$$K_a = \prod_i f_i^{v_i} = \left(\prod_i \phi_i^{v_i}\right)\left(\prod_i y_i^{v_i}\right) P^v = K_\phi K_y P^v \tag{4.557}$$

where

$$v = \sum_i v_i$$

and ϕ_i is the fugacity coefficient of i in the mixture. If the gas is an ideal-gas mixture, then Equation (4.557) reduces to

$$K_a = K_y P^v \quad \text{(ideal-gas mixture)} \tag{4.558}$$

For liquid mixtures, where (as shown earlier)

$$\frac{f_i}{f_i^{p,o}} = \frac{f_i^p}{f_i^{p,o}} \gamma_i x_i$$

then Equation (4.546) is given by

$$K_a = \left(\prod_i \left(\frac{f_i^p}{f_i^{p,o}}\right)^{v_i}\right)\left(\prod_i \gamma_i^{v_i}\right)\left(\prod_i x_i^{v_i}\right) \tag{4.559}$$

If the standard state is chosen to be the pure liquid in the same phase at a pressure of 1 bar or its vapor pressure, then each $f_i^p / f_i^{p,0}$ is usually not much different from unity, and so the equilibrium constant reduces to

$$K_a = \left(\prod_i \gamma_i^{v_i}\right)\left(\prod_i x_i^{v_i}\right) = K_\gamma K_x \quad \text{(condensed phase; pressure correction neglected)} \tag{4.560}$$

The pressure correction for each $f_i^p \,/\, f_i^{p,0}$ can, however, be readily evaluated. If the liquid solution is ideal (so that $\gamma_i = 1$), a further simplification results:

$$K_a = K_x \quad \text{(ideal solution; pressure correction neglected)} \tag{4.561}$$

For an equilibrium constant of a heterogeneous chemical reaction where the components are present in separate phases, the standard states of each component may be different. Let there be a reaction between a pure solid, say component 1, and additional components all present in the vapor phase. The equilibrium constant is now expressed as

$$K_a\left(\frac{f_1^p}{f_1^{p,o}}\right)^{v_1}\prod_{i\neq 1} f_i^{v_i}$$

where, in the gas phase, the standard-state fugacities are taken as unit fugacity. With the standard state of the pure solid chosen to be a pressure of 1 bar or the solid's vapor pressure at the given temperature, $f_1^p \,/\, f_1^{p,0}$ is often taken as being approximately equal to unity. Hence, the equilibrium constant reduces to

$$K_a = \prod_i f_i^{v_i} \quad \text{(pressure correction of the solid neglected)} \tag{4.562}$$

Further simplification would result if the gaseous components were assumed to behave as an ideal-gas mixture (see Equation [4.558]).

Example 4.29

Calculate the equilibrium mole fractions for the decomposition of nitrogen tetroxide as a result of the reaction N_2O_4 (g) = 2 NO_2 (g) at 25°C and 1 bar. Assume the components form an ideal-gas mixture. Initially there is only 1 mol of N_2O_4.

Solution

The equilibrium relation is given by Equation (4.557), in which

$$K_a = \prod_i f_i^{v_i} = \left(\prod_i \phi_i^{v_i}\right)\left(\prod_i y_i^{v_i}\right)P^v = \frac{y^2\mathrm{NO_2}}{y\mathrm{N_2O_4}} = \exp[-\Delta g_{rx}^o(T = 25°\mathrm{C},\ P = 1\ \mathrm{bar})/RT]$$

where the fugacity coefficients are all unity, since the components form an ideal-gas mixture and the standard-state fugacities were chosen as 1 bar. The pressure also cancels out of the equation, since $P = 1$ bar. Using the table provided at the end of this chapter for the Gibbs energy of formation for each component, then, with Equation (4.548),

$$\Delta g_{rx}^0(T = 25°\mathrm{C},\ P = 1\ \mathrm{bar}) = 2\Delta g_{f,\mathrm{NO_2}}^0 - \Delta g_{f,\mathrm{N_2O_4}}^0 = 4.7\ \mathrm{kJ/mol}$$

so that $K_a = 0.15$.

If ξ moles of N_2O_4 react, there will be $1 - \xi$ moles of N_2O_4 remaining. In addition, 2ξ moles of NO_2 would have been produced. Therefore, there will be $(1 - \xi) + (2\xi) = 1 + \xi$ total moles at equilibrium. Hence, the equilibrium mole fractions of each species will be given by

$$y_{N_2O_4} = \frac{1-\xi}{1+\xi} \quad y_{NO_2} = \frac{2\xi}{1+\xi}$$

Now, at equilibrium

$$K_a = \frac{y^2NO_2}{yN_2O_4} \quad \text{or} \quad 0.15 = \frac{4\xi}{(1-\xi)(1+\xi)}$$

Solution of the above equation yields

$$\xi = 0.19 \text{ moles} \quad y_{N_2O_4} = 0.68 \quad y_{NO_2} = 0.32$$

In this case, 19% of the initial amount of N_2O_4 was decomposed by the reaction.

If the reaction had proceeded with 1 mol of nitrogen present (as an inert), the equilibrium constant would still have the same value. (Those components not participating in the reaction do not appear in either Equation (4.541) or Equation (4.544).) But with 1 mol of nitrogen still present after the reaction has taken place, the total number of moles at equilibrium would now be 1 + (1 + ξ) = 2 + ξ, so that

$$y_{N_2O_4} = \frac{1-\xi}{2+\xi} \quad y_{NO_2} = \frac{2\xi}{2+\xi} \quad y_{N_2} = \frac{1}{2+\xi}$$

Thus,

$$K_a = \frac{y^2_{NO_2}}{y_{N_2O_4}} 0.15 = \frac{4\xi^2}{(1-\xi)(2+\xi)}$$

where now

$$\xi = 0.25 \text{ moles} \quad y_{N_2O_4} = 0.33 \quad y_{NO_2} = 0.22 \quad y_{N_2} = 0.44$$

In this case, 25% of the initial amount of N_2O_4 was decomposed by the reaction. The inert, though not changing the value of the equilibrium constant, dilutes the mole fractions of the components, thereby increasing the extent of the reaction.

The above N_2O_4 decomposition is an example of a homogeneous reaction, in that all the components participating in the reaction are found in the same phase. Homogeneous reactions cannot go to completion (in that one of the reacting species is completely consumed). In some cases, however, the equilibrium constant may be so large, or so small, that the reaction does not essentially proceed at all, or goes essentially to completion (with negligible error). In contrast, heterogeneous reactions, in which the components participating in the reaction are found in two or more phases, can go to completion. A qualification is needed, however, for heterogeneous reactions. If some of the reactants and products both appear in the same phase, then the reaction (albeit heterogeneous) cannot go to completion.

As a final example, let us repeat the above decomposition reaction, with the inert, but no longer assuming ideal-gas behavior. Because, by convention, the standard state for components, whether real or ideal, in the gas phase is the unit fugacity of the pure component as an ideal gas, the equilibrium constant is the same as before, K_a = 0.15. One again begins with Equation (4.557),

$$K_a = \prod_i f_i^{v_i} = \left(\prod_i \phi_i^{v_i}\right)\left(\prod_i y_i^{v_i}\right)P^v = K_\phi K_y P^v$$

but the above relation cannot be further simplified. With $P = 1$ bar, we have that

$$0.15 = \frac{y^2 NO_2}{y_{N_2O_4}} \frac{\phi^2_{NO_2}}{\phi_{N_2O_4}}$$

whereas before

$$y_{N_2O_4} - \frac{1-\xi}{2+\xi} \quad y_{NO_2} = \frac{2\xi}{2+\xi} \quad y_{N_2} = \frac{1}{2+\xi}$$

In this nonideal example, the fugacity coefficients are also functions of temperature, pressure (which is 1 bar), and mole fractions. Numerical solution is required for this case, in addition to an expression for the fugacity coefficients of the components of the mixture (see Section 4.2.8).

Example 4.30

Now consider the following two gas-phase reactions with the given equilibrium constants:

$$A + B = C \quad K_{a1} = 1.5$$

$$C + D = 2E \quad K_{a2} = 2.5$$

The reactions occur at 2 bar, and initially there are 2 moles of A, 1 mole of B, and 3 moles of D. Assume the components form an ideal-gas mixture.

Solution

Begin by defining two extents of reaction, ξ_1 and ξ_2. At equilibrium, there will be $2\xi_1$ moles of A, $1\xi_1$ moles of B, $\xi_1 - \xi_2$ moles of C, $3 - \xi_2$ moles of D, and $2\xi_2$ moles of E. Thus, the total number of moles of all species at equilibrium will be $6 - \xi_1$ moles. Therefore,

$$K_{a1} = \frac{y_C}{y_A y_B P} \quad \text{or} \quad 1.5 = \frac{(\xi_1 - \xi_2)(6-\xi_1)}{2(2-\xi_1)(1-\xi_1)}$$

$$K_{a2} = \frac{y_E^2}{y_C y_D} \quad \text{or} \quad 2.5 = \frac{4\xi_2^2}{(\xi_1 - \xi_2)(3-\xi_2)}$$

Numerical solution of the above two expressions yields $\xi_1 = 0.73$ moles and $\xi_2 = 0.54$ moles. Hence, at equilibrium

$$y_A = 0.24 \quad y_B = 0.050 \quad y_C = 0.036 \quad y_D = 0.47 \quad y_E = 0.21$$

Example 4.31

Consider the production of carbon black, C(s), from methane in a reactor maintained at a pressure of 1 bar and a given temperature *T*:

$$CH_4(g) = C(s) + 2H_2(g)$$

With 1 mole of CH_4 charged to the reactor, determine the equilibrium compositions of methane and hydrogen, and the fraction of methane charged that has reacted. Assume methane and hydrogen form an ideal-gas mixture.

Solution

For the given reaction,

$$K_a = \left(\frac{f_C^P}{f_C^{O,o}}\right)\frac{f_{H_2}^2}{f_{CH_4}} = \frac{y_{H_2}^2}{y_{CH_4}}P = \frac{y_{H_2}^2}{y_{CH_4}} = \frac{(1-y_{CH_4})^2}{y_{CH_4}}$$

where, for the ideal-gas components, the standard-state fugacities were chosen as 1 bar, and the ratio of the fugacity of the pure solid to the fugacity of the pure solid in its standard state is equal to approximately unity. The value of K_a is determined from the pure-component standard states of all the species. Solving the above equation yields the one physical root of

$$y_{CH_4} = \left(1+\frac{K_a}{2}\right) - \sqrt{K_a\left(1+\frac{K_a}{4}\right)}$$

As expected, $y_{CH_4} \to 1$ as $K_a \to 0$ and $y_{CH_4} \to 0$ as $K_a \to \infty$. Since K_a is between these limits, y_{CH_4} falls between zero and unity. Hence, the above heterogeneous reaction does not go to completion. Despite the appearance of a second phase (the solid), both methane (reactant) and hydrogen (product) appear in the same gaseous phase, preventing y_{CH_4} (or y_{H_2}) from equaling zero or unity.

With 1 mole of methane charged to the reactor, the final mole fractions of methane and hydrogen are given by

$$y_{CH_4} = \frac{1-\xi}{1+\xi} \quad y_{H_2} = \frac{2\xi}{1+\xi}$$

Hence, the above equilibrium relation can be rewritten in terms of the extent of reaction

$$K_a = \frac{4\xi^2}{(1-\xi)(1+\xi)}$$

which can be rearranged to yield

$$\xi = \sqrt{\frac{K_a}{4+K_a}}$$

Consistent with the trend for the equilibrium composition of methane, the above relation indicates that $\xi \to 0$ as $K_a \to 0$ and $\xi \to 1$ mole as $K_a \to \infty$. Since the initial amount of methane charged

to the reactor is 1 mole, the above equation also describes the fraction of methane that has reacted (as well as providing the number of moles of solid carbon that was produced by the reaction).

4.5.3 Phase Rule for Chemically Reacting Species

The Gibbs phase rule is modified in the following way when both phase and chemical equilibria need to be satisfied:

$$F = n = 2 - \pi - r$$

where n is the number of components, π is the number of phases, and r is the number of independent reactions. Each reaction (via Equation (4.541)) provides another constraint on the chemical potentials of the species participating in the reaction, serving to decrease the number of independently variable intensive properties of the system.

As an example of the application of the phase rule with reaction, consider a mixture of four components in which only two participate in a reaction. If all components are present in the gas phase, then $F = 4 + 2 - 1 - 1 = 4$. Hence, only four intensive variables are independently variable (e.g., T, P, y_1, and y_2; or P, y_1, y_2, and y_3) if the vapor is ideal. For example, the independent reaction yields the following form of the equilibrium constant:

$$K_a(T) = \frac{y_2}{y_1}$$

and not all sets of four intensive variables can be chosen to describe the system. The above reaction-equilibrium relation reveals that T, y_1, and y_2 are not independently variable. Once any two of these three variables are chosen, the value of the other is fixed by the reaction-equilibrium relation. Thus, from the set of four intensive variables denoting the degrees of freedom of the system, T, y_1, and y_2 cannot all be chosen. At least two others, such as p and y_3, must be chosen to generate a complete set of four intensive variables (e.g., T, y_1, P, and y_3).

If the gas phase is not ideal, the restriction on T, y_1, and y_2 is removed. Fugacity coefficients would now appear in the reaction-equilibrium relations, which themselves are functions of T, p, and the mole fractions of the components (say y_1, y_2, and y_3). Hence, the reaction-equilibrium relation no longer provides a constraint on just T, y_1, and y_2, although it still provides a constraint on, p, and all the $(n - 1)$ mole fractions. T, y_1, and y_2 can again be chosen, in addition to a fourth intensive variable (such as p or y_3), to generate a set of four intensive variables denoting the degrees of freedom of the system.

As another example, consider the heterogeneous reaction A (g) + B (g) = C (s). The phase rule states that $F = 3 + 2 - 2 - 1 = 2$, so that only two intensive variables are independently variable. Since C is present as a pure solid, one of those independent variables cannot be a mole fraction of C. Only the mole fraction of A, or B, in the vapor phase is relevant. The appropriate reaction-equilibrium relationship is

$$K_a(T) = \frac{f_C^P / f_C^{P,o}}{(f_A / f_A^{P,o})(f_A / f_A^{P,o})}$$

Now, the left-hand side of the above expression is only a function of T (the standard state of the pure solid is chosen as $P = 1$ bar or the vapor pressure, and so is only a function of T), while the right-hand side is only a function of T, p, and y_A (or y_B). With the degrees of freedom set at two, any two of these intensive variables can be chosen without overspecifying the system.

If we add, however, an additional requirement that A and B are to be fed into a reactor in the stoichiometric ratio 1:1, then as the reaction proceeds (again A (g) + B (g) = C (s)), the mole fractions of A and B will both be fixed at 0.5. (Since the product is a solid, and not a vapor, the chosen stoichiometric feed ratio ensures that $y_A = y_B = 0.5$.) Consequently, another constraint has been applied to the system, thereby decreasing the degrees of freedom of the system. Since $y_A = 0.5$ at all times, T and p are no longer independently variable. For this particular choice of the stoichiometric feed, the degrees of freedom of the system have been reduced to 1 (unity).

This previous example may, at first sight, appear to be an apparent exception to the Gibbs phase rule. The derivation of the Gibbs phase rule, however, does not explicitly account for the additional constraints generated by the case of stoichiometric feeds. The Gibbs phase rule can, of course, be modified as above to handle the additional constraints placed on the system (assuming the experimenter is aware of them). In general, care should be exercised when analyzing the allowed degrees of freedom of a system with both phase and chemical equilibria.

4.5.4 Open Systems with Reaction

Let us now consider an open system with chemical reaction to illustrate how the previously discussed concepts are incorporated. Without loss of generality, let us consider a steady-state flow process with a reactor having a single inlet and outlet stream. The open-system energy balance then becomes

$$0 = \dot{Q} + \dot{W} + H_{in}\dot{n}_{in} - H_{out}\dot{n}_{out} \tag{4.563}$$

where $\dot{n}_{in}, \dot{n}_{out}$ represent molar flow rates and are not necessarily the same due to the possible change of the total molar flow rate due to reaction.

Let us also consider the case in which the reactor is adiabatic and the exiting stream has reached chemical equilibrium (i.e., the kinetics of the reaction is sufficiently fast so that the components reach equilibrium before exiting the reactor). For this adiabatic case, we are interested in computing the exiting temperature of the outlet stream, which is commonly referred to as the *adiabatic reaction temperature*. The outlet, or adiabatic reaction, temperature is determined from both the energy balance and the relations for chemical equilibrium.

In the adiabatic limit with no shaft work generated or done on the reactor, the energy balance reduces to

$$H_{in}\dot{n}_{in} = H_{out}\dot{n}_{out} \tag{4.564}$$

Since the incoming and outgoing streams are mixtures, the molar enthalpy of the streams can be expressed in terms of the partial molar enthalpies of each component,

$$H_{in} = \sum_i y_{in,i} \quad \text{and} \quad H_{in} = \sum_i y_{out,i}\bar{H}_{out,i} \tag{4.565}$$

where, for example, $\bar{H}_{in,i}$ is evaluated at the temperature, pressure, and composition of the inlet stream. Now, the mole balance for each component participating in the reaction is given by

$$\dot{n}_{out,i} = \dot{n}_{in,i} + v_i\dot{\xi} \tag{4.566}$$

where ξ is the steady-state rate of the extent of reaction. The above mole balance implies that

$$\dot{n}_{out} = \sum_i \dot{n}_{out,i} = \dot{n}_{in} + \dot{\xi}\sum_i v_i \tag{4.567}$$

with the energy balance being rewritten as

$$H_{in}\dot{n}_{in} = \dot{n}_{in}\sum_i y_{in,i}\bar{H}_{in,i} = \dot{n}_{out}\sum_i y_{out,i}\bar{H}_{out,i} = H_{out}\dot{n}_{out} \tag{4.568}$$

which yields, in combination with the mole balance, Equation (4.567), the following upon rearrangement:

$$\sum_i \dot{n}_{in,i}(\bar{H}_{out,i} - \bar{H}_{in,i}) = -\dot{\xi}\sum_i v_i\bar{H}_{out,i} = -\dot{\xi}\Delta\bar{H}_{rxn,out} \tag{4.569}$$

where $\Delta\bar{H}_{rxn,out}$ is the heat of reaction based on the outlet conditions and is calculated not from the enthalpies of the pure components, but from their partial molar enthalpies (so that enthalpy of mixing effects are included in this term).

Equation (4.569) is a general result for the steady-state adiabatic reactor with a single inlet and outlet stream. For convenience, let us assume that we have an ideal-gas mixture, so that $\bar{H}_i = H_i(T)$, where H_i is the pure-component molar enthalpy of species i. Therefore, Equation (4.569) becomes

$$\sum_i \dot{n}_{in,i}(H_i(T_{out}) - H_i(T_{in})) = -\dot{\xi}\Delta h_{rxn}(T_{out}) \tag{4.570}$$

where $\Delta h_{\text{rxn}}(T_{\text{out}})$ is now the heat of reaction (as defined by Equation (4.549)) at the exiting temperature T_{out}. The left side of Equation (4.570) can be rewritten as an integral over the pure-component isobaric heat capacities from T_{in} to T_{out}, while the heat of reaction, if known at some reference temperature T_0, can be rewritten using Equation (4.551), so that

$$\sum_i \dot{n}_{in,i}\int_{T_{in}}^{T_{out}} C_{p,i}dT = -\dot{\xi}\Delta h^0_{rxn}(T_0) - \dot{\xi}\sum_i v_i\int_{T_0}^{T_{out}} C_{p,i}dT \tag{4.571}$$

or

$$\dot{\xi} = \frac{-\sum_i \dot{n}_{in,i}\int_{T_{in}}^{T_{out}} C_{p,i}dT}{\Delta h^0_{rxn}(T_0) - \sum_i v_i\int_{T_0}^{T_{out}} C_{p,i}dT} \tag{4.572}$$

with T_{in} known, and $\dot{\xi}$ is just a function of T_{out}.

Since the exiting stream is at chemical equilibrium, we are able to use the equilibrium relations discussed in Section 4.5.2. With the exiting temperature equal to T_{out}, the equilibrium constant for the ideal-gas mixture at the outlet is equal to

$$K_a(T_{out}) = \left(\prod_i y_{out,i}^{\nu_i}\right) P_{out}^{\nu} \tag{4.573}$$

The exiting compositions are related to $\dot{\xi}$ in the following manner:

$$y_{out,i} = \frac{\dot{n}_{out,i}}{\dot{n}_{out}} = \frac{\dot{n}_{in,i} + \nu_i \dot{\xi}}{\dot{n}_{in} + \dot{\xi}\sum_i \nu_i} \tag{4.574}$$

Since the pressure of the reactor is typically known, along with the molar flow rates of the components of the inlet stream, Equations (4.572) and (4.573) provide two equations with two unknowns, which can be solved for $\dot{\xi}$ and T_{out}. In other words, the energy balance and the chemical equilibrium relations generate a complete set of equations to determine the adiabatic reaction temperature. Whether T_{out} is greater than or less than T_{in} depends upon whether the reaction is exothermic or endothermic.

Example 4.32

Determine the outlet temperature and equilibrium composition of ammonia synthesized in an adiabatic reactor from the following reaction:

$$N_2 + 3H_2 = 2NH_3$$

N_2 and H_2 are fed into the reactor at 25°C with molar flow rates of 1 mol/s and 3 mol/s, respectively. The reactor is held at a pressure of 300 bar, and the components form an ideal-gas mixture.

Solution

From Equation (4.574), the equilibrium compositions are

$$y_{out,N_2} = \frac{1-\dot{\xi}}{4-2\dot{\xi}} \quad y_{out,H_2} = \frac{3-3\dot{\xi}}{4-2\dot{\xi}} \quad y_{out,NH_3} = \frac{2\dot{\xi}}{4-2\dot{\xi}}$$

so that Equation (4.573) is given by

$$K_a(T_{out}) = \frac{4\dot{\xi}^2(4-2\dot{\xi})^2}{(1-\dot{\xi})(3-3\dot{\xi})^3 P_{out}^2} = \frac{16\dot{\xi}^2(2-\dot{\xi})^2}{27(1-\dot{\xi})^4 P_{out}^2} \tag{4.575}$$

or, equivalently,

$$\frac{P_{out}\sqrt{27K_a(T_{out})}}{4} = \frac{\dot{\xi}(2-\dot{\xi})}{(1-\dot{\xi})^2}$$

We can solve the above relation for $\dot{\xi}$, retaining the one root for which the mole fractions are positive (i.e., $0 \le \dot{\xi} \le 1$),

$$\dot{\xi} = 1 - \sqrt{\frac{1}{1 + \Gamma(T_{out})}}$$

where

$$\Gamma(T_{out}) = \frac{P_{out}\sqrt{27 H_a(T_{out})}}{4}$$

The value of K_a at T_{out} can be determined from Equation (4.554). For T_0 = 298.15° and a unit ideal-gas fugacity of P = 1 bar, $\Delta g^0_{f,\text{N}_2} = 0$, $\Delta g^0_{f,\text{H}_2} = 0$, and $\Delta g^0_{f,\text{NH}_3} = -16.5$ kJ/mol, so that $\Delta g^0_{\text{rx}}(T_0)$ = –33 kJ/mol, and $\Delta h^0_{f,N_2} = 0$, $\Delta h^0_{f,H_2} = 0$, and $\Delta h^0_{f,\text{NH}_3}$ = –46.1 kJ/mol, so that $\Delta h^0_{rx}(T_0)$ = –92.2 kJ/mol. (These values were taken from Table 4.7.) Therefore, ln K_a (T = 298.15 K) = 13.3. Isobaric heat capacities of the components are found in Smith et al. (2001).

Using the given data, one finds from Equation (4.554) that, for example, ln K_a(T = 800°K) = –11.6. Since the heat of reaction is negative, K_a decreases with an increase in T_{out}. Thus, Equation (4.575) indicates that $\dot{\xi}$ decreases with an increase in T_{out}. For P_{out} = 300 bar, $\dot{\xi}$ ranges from $\dot{\xi}$ = 0.998 mol/s at T_{out} = 298.15 to $\dot{\xi}$ = 0.0955 mol/s at T_{out} = 1000°K.

Now, $\dot{\xi}$ is also related to T_{out} via the energy balance relation, Equation (4.572). Since the heat of reaction is negative and the reactor is adiabatic, Equation (4.572) reveals that an increase in $\dot{\xi}$ results in an increase in T_{out}. For example, with T_{in} = 298.15° = 25°C, T_{out} = 300° corresponds to $\dot{\xi}$ = 0.00232 mol/s, while T_{out} = 800° corresponds to $\dot{\xi}$ = 0.753 mol/s.

When plotted as $\dot{\xi}$ versus T_{out}, Equation (4.572) shows $\dot{\xi}$ increasing with an increase in T_{out}, while Equation (4.573) shows $\dot{\xi}$ decreasing with an increase in T_{out}. The point at which Equation (4.572) and Equation (4.575) intersect determines the adiabatic outlet temperature and the extent of reaction. For T_{in} = 298.15, we find that T_{out} = 688 and $\dot{\xi}$ = 0.563 mol/s. Thus, the outlet compositions are equal to $y_{\text{out,N}_2} = 0.152$, $y_{\text{out,H}_2} = 0.456$, and $y_{\text{out,NH}_3} = 0.392$.

4.5.5 Stoichiometric Formulation

As stated in Section 4.5.1, even if the actual chemical reaction pathways are not known, linear independent reactions can be generated from the given components, thereby allowing one to determine equilibrium compositions via Equation (4.541). This approach, known as the stoichiometric formulation, is discussed below. Although the independent reactions generated by this method do not necessarily describe the chemical reactions that occur in the system, they enable one, however, to relate the mole changes of each species in each reaction to changes in the extent of reaction via a stoichiometric coefficient. Since the final equilibrium state is independent of the particular pathway taken, the final equilibrium compositions of the given species are still correctly described by the chemical equilibrium condition in Equation (4.541).

The stoichiometric formulation begins with the introduction of a matrix **D** in which each element d_{ij} denotes the number of atoms of type i in component j. Each row of the matrix therefore represents an element found in each component, while the columns represent a given component present in the system. Let there be m total elements and n' total components. Note that components found in two or more phases, e.g., H_2O (l) and H_2O (g), are counted as distinct components. Thus, if there are up to n components in each of p phases, then $n \leq n' \leq np$.

Example 4.33

Given CO_2, H_2, C, and H_2O in the gaseous phase and H_2O in a separate liquid phase, generate the corresponding matrix **D**.

TABLE 4.7
Standard Enthalpies and Gibbs Energies of Formation (kJ/mol) at 298.15° for 1 Mole of Each Substance from Its Elements

Chemical Species		State	Δh_f^0	Δg_f^0
Paraffins				
Methane	CH_4	(g)	–74.5	–50.5
Ethane	C_2H_6	(g)	–83.8	–31.9
Propane	C_3H_8	(g)	–104.7	–24.3
n-Butane	C_4H_{10}	(g)	–125.8	–16.6
1-Alkenes				
Ethylene	C_2H_4	(g)	52.5	68.5
Propylene	C_3H_6	(g)	19.7	62.2
1-Butene	C_4H_8	(g)	1.2	70.3
Miscellaneous organics				
Acetylene	C_2H_2	(g)	227.5	210.0
Benzene	C_6H_6	(l)	49.1	124.5
Toluene	C_7H_8	(l)	12.2	113.6
Cyclohexane	C_6H_{12}	(l)	–156.2	26.9
Ethanol	C_2H_6O	(l)	–277.7	–174.8
Methanol	CH_4O	(l)	238.7	–166.3
Inorganic compounds				
Ammonia	NH_3	(g)	–46.1	–16.5
Carbon dioxide	CO_2	(g)	–393.5	–394.4
Carbon monoxide	CO	(g)	–110.5	–137.2
Nitrogen dioxide	NO_2	(g)	33.2	51.3
Nitrogen tetroxide	N_2O_4	(g)	9.2	97.9
Water	H_2O	(g)	–241.8	–228.6
Water	H_2O	(l)	–285.8	–237.1

Note: All standard states are at 25°C. The standard state for a gas (g) is the pure ideal gas at 1 bar. For liquids (l), the standard state is the substance as a liquid at 25°C and 1 bar.

Source: Adapted from data provided by Sandler, S. I. *Chemical and Engineering Thermodynamics*, 3rd ed., New York: John Wiley & Sons, 1999.

Solution

The matrix **D** is given by

		CO_2	H_2	C	$H_2O(g)$	$H_2O(l)$
	C	1	0	1	0	0
D =	H	0	2	0	2	2
	O	2	0	0	1	1

Once the matrix **D** is determined, the smallest number of linear independent reactions can be generated from the known set of components. Let the rank of the matrix **D** be denoted by c. With

the number of components given as n', the number of independent reactions is equal to $n' - c$. The stoichiometric coefficient for component j participating in reaction r ($r = 1,\ldots,n' - c$) can be obtained from the following vector equation:

$$\mathbf{D}\mathbf{v}_r = 0 \tag{4.576}$$

where $\mathbf{v}_r$ is a column vector of stoichiometric coefficients $v_{j,r}$ in which the stoichiometric coefficient of component j in the independent reaction r is $v_{j,r}$, where $r = 1,\ldots,n' - c$.

Example 4.34

Determine the number of independent reactions, and suggest some possible reaction pathways for CO_2, H_2, C, CO, and H_2O.

Solution

The matrix **D** is given by

D =		CO_2	H_2	C	CO	H_2O
	C	1	0	1	0	0
	H	0	2	0	0	2
	O	2	0	0	1	1

When the matrix is reduced to echelon form by Gauss-Jordan elimination, the rank of the matrix can be shown to be equal to 3. With $n' = 5$, the number of independent reactions is $5 - 3 = 2$. Equation (4.575) requires that, for each of the two independent reactions,

$$\begin{pmatrix} d_{11} & d_{12} & d_{13} & d_{14} & d_{15} \\ d_{21} & d_{22} & d_{23} & d_{24} & d_{25} \\ d_{31} & d_{32} & d_{33} & d_{34} & d_{35} \end{pmatrix} \times \begin{pmatrix} v_1 \\ v_2 \\ v_3 \\ v_4 \\ v_5 \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \\ 0 \end{pmatrix}$$

With the given elements of the matrix **D**, the above vector equation reduces to

$$\begin{array}{cccccc} v_1 & & +v_3 & +v_4 & & = 0 \\ & +2v_2 & & & +2v_5 & = 0 \\ 2v_1 & & & +v_4 & +v_5 & = 0 \end{array}$$

These relations describe a set of three equations with five unknowns. Hence, we are free to choose the values of any two coefficients. For example, let us choose $v_1 = 1$ and $v_2 = 0$. Therefore, $v_3 = 1$, $v_4 = -2$, and $v_5 = 0$. Thus, one independent reaction would be

$$CO_2 + C - 2CO = 0$$

when $v_1 = 0$ and $v_2 = 1$, so that $v_3 = -1$, $v_4 = 1$, and $v_5 = -1$, and the second independent reaction would be

$$H_2 - C + CO - H_2O = 0$$

The above reactions represent two possible independent reactions. Other initial choices for two out of the five stoichiometric coefficients may generate different reactions, but these new reactions can always be generated by linear combinations of the two reactions given above.

Repeating the above problem, but with H_2O in both the liquid and vapor phases (note that we have implicitly considered in the previous example components in different phases, since the component C would most likely be found in the solid phase), then

		CO_2	H_2	C	CO	$H_2O(g)$	$H_2O(l)$
	C	1	0	1	1	0	0
D =	H	0	2	0	0	2	2
	O	2	0	0	1	1	1

The rank of this matrix is again three. With $n' = 6$, the number of independent reactions is now 6 − 3 = 3. With the above given elements of the matrix **D**, the vector equation for the stoichiometric coefficients reduces to

$$\begin{aligned} v_1 \quad + v_3 + v_4 &= 0 \\ +2v_2 \quad + 2v_5 + 2v_6 &= 0 \\ 2v_1 \quad + v_4 + v_5 + v_6 &= 0 \end{aligned}$$

The above relations describe a set of three equations with six unknowns. Hence, we are free to choose the values of any three coefficients. For example, let us choose $v_1 = 1$ and $v_2 = v_5 = 0$. Therefore, $v_3 = 1$, $v_4 = -2$, and $v_6 = 0$. Thus, one independent reaction is the same as before,

$$CO_2 + C - 2CO = 0$$

Now choose $v_1 = v_6 = 0$ and $v_2 = 1$, so that $v_3 = -1$, $v_4 = 1$, and $v_5 = -1$. The second independent reaction is again equal to

$$H_2 - C + CO - H_2O\ (g) = 0$$

Finally, choose $v_1 = v_2 = 0$ and $v_5 = 1$, so $v_3 = 0$, $v_4 = 0$, and $v_6 = -1$. Thus, the third independent reaction is

$$H_2O\ (g) - H_2O\ (l) = 0$$

This reaction is simply a restatement of the phase-equilibrium condition of equality of chemical potentials of a given component in the phases in which it is found.

5.1 INTRODUCTION

The flow behavior of fluids is crucial to virtually every aspect of the chemical process and related industries. The most common application involves the transportation of fluids through piping systems containing fittings, valves, etc., by means of a driving force such as that provided by a pump, static elevation change, or some other source of pressure. While this is indeed important, an understanding of fluid flow is the key to various other operations such as packed and fluidized beds, fluid-solid separations, safety relief systems, flow metering and control, etc. These flows may be either laminar or turbulent, and the fluids may be either incompressible Newtonian or non-Newtonian liquids, compressible gases, or complex two-phase flows involving gas-liquid, solid-liquid, or solid-gas combinations. Various aspects of each of these will be considered in this chapter.

5.2 FLUID PROPERTIES

The properties of a fluid that influence flow behavior are its density and viscosity. Fluids may be classified as incompressible or compressible, depending upon whether the density is constant or a

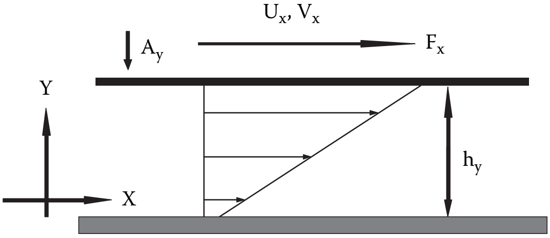

FIGURE 5.1 Simple shear.

function of pressure, and as Newtonian or non-Newtonian, depending upon whether the viscosity is constant or a function of flow conditions. Liquids can usually be considered to be incompressible, but may be either Newtonian or non-Newtonian. Gases are compressible, but are invariably Newtonian. Both liquids (Newtonian and non-Newtonian) and gases will be considered.

5.2.1 Classification of Material/Fluid Properties

The flow behavior of a fluid is determined by the fluid properties and how it responds to the forces exerted on or within the fluid. The forces, F_j (and the corresponding stress components, $\sigma_{ij} = F_j/A_i$), acting at any point within a fluid, may be either isotropic (i.e., uniform in all directions, such as pressure, P) or anisotropic (such as shear stresses, τ_{ij}, which are directionally dependent):

$$\sigma_{ij} = -P\delta_{ij} + \tau_{ij} \tag{5.1}$$

where δ_{ij} is the "unit tensor" (or Kronecker delta). The pressure P is a negative (compressive) stress, since tensile stresses are defined as positive. In laminar flows, the shear stresses τ_{ij} depend on the relative motion (deformation) within the fluid and the *rheological properties** as defined by a *constitutive equation*, which is a unique property of the fluid structure. In turbulent flows, these stress components are dominated by the inertial momentum flux associated with turbulent eddy motion and the fluid density. These shear stresses are zero in any fluid in a state of rest or uniform motion.

The rheological nature of a material can be defined by a relation between components of stress and deformation in *simple shear*, as illustrated in Figure 5.1.

The shear stress (τ_{yx}) and the shear strain (γ_{yx}) are given by

$$\tau_{yx} = F_x / A_y \tag{5.2}$$

$$\gamma_{yx} = U_x / h_y = \frac{du_x}{dy} \tag{5.3}$$

A material that is a *rigid solid* does not deform no matter how much force is applied, i.e.,

$$\gamma_{yx} = 0 \tag{5.4}$$

However, if the material is a *linear elastic (Hookean) solid*,

* Rheology is the study of the deformation and flow behavior of materials, both fluids and solids.

$$\tau_{yx} = G\gamma_{yx} \tag{5.5}$$

where G is the *shear modulus*, and is constant. When the stress is removed, the strain also goes to zero, representing a material with a "perfect memory." However, a material that exhibits a "memory," but for which the displacement is a nonlinear function of the applied force, is a *nonlinear (non-Hookean) elastic solid*:

$$G = \tau_{yx} / \gamma_{yx} = fn\ (\tau \text{ or } \gamma) \tag{5.6}$$

G is still the shear modulus, but it is no longer a constant; it is a *function* of the displacement gradient (strain) (γ_{yx}), or of the magnitude of the applied stress (τ_{yx}), i.e., $G(\gamma)$ or $G(\tau)$. The particular form of the function depends upon the specific nature (i.e., constitution) of the material.

If the material is a fluid with negligible resistance to deformation (e.g., a low-pressure gas), the governing equation is

$$\tau_{yx} = 0 \tag{5.7}$$

This is called an *inviscid (Pascalian) fluid*. However, if the fluid molecules exhibit a significant attraction, and the resistance to flow is directly proportional to the relative motion, the material is a *Newtonian fluid*:

$$\tau_{yx} = \mu\dot{\gamma}_{yx} \tag{5.8}$$

where $\dot{\gamma}_{yx}$ is the *rate of shear strain* or, for short, *shear rate*:

$$\dot{\gamma}_{yx} = \frac{d\gamma_{yx}}{dt} = \frac{dv_x}{dy} = \frac{V_x}{h_y} \tag{5.9}$$

Here μ is the fluid *viscosity*, defined as $\mu = d\tau_{yx}/d\dot{\gamma}_{yx}$. If the shear stress and shear rate are not proportional, the fluid is *non-Newtonian*, in which case the viscosity is not constant but is a *function* of either the shear rate or shear stress:

$$\eta = \frac{\tau_{yx}}{\dot{\gamma}_{yx}} = fn\ (\tau \text{ or } \dot{\gamma}) \tag{5.10}$$

Most common fluids of simple structure are Newtonian (i.e., water, air, glycerine, oils, etc.). However, fluids with complex structures (i.e., high polymer melts or solutions, suspensions, emulsions, foams, etc.) are generally non-Newtonian. Examples of non-Newtonian behavior include mud, paint, ink, mayonnaise, shaving cream, polymer melts and solutions, toothpaste, etc. Many "two-phase" systems (e.g., suspensions, emulsions, foams, etc.) are purely viscous fluids and do not exhibit significant elastic or "memory" properties. However, many high polymer fluids (e.g., melts and solutions) are *viscoelastic* and exhibit both elastic (memory) as well as nonlinear viscous (flow) properties. A classification of material behavior is summarized in Table 5.1 (in which the subscripts have been omitted for simplicity). Only purely viscous Newtonian and non-Newtonian fluids are considered here. The properties and flow behavior of viscoelastic fluids are the subject of numerous books and papers (e.g., Darby, 1976; Bird et al., 1987).

TABLE 5.1

5.2.2 Measurement of Viscosity

Two common methods for measuring viscosity are the cup and bob (Couette) and the tube flow (Poiseuille) viscometers.

5.2.2.1 Cup and Bob (Couette) Viscometer

This viscometer consists of two concentric cylinders, the outer "cup" and the inner "bob," with the test fluid in the annular gap. The radius of the bob is R_i, that of the cup is R_o, and the length of surface in contact with the sample is L. One of the cylinders (preferably the cup) is rotated at various controlled angular velocities (Ω), and the resulting torque (T) is measured. The shear stress is

$$\tau_{r\theta} = \frac{T}{2\pi r^2 L} = \tau \tag{5.11}$$

Setting $r = R_i$ gives the stress on the bob surface, and $r = R_o$ gives the stress on the cup. If the gap is small (i.e., $(R_o - R_i)/R_i \le 0.02$), the average shear stress is evaluated at $(R_i + R_o)/2$, and the corresponding average shear rate is given by

$$\dot{\gamma}_{yx} = \frac{dv_\theta}{dr} = \frac{\Omega}{1-\beta} = \dot{\gamma} \tag{5.12}$$

where $\beta = R_i/R_o$. If the gap is not small, the shear rate at the bob is given by

$$\dot{\gamma} = \frac{2\Omega}{n'(1-\beta^{2/n'})} \tag{5.13}$$

which is accurate to 1–2% in most cases, with an extreme error of about 5% in the worst case, for any size gap and any type of fluid (e.g., Darby, 1985). Here n' is the point slope of the log-log plot of T versus Ω:

$$n' = \frac{d(\log T)}{d(\log Q)} \tag{5.14}$$

A series of data points of T versus Ω must be obtained in order to determine n' at each point. The viscosity at each shear rate (or shear stress) is then determined by dividing the shear stress at the bob by the shear rate at the bob for each data point.

5.2.2.2 Tube Flow (Poiseuille) Viscometer

Viscosity can also be determined by measuring the total pressure drop ($\Delta\Phi = \Delta P + \rho g \Delta z$) and flow rate ($Q$) in steady laminar flow through a uniform circular tube of length L and diameter D (this is called *Poiseuille flow*). The shear stress at the tube wall (τ_w) is determined from the measured pressure drop:

$$\tau_w = -\frac{\Delta\Phi}{4L/D} \tag{5.15}$$

and the shear rate at the tube wall ($\dot{\gamma}_w$) is given by

$$\dot{\gamma}_w = \Gamma\left(\frac{3n'+1}{4n'}\right) \tag{5.16}$$

where

$$\Gamma = \frac{32Q}{\pi R} = \frac{8V}{D} \tag{5.17}$$

and

$$n' = \frac{d\log\tau_w}{d\log\Gamma} = \frac{d\log(-\Delta\Phi)}{d\log Q} \tag{5.18}$$

is the point slope of the log-log plot of $\Delta\Phi$ versus Q, evaluated at each data point. This n' is the same as that determined by the cup and bob viscometer for a given fluid.

5.2.3 Viscous Fluid Models

The nature of the dependence of the shear stress (or viscosity) upon shear rate determines the class of viscous fluid behavior (Figures 5.2 and 5.3). The shear stress and shear rate may both be either positive or negative, although (by the usual "mechanics" convention) they always have the same sign.

A *Newtonian fluid* obeys the equation

$$\tau = \mu\dot{\gamma} \tag{5.19}$$

where μ is the viscosity.

If the shear stress–shear rate data appear linear but intersect the shear stress axis at a value of τ_o, the material is called a *Bingham plastic:*

$$\tau = \tau_o + \mu_\infty\dot{\gamma} \quad \text{for } |\tau| \geq \tau_o \tag{5.20}$$

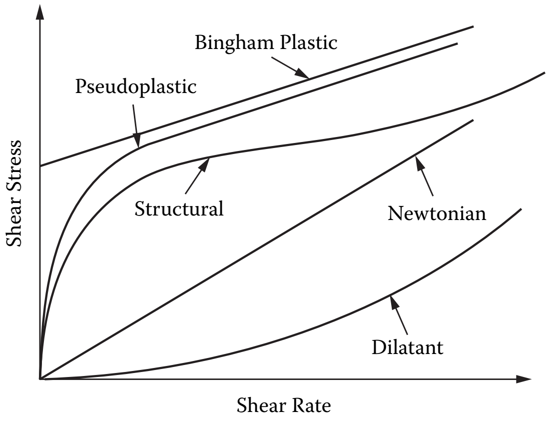

FIGURE 5.2 Shear stress versus shear rate for various fluids.

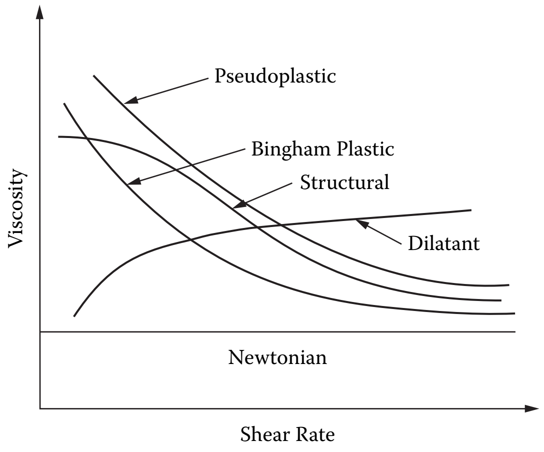

FIGURE 5.3 Viscosity versus. shear rate for fluids in Figure 5.4.

The two rheological properties required—the *yield stress*, τ_o, and the *high-shear-limiting (or plastic) viscosity*, μ_∞—determine the flow behavior of a Bingham plastic. The viscosity function for the Bingham plastic is

$$\eta(\dot{\gamma}) = \frac{\tau_o}{\dot{\gamma}} + \mu_\infty \tag{5.21}$$

or

$$\eta(\tau) = \frac{\mu_\infty}{1 - \tau/\tau} \tag{5.22}$$

Since this material will not "flow" unless the shear stress exceeds the yield stress, these equations apply only when $|\tau| > \tau_o$. For smaller values of the shear stress, the material behaves as a rigid solid, i.e.,

$$\text{for } |\tau| < \tau_o \quad \dot{\gamma} = 0 \tag{5.23}$$

The Bingham plastic is *shear thinning*, i.e., the higher the shear stress or shear rate, the lower is the viscosity. This behavior is typical of many concentrated slurries and suspensions, such as muds, paints, foams, emulsions (e.g., mayonnaise), ketchup, blood, etc.

If the data (either shear stress or viscosity) exhibit a straight line on a log-log plot, the fluid follows the *power law* (or Ostwald deWaele) model:

$$\textit{Power Law}: \tau = m\dot{\gamma}^n \tag{5.24}$$

The viscosity parameters are the *consistency coefficient* (m) and the *flow index* (n). The apparent viscosity function for the power law model can be expressed in terms of either the shear rate or the shear stress:

$$\eta(\dot{\gamma}, \tau) = m\dot{\gamma}^{n-1} = m^{1/n}\tau^{(n-1)/n} \tag{5.25}$$

For $n = 1$, the power law fluid model represents Newtonian behavior; for $n < 1$, the fluid is *shear thinning* (or *pseudoplastic*); and for $n > 1$, the model represents *shear thickening* (or *dilatant*) behavior. Most non-Newtonian fluids are shear thinning, whereas shear-thickening behavior is relatively rare, being observed primarily for some concentrated suspensions of very small particles (e.g., starch suspensions) and some unusual polymeric fluids (e.g., molecules that exhibit shear-induced structure). Although the power law model is very popular for curve-fitting viscosity data over a limited range of shear rate, it is dangerous to use this model to extrapolate beyond the range of the data because (for $n < 1$) it predicts an ever-increasing viscosity as the shear rate decreases, and an ever-decreasing viscosity as the shear rate increases, both of which are physically unrealistic.

A typical viscosity characteristic of many non-Newtonian fluids (e.g., polymeric fluids, flocculated suspensions, colloids, foams, gels, etc.) is illustrated by the curves labeled *structural viscosity* in Figures 5.2 and 5.3. These fluids exhibit Newtonian behavior at very low and very high shear rates, with shear thinning or pseudoplastic behavior at intermediate shear rates. This can often be attributed to a reversible "structure" or network that forms in the "rest" or equilibrium state. When the material is sheared, the structure breaks down, resulting in a shear-dependent (shear thinning) behavior. This type of behavior is exhibited by fluids as diverse as polymer solutions, blood, latex emulsions, paint, mud (sediment), etc. An example of a useful model that represents this type of behavior is the *Carreau* model:

$$\textit{Carreau}: \eta(\dot{\gamma}) = \eta_\infty + \frac{\eta_o - \eta_\infty}{[1 + (\lambda\dot{\gamma})^2]^p} \tag{5.26}$$

This model contains four rheological parameters: the *low shear limiting viscosity*, η_o; the *high shear-limiting viscosity*, η_∞; a *time constant*, λ; and the *shear-thinning index*, p. This viscosity model can represent a wide variety of materials, although data over a range of six to eight *decades* of shear rate may be required to define the complete shape of the curve (and to determine values for all four parameters). The Carreau model reduces to various other popular models over certain ranges of shear rate (including the Bingham plastic and power law models) as follows:

1. *Low to intermediate shear rate range*: If $\eta_\infty \ll (\eta, \eta_o)$, the Carreau model reduces to a three-parameter model (η_o, λ, and p) called the *Ellis* model, which is equivalent to a power law model with a low shear-limiting viscosity:

$$\textit{Ellis}: \eta(\dot{\gamma}) = \frac{\eta_o}{[1 + (\lambda\dot{\gamma})^2]^p} \tag{5.27}$$

2. *Intermediate to high shear rate range*: If $\eta_o \gg (\eta, \eta_\infty)$ and also $(\lambda\dot{\gamma})^2 \gg 1$, the model reduces to the equivalent of a power law model with a high shear-limiting viscosity, called the *Sisko* model:

$$\textit{Sisko}: \eta(\dot{\gamma}) = \eta_\infty + \frac{\eta_o}{(\lambda\dot{\gamma})^{2p}} \tag{5.28}$$

Although this appears to have four parameters, it is in reality a three-parameter model, since the combination $\eta_o/(\lambda)^{2p}$ is a single parameter, along with p and η_∞. If the value

of p in the Sisko model is set equal to 1/2, the result is equivalent to the *Bingham plastic* model:

$$\text{Bingham: } \eta(\dot{\gamma}) = \eta_\infty + \frac{\eta_o}{\lambda\dot{\gamma}} \tag{5.29}$$

where the yield stress τ_o corresponds to η_o/λ, and η_∞ is the (high shear) limiting viscosity.

3. *Intermediate shear rate*: For $\eta_\infty << \eta << \eta_o$ and $(\lambda\dot{\gamma})^2 >> 1$, the Carreau model reduces to the *power law model*:

$$\text{Power Law: } \eta(\dot{\gamma}) = \frac{\eta_o}{(\lambda\dot{\gamma})^{2p}} \tag{5.30}$$

where the power law parameters m and n are equivalent to the following combination of Carreau parameters:

$$m = \frac{\eta_o}{\lambda^{2p}}, \quad n = 1 - 2p \tag{5.31}$$

Other models have been proposed to provide a more accurate fit of some detailed viscosity data. Two of these are the *Meter model*, a stress-dependent viscosity model that has the same general characteristics as the Carreau model:

$$\textit{Meter}\text{: } \eta(\dot{\gamma}) = \eta_\infty + \frac{\eta_o - \eta_\infty}{[1 + (\tau/\sigma)^{2a}]} \tag{5.32}$$

where σ is a characteristic stress parameter and a is the shear-thinning index, and the *Yashuda model*. The Yashuda model (1981) is also similar to the Carreau model, but with one additional parameter (a total of five parameters):

$$\textit{Yashuda}\text{: } \eta = \eta_\infty + \frac{(\eta_o - \eta_\infty)}{[1 + (\lambda\dot{\gamma})^{2a}]^{p/a}} \tag{5.33}$$

which reduces to the Carreau model for $a = 1$. (This is also sometimes called the *Carreau-Yashuda* model.) This model is particularly useful for representing polymer melt data for broad-molecular-weight polymers for which the zero-shear viscosity is approached very gradually. Each of these last three models reduces to Newtonian behavior at very low and very high shear rates, and to power law behavior at intermediate shear rates.

It should be stressed that the specific model that best represents a given non-Newtonian, and the values of the parameters defined by the model, cannot be predicted accurately from first principles or from more basic information. The specific function and the values of the parameters must be determined from laboratory viscosity measurements.

Example 5.1

The following data were taken in a cup and bob viscometer, having a bob radius of 2.5 cm, a cup radius of 2.75 cm, and a bob length of 6.5 cm. Determine the viscosity of the sample and the nature of the shear dependence of this viscosity.

Torque (dyne-cm)	Speed (rpm)
3,000	2
6,000	4
11,700	10
14,500	20
17,800	40

Solution

The viscosity is the shear stress at the bob [Equation (5.11)] divided by the shear rate at the bob [Equation (5.13)]. The value of n' in Equation (5.13) is determined from the *point slope* of the (log T) vs. (log rpm) plot at each data point. The plot is shown in Figure 5.4. In general, if the data do not fall on a straight line on this plot, the point slope (tangent) at each data point must be determined, giving a different value of n' for each data point. The slope can be determined graphically by using numerical techniques, or by averaging the local slopes between successive points. Best results are usually obtained if the data are smoothed before the slopes are computed. The results of the calculations are shown below, where the values of n' are determined by averaging the slopes between successive points, Equation (5.13) gives the shear rate, and Equation (5.11) gives the shear stress:

Shear Stress at Bob (dyn/cm^2)	n'	Shear Rate at Bob (1/s)	Viscosity (Poise)
11.8	1	2.41	4.87
23.5	0.864	4.90	4.80
45.8	0.519	13.1	3.49
56.8	0.303	29.6	1.92
69.7	0.296	59.6	1.17

Note: 10 dyn/cm^2 = 1 Pa, and a viscosity of 10 Poise = 1 Pa·s = 1000 cP

A plot of viscosity vs. shear rate (Figure 5.5) shows that the fluid approaches Newtonian behavior at low shear rates and is shear thinning at higher shear rates, with power law–type behavior. As shown in Figure 5.5, the Ellis model gives a good representation of these data.

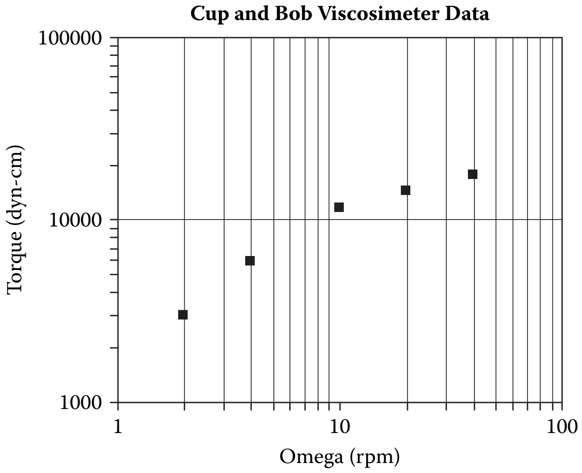

FIGURE 5.4 Cup and bob viscosimeter data.

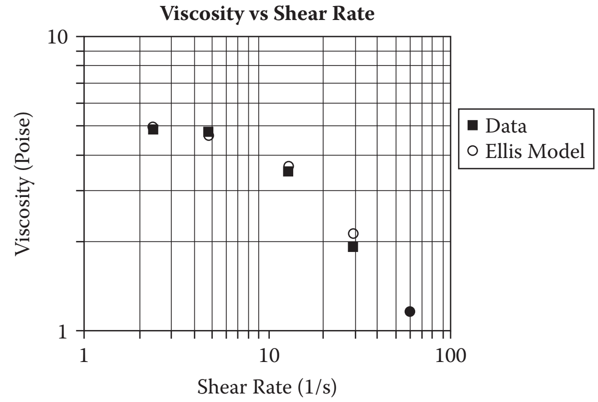

FIGURE 5.5 Viscosity vs. shear rate.

5.3 CONSERVATION PRINCIPLES

The flow behavior of fluids is governed by the basic laws for conservation of mass, energy, and momentum coupled with appropriate expressions for the irreversible rate processes (e.g., friction loss) as a function of fluid properties, flow conditions, geometry, etc. These conservation laws can be expressed in terms of "microscopic" or point values of the variables, or in terms of "macroscopic" or integrated average values of these quantities. In principle, the macroscopic balances can be derived by integration of the microscopic balances. However, unless the "local" microscopic details of the flow field are required, it is often easier and more convenient to start with the macroscopic balance equations.

5.3.1 Conservation of Mass

The macroscopic conservation of mass, or continuity, equation for any system is

$$\sum_{in} \dot{m}_i - \sum_{out} \dot{m}_o = \frac{dm_s}{dt} \tag{5.34}$$

where $\dot{m}_i$ and $\dot{m}_o$ are the rate of mass entering with streams (i) and leaving with streams (o), respectively, and m_s is the mass of the system. For a flow system at steady state,

$$\sum_{in} \dot{m}_i = \sum_{out} \dot{m}_o \tag{5.35}$$

or

$$\sum_{in} (\rho VA)_i = \sum_{out} (\rho VA)_o \tag{5.36}$$

For only one inlet and one outlet stream, this becomes

$$\dot{m}_i = \dot{m}_o \tag{5.37}$$

5.3.2 Conservation of Energy

The most common forms of energy that must be considered in flowing fluids are internal (thermal), kinetic, potential (due to gravity), mechanical (work), and heat. Energy can enter or leave any system either with the streams entering or leaving or through the boundary of the system. The latter includes heat (Q) and "shaft" work (W), so called because it is commonly associated with work done by a pump, compressor, mixer, etc., which is driven by a shaft. The sign conventions for heat (Q) and work (W) are arbitrary, and vary from one reference to another. The common "engineering" conventions are that heat *added* to the system and work that is *generated by* the system (such as a turbine) are *positive*, but work that is *consumed* by the system (e.g., by a pump) is *negative*. This convention is also more consistent with the "driving force" interpretation of the terms in the Bernoulli form of the energy balance, as shown below.

5.3.2.1 Macroscopic Energy Balance

The macroscopic conservation of energy for any system is

$$\sum\left(h+gz+\frac{V^2}{2}\right)_i \dot{m}_i - \sum\left(h+gz+\frac{V^2}{2}\right)_o \dot{m}_o + \dot{Q} - \dot{W} = \frac{d}{dt}\left[\left(u+gz+\frac{V^2}{2}\right)_{sys} m_{sys}\right] \quad (5.38)$$

where $h = u + P/\rho$ is the *enthalpy* per unit mass of fluid. For only one inlet and one exit stream, $\dot{m}_i = \dot{m}_o = \dot{m}$ and, for steady state, this can be written as

$$\Delta h + g\Delta z + \frac{1}{2}\Delta V^2 = q - w \quad (5.39)$$

where $q = \dot{Q}/\dot{m}$, $w = \dot{W}/\dot{m}$ are the heat added to the system and the work done by the system, respectively, per unit mass of fluid. From the definition of enthalpy, and accounting for the irreversible dissipation of energy (i.e., friction loss), this is equivalent to

$$\int_{P_i}^{P_o} \frac{dP}{\rho g} + (z_o - z_i) + \frac{1}{2g}(\alpha_o V_o^2 - \alpha_i V_i^2) + \frac{e_f}{g} + \frac{w}{g} = 0 \quad (5.40)$$

where

$$e_f = (u_o - u_i) - q + \int_{\rho_i}^{\rho_o} P d\left(\frac{1}{\rho}\right) \quad (5.41)$$

is the irreversible energy dissipation due to "friction." Equation (5.40) is the "generalized" or "engineering" Bernoulli equation, and is the most useful equation for analysis of flows in conduits. For an incompressible (constant density) fluid, the equation can be written as

$$H_P + H_s + h_w = h_f + H_v \quad (5.42)$$

which is the "head" form of the equation, since all terms have dimensions of length. Here, H_P (= $-\Delta P/\rho g$) is the decrease in "pressure head"; H_z (= $-\Delta z$) is the decrease in "static head"; h_w (= $-w/g$) is the "pump head"; h_f (= e_f/g) is the friction "head loss"; and H_v (= $\Delta[\alpha V^2/2g)$ is the increase in

"velocity head." For gases, if the pressure change is less than about 20%, the incompressible equation can be applied with reasonable accuracy by assuming the fluid density to be constant at a value equal to the average density in the system.

The α factors in the kinetic energy (or velocity head) term represent a correction factor to account for the deviation from plug flow through the conduit. For a Newtonian fluid in laminar flow in a circular tube, the profile is parabolic and the value of α is 2. For a highly turbulent flow, the profile is much flatter and $\alpha \approx 1.06$ (depending on the Reynolds number), although for practical purposes it is usually assumed that $\alpha = 1$ for turbulent flow.

Example 5.2

The mass flow rate of a hot coal-oil slurry can be determined by injecting a small sidestream of cool oil at a controlled rate and measuring the change in temperature downstream of the injection point. Calculate the flow rate of a slurry that is initially at 146.9°C (300°F) and has a density of 1200 kg/m^3 and a specific heat of 0.7 kcal/kg°C (Btu/lb$_m$°F), if a sidestream of oil is injected at a rate of 0.454 kg/s (1 lb$_m$/s). The temperature of the sidestream is 15.6°C (60°F), and it has a density of 800 kg/m^3 and a specific heat of 0.6 kcal/kg°C (Btu/lb$_m$°F). The temperature of the slurry downstream of the injection point is 147.8°C (298°F) with no sidestream injected, and 146.1°C (295°F) with the stream injected.

Solution

The steady-state energy balance applied to the slurry and sidestreams, excluding any pump in the line, is

$$\sum_{in}(h + gz + V^2/2)_i \dot{m}_i - \sum_{out}(h + gz + V^2/2)_o \dot{m}_o + \dot{Q} = 0$$

Assuming negligible change in elevation and kinetic energy, this becomes

$$h_{s1}\dot{m}_s + h_o\dot{m}_o - h_{s2}\dot{m}_s - h_{o2}\dot{m}_o + \dot{Q} = 0$$

where the subscripts s = slurry, o = oil, 1 = point upstream of injection point, and 2 = point downstream of injection point. $\dot{Q}$ is the rate of heat lost from the pipe between point 1 and point 2. Assuming $\Delta h = c_p \, \Delta T$ (i.e., negligible pressure drop), this becomes

$$\dot{m}_s c_{ps}(T_1 - T_2) + \dot{m}_o p_{po}(T_o - T_1) + \dot{Q} = 0$$

For no sidestream injection, $T_2 = T'_2$ = 147.8°C (298°F):

$$\dot{Q} = \dot{m}_s c_{ps}(T'_2 - T_1)$$

Inserting this into the previous equation and solving for $\dot{m}_s$,

$$\dot{m}_s = \frac{\dot{m}_o c_{po}(T_2 - T_o)}{c_{ps}(T'_2 - T_2)} = \frac{(0.454\ \text{kg/s})(0.6\ \text{kcal/kgC})(146.1\text{–}15.6)°\text{C}}{(0.7\ \text{kcal/kgC})(147.8\text{–}146.1)°\text{C}} = 29.9\ \text{kg/s}$$

5.3.3 Conservation of Momentum

Because momentum is a vector quantity, the directional properties of each term must be considered. Also, Newton's second law provides an equivalence between force and the rate of momentum. Thus, for a flow system, the conservation of momentum must include the forces that act on the fluid mass of the system as well as the momentum carried into and out of the system.

The macroscopic momentum balance equation is

$$\sum_{On\,Fluid} \vec{F} + \sum_{in} (\dot{m}\vec{V})_i - \sum_{out} (\dot{m}\vec{V})_o = \frac{d}{dt}(m\vec{V})_{sys} \tag{5.43}$$

For three-dimensional space, this equation is represented by three component equations, one for each direction. If there is only one entering and one leaving stream, then $\dot{m}_i = \dot{m}_o = \dot{m}$. For steady state, the momentum equation becomes

$$\sum_{On\,Fluid} \vec{F} = \sum_{out} (\dot{m}\vec{V})_o - \sum_{in} (\dot{m}\vec{V})_i \tag{5.44}$$

Note that $\dot{m}$ is a scalar (i.e., $\dot{m} = \rho\vec{V}\cdot\vec{A}$ is a scalar product) and

$$\sum_{On\,Fluid} \vec{F}$$

represents all of the forces that can act *on* the fluid "*system*." All of these forces, as well as each velocity component, must be referenced to a common reference frame or coordinate system. All forces due to pressures acting on the fluid in the system should be determined from the *gage* pressure, provided that the atmospheric pressure surrounding the system is uniform.

Example 5.3

A vessel containing water at 15.6°C (60°F) is fitted with a relief valve to keep the pressure in the vessel at or below 791 kPa (100 psig). The valve has a 101.6-mm (4-in.) inlet and is attached to the top of the vessel, and opens when the pressure reaches 791 kPa (100 psig). Determine the force (magnitude and direction) exerted on the valve at maximum flow conditions when the valve is open. The valve discharge is 90° from the direction of the inlet flow through a 152.4-mm (6-in.) diameter exit (see Figure 5.6) to the atmosphere. The loss coefficient for the open valve is 3 (see Section 5.7). Assume a steady state, and neglect gravity forces.

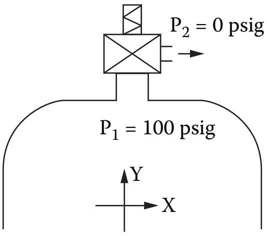

FIGURE 5.6 Force on relief valve.

Solution

The system is the fluid between the tank exit (at 791 kPa) and the valve exit (at 101 kPa). The loss coefficient relates the friction loss in the valve to the velocity leaving the valve, $e_f = K_f V_2^2/2$. Since the tank is much larger than the valve discharge, the velocity (and kinetic energy) in the tank can be neglected, and the flow is highly turbulent (which can be verified), so that α = 1. The exit velocity (V_2) is then determined from the Bernoulli equation:

$$V_2 = \left[\frac{2(P_1 - P_2)}{\rho(1+K_f)}\right]^{1/2} = \left[\frac{2(690\times 10^3\ \text{Pa})}{(1000\ \text{kg/m}^3)(1+3)}\right]^{1/2} = 18.6\ \text{m/s}$$

and the mass flow rate through the valve is determined from the continuity equation:

$$\dot{m} = \rho V_2 A_2 = (1000\ \text{kg/m}^3)(18.6\ \text{m/s})\frac{\pi}{4}(0.1524\ \text{m})^2 = 339\ \text{kg/s}$$

The x and y components of the force on the valve are determined from the corresponding components of the momentum balance equation:

$$\sum_{On\ Fluid} F_x = -(F_x)_{On\ Valve} = \dot{m}(V_{x2} - V_{x1}) = (339\ \text{kg/s})(18.6\ \text{m/s}) = 6305N$$

$$\sum_{On\ Fluid} F_y = -(F_y)_{On\ Valve} + P_1 A_1 = \dot{m}(V_{2y} + V_{1y}) = 0$$

$$(F_y)_{On\ Valve} = (791\times 10^3\ \text{Pa})\frac{\pi}{4}(0.1016\ \text{m})^2 = 6413N$$

$$\theta = \tan^{-1}(F_y / F_x) = 45.5°$$

Thus there is a force component in the $-x$ direction of 6300 N and in the $+y$ direction of 5600 N. The net force is $|F| = \sqrt{F_x^2 + F_y^2}$ = 9000 N, and it acts in a direction up and to the left at an angle of 45.5° from the horizontal.

5.4 FLUID STATICS

5.4.1 The Basic Equation of Fluid Statics

If there is no *relative* motion within the fluid, the differential form of the energy balance (Bernoulli equation) reduces to

$$\frac{dP}{dz} = -\rho g \tag{5.45}$$

Integration of this equation gives the pressure as a function of elevation (z) if the variations of g and ρ are known. Various special cases follow.

5.4.1.1 Constant Density

For a constant-density "isochoric" (or incompressible) fluid, under constant gravity,

$$P_1 - P_2 = \rho g(z_2 - z_1) \tag{5.46}$$

or

$$\Phi_1 = \Phi_2 = constant \tag{5.47}$$

where $\Phi = P + \rho gz$ is the sum of the local pressure (P) and static head (ρgz). Φ is a constant at all points within a continuous incompressible fluid. For example, this can be applied to a manometer containing a fluid with density ρ_m attached to a vessel or conduit containing a fluid with density ρ_f to relate the manometer reading (Δh) to the combined pressure/head difference ($\Delta\Phi$):

$$\Delta\Phi = -\Delta\rho g\Delta h \tag{5.48}$$

where $\Delta\Phi = \Phi_2 - \Phi_1$, $D\rho = \rho_m - \rho_f$, Δh = manometer reading, $\Phi = P + \rho gz$, and z is the elevation of the pressure tap. This is the basic *manometer equation* and may be applied to any manometer in any orientation.

5.4.1.2 Ideal Gas

If the fluid is described by the ideal gas law ($\rho = PM/RT$), and the temperature and g are constant over all z, the integral of the basic equation from (P_1, z_1) to (P_2, z_2) gives

$$P_2 = P_1 \exp\left(-\frac{Mg\Delta z}{RT}\right) \tag{5.49}$$

where $\Delta z = z_2 - z_1$, M is the molecular weight, T is absolute temperature, and R is the gas constant.

For an ideal gas under *isentropic* conditions,

$$\frac{P}{\rho^k} = constant = \frac{P_1}{\rho_1^k} \tag{5.50}$$

where $k = c_p/c_v$ is the specific heat ratio for the gas (for an ideal gas, $c_p = c_v + R/M$). If the density is eliminated from this and the ideal gas law, the temperature-pressure relation becomes

$$\frac{T}{T_1} = \left(\frac{P}{P_1}\right)^{(k-1)/k} \tag{5.51}$$

Using this and the ideal gas law to eliminate ρ and T from Equation (5.45), the latter can be integrated to give

$$P_2 = P_1\left[1 - \left(\frac{k-1}{k}\right)\frac{gM\Delta z}{RT_1}\right]^{k/(k-1)} \tag{5.52}$$

The corresponding temperature-elevation relation is

$$T_2 = T_1\left[1 - \left(\frac{k-1}{k}\right)\frac{gM\Delta z}{RT_1}\right] \tag{5.53}$$

5.4.1.3 The Standard Atmosphere

The "standard atmosphere" is based on a representative observed average of the temperature distribution in the atmosphere, averaged over the entire earth and over all seasons:

$$\text{For } 0 < z < 11 \text{ km: } \frac{dT}{dz} = -6.5°/\text{km} = -G \quad (5.54)$$

$$\text{For } z > 11 \text{ km: } T = -56.5°\text{C}$$

where the average temperature at sea level ($z = 0$) is taken to be 15°C (285 K). Using this expression along with the ideal gas law gives the pressure as a function of elevation:

$$P_2 = P_1\left[1 - \frac{G\Delta z}{T_0 - Gz_1}\right]^{Mg/RG} \quad (5.55)$$

where T_0 = 285 K.

5.4.2 Moving Systems

The basic equation of statics also applies to fluids in motion, as long as there are no *relative* motion or velocity *gradients* that give rise to shear stresses. If the motion involves a uniform acceleration, an additional component of the pressure gradient results, as illustrated.

If the fluid accelerates upward with an acceleration of a_z, this is equivalent to an increase in the gravitational acceleration, i.e.,

$$\frac{dP}{dz} = -\rho(g + a_z) \quad (5.56)$$

Likewise, an acceleration in any direction, such as the i direction, will result in a pressure gradient within the fluid in the $-i$ direction of magnitude ρa_i:

$$\frac{\partial P}{\partial x_i} = -\rho a_i \quad (5.57)$$

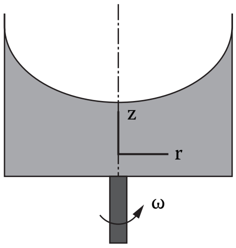
Example 5.4

Determine the shape of the free surface in an open container that is rotating uniformly at an angular velocity of ω (see Figure 5.7).

Solution

The uniform rotation results in an (inward) radial acceleration equal to $\omega^2 r$. This gives rise to a radial pressure gradient in the fluid, which is in addition to the vertical pressure gradient due to gravity. The total pressure differential within the fluid is thus

$$dP = \left(\frac{\partial P}{\partial z}\right)dz + \left(\frac{\partial P}{\partial r}\right)dr = \rho(-g\,dz + \omega^2 r\,dr)$$



Rotating Fluid

FIGURE 5.7 Rotating fluid.

Since the pressure on the surface is constant,

$$(dP)_s = 0 = -\rho g(dz)_s + \rho\omega^2(rdr)_s$$

This can be integrated to give

$$z = z_o + \frac{\omega^2 r^2}{2g}$$

which is the equation of a parabola.

5.4.3 Static Forces on Solid Boundaries

The force exerted on a solid boundary by a fluid pressure is given by

$$\vec{F}\int_A Pd\vec{A} \tag{5.58}$$

Since both force and area are vectors (whereas pressure is a scalar), the direction of the force is determined by the orientation of the surface on which the pressure acts, i.e., the *projected* area of the surface corresponding to the component of force.

This can be applied, for example, to determine the required pipe wall thickness (t) that will withstand a given pressure (P) for a given pipe size ($D = 2R$) and "working stress" of the metal (σ):

$$t = \frac{RP}{\sigma} \tag{5.59}$$

The dimensionless pipe wall thickness (times 1000) is the *schedule number* of the pipe. This expression is only approximate, as it does not make any allowance for such factors as pipe threads, corrosion, etc. To compensate for these effects, an additional allowance is made in the wall thickness for the working definition of the "schedule thickness," t_s:

$$\text{Schedule Number} = \frac{1000P}{\sigma} = \frac{1750t_s - 200}{D_o} \tag{5.60}$$

where both t_s and D_o (the pipe outside diameter) are in inches. This expression only applies to pipe larger than about 3 in., since smaller pipes must have a thicker wall just for dimensional integrity and rigidity. Standard pipe dimensions are given in Table 5.2.

TABLE 5.2

Note: 5S, 10S, and 40S are extracted from Stainless Steel Pipe, ANSI B36.19–1976, with permission of the publisher, the American Society of Mechanical Engineers, New York. ST = standard wall, XS = extra strong wall, XX = double extra strong wall, and Schedules 10 through 160 are extracted from Wrought-Steel and Wrought-iron Pipe, ANSI B36.10–1975, with permission of the same publisher. Decimal thicknesses for respective pipe sizes represent their nominal or average wall dimensions. Mill tolerances as high as ±12 1/2% are permitted.

Plan-end pipe is produced by a square cut. Pipe is also shipped from the mills threaded, with a threaded coupling on one end, or with the ends beveled for welding, or grooved or sized for patented couplings. Weights per foot for threaded and coupled pipe are slightly greater because of the weight of the coupling, but it is not available larger than 12 in or lighter than Schedule 30 sizes 8 through 12 in, or Schedule 40 sizes 6 in. and smaller.

To convert inches to millimeters, multiply by 25.4; to convert square inches to square millimeters, multiply by 645; to convert feet to meters, multiply by 0.3048; to convert square feet to square meters, multiply by 0.0929; to convert pounds per foot to kilograms per meter, multiply by 1.49; to convert gallons to cubic meters, multiply by 3.7854×10^{-3}: and to convert pounds to kilograms, multiply by 0.4536.

5.5 PIPE FLOW

5.5.1 Flow Regimes

The flow regime in a pipe is determined by the Reynolds number. For a Newtonian fluid:

$$N_{\text{Re}} = \frac{DV\rho}{\mu} = \frac{\rho V^2}{\mu V / D} \tag{5.61}$$

This represents the ratio of the momentum flux carried by the fluid axially along the tube to the viscous momentum flux transported normal to the flow in the radial direction. Laminar flows are dominated by the fluid viscosity and are stable, whereas turbulent flows are dominated by the fluid density inertia and are unstable.

5.5.2 Pressure-Flow Relations for Pipe Flows

For steady, fully developed one-dimensional flow in a uniform pipe, the engineering Bernoulli and momentum equations provide equivalent interpretations of the friction loss:

$$e_f = K_f \frac{V^2}{2} = \frac{\tau_w}{\rho}\left(\frac{4fL}{D}\right) \tag{5.62}$$

where K_f is the "loss coefficient" and τ_w is the wall shear stress. For pipe, these are related to the dimensionless (Fanning) friction factor (f) by

$$K_f = \frac{4fL}{D}; \quad \tau_w = \frac{f}{2}\rho V^2 \tag{5.63}$$

A loss coefficient can be defined for any element in which energy is dissipated (pipe, fittings, valves, etc.), although the friction factor is defined only for pipe flow. All that is necessary to describe the pressure-flow relation for pipe flows is Bernoulli's equation and a knowledge of the friction factor, which depends upon flow conditions, pipe size, and fluid properties.

5.5.3 Newtonian Fluids

5.5.3.1 Laminar Flow

For a Newtonian fluid in laminar flow,

$$f = \frac{4\pi D\mu}{Q\rho} = \frac{16\mu}{DV\rho} = \frac{16}{N_{\text{Re}}} \tag{5.64}$$

i.e., only one dimensionless group, fN_{Re}, is required to characterize laminar pipe flow, which has a value of 16. When this is introduced into the Bernoulli equation, the result is

$$Q = -\frac{\pi \Delta\Phi D^4}{128\mu L} \tag{5.65}$$

which is the *Hagen-Poiseuille* equation.

5.5.3.2 Turbulent Flow

For smooth pipe for Reynolds numbers from 4000 to 10^6, the *von Karman* equation provides an implicit relation between the friction factor and the Reynolds number:

$$\frac{1}{\sqrt{2}} = 4.0\log(N_{\mathrm{Re}}\sqrt{f}) - 0.04 \tag{5.66}$$

where $N_{\mathrm{Re}}\sqrt{f}$ is

$$N_{\mathrm{Re}}\sqrt{f} = \left(\frac{e_f D^3 \rho^2}{2L\mu^2}\right)^{1/2} \tag{5.67}$$

which is independent of flow rate.

5.5.3.3 Rough Pipe

Colebrook extended the von Karman equation to account for tube wall roughness (ε/D) as follows:

$$\frac{1}{\sqrt{f}} = -4\log\left[\frac{\varepsilon/D}{3.7} + \frac{1.255}{N_{\mathrm{Re}}\sqrt{f}}\right] \tag{5.68}$$

The Colebrook equation is convenient for determining the flow rate from the allowable friction loss (e.g., driving force), tube size, and fluid properties. Published plots of f vs. N_{Re} and ε/D (i.e., the Moody diagram) are usually generated from the Colebrook equation.

The actual size of the roughness elements on any surface will vary with the material, age and usage, deposits, dirt, scale, rust, etc. Typical values for various materials are given in Table 5.3. The most common pipe material—clean, new, commercial steel—has an effective roughness of about 0.0018 in. (0.045 mm). Other surfaces, such as concrete, may vary as much as several orders of magnitude, depending upon the nature of the surface finish.

5.5.3.4 All Flow Regimes

The expressions for the friction factor in both laminar and turbulent flows were combined into a single expression by Churchill (1977) as follows:

$$f = 2\left[\left(\frac{8}{N_{\mathrm{Re}}}\right)^{12} + \frac{1}{(A+B)^{3/2}}\right]^{1/12} \tag{5.69}$$

where

$$A = \left[2.457\ln\left(\frac{1}{\left(\frac{7}{N_{\mathrm{Re}}}\right)^{0.9} + \frac{0.27\varepsilon}{D}}\right)\right]^{16} \tag{5.70}$$

TABLE 5.3
Equivalent Roughness of Various Surfaces

Material	Condition	Roughness Range	Typical Value
Drawn Brass, Copper, Stainless	New	0.01-0.0015 mm (0.0004-0.00006 in.)	0.002 mm (0.00008 in.)
Commercial Steel	New	0.1-0.02 mm (0.004-0.0008 in.)	0.045 mm (0.0018 in.)
	Light Rust	1.0-0.15 mm (0.04-0.006 in.)	0.3 mm (0.015 in.)
	General Rust	3.0-1.0 mm (0.1-0.04 in.)	2.0 mm (0.08 in.)
Iron	Wrought, New	0.045 mm (0.002 in.)	0.045 mm (0.002 in.)
	Cast, New	1.0-0.25 mm (0.04-0.01 in.)	0.30 mm (0.025 in.)
	Galvanized	0.15-0.025 mm (0.006-0.001 in.)	0.15 mm (0.006 in.)
	Asphalt Coated	1.0-0.1 mm (0.04-0.004 in.)	0.15 mm (0.006 in.)
Sheet Metal	Ducts Smooth Joints	0.1-0.02 mm (0.004-0.0008 in.)	0.03 mm (0.0012 in.)
Concrete	Very Smooth	0.18-0.025 mm (0.007-0.001 in.)	0.04 mm (0.0016 in.)
	Wood Floated, Brushed	0.8-0.2 mm (0.03-0.007 in.)	0.3 mm (0.012 in.)
	Rough, Visible Form Marks	2.5-0.8 mm (0.1-0.03 in.)	2.0 mm (0.08 in.)
Wood	Stave, Used	1.0-0.25 mm (0.035-0.01 in.)	0.5 mm (0.02 in.)
Glass or Plastic	Drawn Tubing	0.01-0.0015 mm (0.0004-0.00006 in.)	0.002 mm (0.00008 in.)
Rubber	Smooth Tubing	0.07-0.006 mm (0.003-0.00025 in.)	0.01 mm (0.0004 in.)
	Wire Reinforced	4.0-0.3 mm (0.15-0.01 in.)	1.0 mm (0.04 in.)

$$B = \left(\frac{37,530}{N_{\text{Re}}} \right)^{16} \tag{5.71}$$

This equation gives the Fanning friction factor over the entire range of Reynolds numbers within the accuracy of the data used to construct the Moody diagram, including a reasonable estimate for the intermediate or transition region between laminar and turbulent flows. Corresponding expressions for the friction factor for non-Newtonian fluids in pipes are given below for two (two-parameter) models: the power law and Bingham plastic.

Example 5.5

Determine the power required to pump water at 60°F at a rate of 500 gpm through a 6-in. sch 40 pipe, 10 miles long, if the pressure at the entrance and discharge of the line is atmospheric.

Solution

At this temperature, the viscosity of water is 1 cP and the density is 1 g/cc. The actual ID of the sch 40 pipe is 154.1 mm (6.065 in.), and it is assumed to have a roughness of 0.045 mm (0.0018 in.). The power is the work done by the pump per unit mass of fluid ($-w$) times the mass flow rate, $\dot{m}$. From the Bernoulli equation for no change in pressure or elevation, this is

$$-w\dot{m} = e_f\dot{m} = \left(\frac{4fL}{D}\right)\left(\frac{V^2}{2}\right)\rho Q = \frac{32fLQ^3}{\pi^2 D^5}$$

The friction factor (f) depends on the Reynolds number ($N_{Re} = 4Q\rho/\pi D\mu = 2.61 \times 10^5$) and the relative roughness ($\varepsilon/D = 2.97 \times 10^{-4}$). From the Churchill equation (or the Colebrook equation, by iteration), $f = 0.00432$. Using this value in the above equation gives $-w\dot{m} = 81.3$ kW (109 hp).

5.5.3.5 Water in Sch 40 Pipe

For the special case of water at 60°F in sch 40 steel ($\varepsilon = 0.045$ mm or 0.0018 in.) pipe, the relation between flow rate, velocity, pressure drop, and pipe size is tabulated in Table 5.4. The range of values tabulated covers most of the range that would be expected in practice. Note that the friction loss is tabulated as "pressure drop" in psi per 100 ft of pipe, which is equivalent to ($100\ \rho e_f/L$) in English engineering units.

5.5.4 Power Law Fluids

The power law model is very popular for representing the viscosity of a wide variety of non-Newtonian fluids because of its simplicity and versatility. However, care should be exercised in its application; for reliable results, the range of shear stress (or shear rate) expected in the application should not extend beyond the range of the rheological data used to evaluate the model parameters. Both laminar and turbulent pipe flow of highly loaded slurries of fine particles, for example, can often be adequately represented by either of these two models, as shown by Darby et al. (1992).

5.5.4.1 Laminar Flow

The form of the power law model that applies to tube flow is

$$\tau_{rx} = -m\left(-\frac{dv_x}{ddr}\right)^n \tag{5.72}$$

since the velocity gradient (shear rate) and shear stress are negative. This can be integrated to give the flow rate:

$$Q = \pi\left(\frac{\tau_w}{mR}\right)^{1/n}\left(\frac{n}{3n+1}\right)R^{(3n+1)/n} \tag{5.73}$$

which is the power law fluid equivalent of the Hagen-Poiseuille equation. The dimensionless form of this equation is

$$fN_{Re\,PL} = 16 \tag{5.74}$$

Note: For pipe lengths other than 100 ft, the pressure drop is proportional to the length. Thus, for 50 ft of pipe, the pressure drop is approximately one half the value given in the table for 300 feet, three times the given value, etc.

Velocity is a function of the cross-sectional flow area; thus, it is constant for a given flow rate and is independent of pipe length.

For calculations for pipe other then Schedule 40, see explanation on next page.

Source: Darby, R., *Chemical Engineering Fluid Mechanics,* 2nd ed., New York: Marcel Dekker, 2001.

where

$$N_{\mathrm{Re}PL} = \frac{8D^n V^{2-n} \rho}{m[2(3n+1)/n]^n} \tag{5.75}$$

is the power law Reynolds number.

5.5.4.2 All Flow Regimes

There are insufficient data in the literature to provide a reliable estimate of the effect of roughness on friction loss for non-Newtonian fluids in turbulent flow. However, the influence of roughness is normally neglected, since the laminar boundary layer thickness for such fluids is typically much larger than for Newtonian fluids (i.e., the flow conditions most often fall in the "hydraulically smooth" range for common pipe materials). An expression by Darby et al. (1992) for f for the power law fluid, which applies to both laminar and turbulent flow, is

$$f = (1-\alpha) f_L + \frac{\alpha}{[f_T^{-8} + f_{Tr}^{-8}]^{1/8}} \tag{5.76}$$

where

$$f_L = \frac{16}{N_{\mathrm{Re}PL}} \tag{5.77}$$

$$f_T = \frac{0.0682 n^{-1/2}}{N_{\mathrm{Re}PL}^{1/(1.87+2.39n)}} \tag{5.78}$$

$$f_{Tr} = 1.79 \times 10^{-4} \exp(-5.24n) N_{\mathrm{Re}PL}^{(0.414+0.757n)} \tag{5.79}$$

and the parameter α is given by

$$\alpha = \frac{1}{(1+4^{-\Delta})} \tag{5.80}$$

where

$$\Delta = N_{\mathrm{Re}PL} - N_{\mathrm{Re}PLc} \tag{5.81}$$

and the "critical" Reynolds number that corresponds to the onset of turbulence is given by

$$N_{\mathrm{Re}PLc} = 2100 + 875(1-n) \tag{5.82}$$

5.5.5 Bingham Plastic Fluids

The Bingham plastic model usually provides a good representation for the viscosity of concentrated slurries, suspensions, sediments, emulsions, foams, etc. Such materials often exhibit a yield stress,

which must be exceeded before the material will flow at a significant rate. Other examples include paint, ink, shaving cream, mayonnaise, etc. There are also many fluids that may have a yield stress that is less pronounced, such as blood, fine silt, etc.

A "plastic" is really two materials. At low stresses, below the yield stress (τ_o), it behaves as a solid, whereas above the yield stress it behaves as a fluid. The Bingham model for this material is

$$\begin{aligned} &\text{For } |\tau| < \tau_o: \quad \dot{\gamma} = 0 \\ &\text{For } |\tau| > \tau_o: \quad \tau = \pm\tau_o + \mu_\infty \dot{\gamma} \end{aligned} \tag{5.83}$$

Since the shear stress and shear rate can be either positive or negative, the "plus" is used in the former case, and the "minus" for the latter. For tube flow, the "minus" sign should be used.

5.5.5.1 Laminar Flow

There is a finite distance from the center of the pipe over which the stress is always less than the yield stress, so in this region the material behaves as a solid and does not "yield" but moves as a rigid "plug." The radius of this plug (r_o) is

$$r_o = R\frac{\tau_o}{\tau_w} \tag{5.84}$$

Outside of this plug region, the stress exceeds the yield stress and the material will flow. The total flow rate is determined by combining the flow in the "plug" with that in the "fluid" region to give

$$Q = \frac{\pi R^3 \tau_w}{4\mu_\infty}\left[1 - \frac{4}{3}\left(\frac{\tau_o}{\tau_w}\right) + \frac{1}{3}\left(\frac{\tau_o}{\tau_w}\right)^4\right] \tag{5.85}$$

which is known as the *Buckingham–Reiner* equation. In dimensionless form, it can be written as

$$f_L = \frac{16}{N_{\text{Re}}}\left[1 + \frac{N_{\text{He}}}{6N_{\text{Re}}} - \frac{1}{3}\frac{N_{\text{He}}^4}{f^3 N_{\text{Re}}^7}\right] \tag{5.86}$$

where the Reynolds number is given by

$$N_{\text{Re}} = \frac{DV\rho}{\mu_\infty} \tag{5.87}$$

and

$$N_{\text{He}} = \frac{D^2 \rho \tau_o}{\mu_\infty^2} \tag{5.88}$$

is the *Hedstrom number*. Note that the Bingham plastic reduces to a Newtonian fluid if $\tau_o = N_{\text{He}} = 0$, for which $fN_{\text{Re}} = 16$. There are actually only two independent dimensionless groups in Equation (5.86), i.e., fN_{Re} and $N_{\text{He}}/N_{\text{Re}}$ (which is also called the *Bingham number*, $N_{\text{Bi}} = [D\tau_o/\mu V]$). The

Buckingham-Reiner equation is implicit in f, so it must be solved by iteration for known values of N_{Re} and N_{He}.

5.5.5.2 All Flow Regimes

For the Bingham plastic fluid, there is no abrupt transition from laminar to turbulent flow, as is observed for Newtonian fluids. Instead, a gradual deviation from purely laminar flow to fully turbulent flow occurs. For turbulent flow, the friction factor can be represented by the empirical expression of Darby and Melson (1982) (as modified by Darby et al., 1992):

$$f_T = \frac{10^a}{N_{\text{Re}}^{0.193}} \tag{5.89}$$

where

$$a = -1.41[1 + 0.146\exp(-2.9 \times 10^{-5} N_{\text{He}})] \tag{5.90}$$

For all values of N_{Re} and N_{He}, f is given by

$$f = (f_L^m + f_T^m)^{1/m} \tag{5.91}$$

where

$$m = 1.7 + \frac{40,000}{N_{\text{Re}}} \tag{5.92}$$

and f_L is given by the Buckingham–Reiner equation (5.86).

Example 5.6

Calculate the power required to pump a coal slurry that is 50% (by weight) solids at a rate of 315.5 m^3/s (500 gpm) through a 6-in. sch 40 pipeline (ID = 154.1 mm) that is 16.1 km (10 mi) long. The slurry behaves as a Bingham plastic, with a yield stress of 1.16 Pa, a limiting viscosity of 40.6×10^{-3} Pa·s, and a density of 1162 kg/m^3.

Solution

The same general equation used in Example 5.5 applies, i.e.,

$$-w\dot{m} = e_f\dot{m} = \left(\frac{4fL}{D}\right)\left(\frac{V^2}{2}\right)\rho Q = \frac{32fL\rho Q^3}{\pi^2 D^5}$$

where now the friction factor depends on both the Reynolds number ($N_{\text{Re}} = 4Q\rho/\pi D\mu_\infty = 6.42 \times 10^3$) and the Hedstrom number ($N_{\text{He}} = D^2\rho\tau_o/\mu^\infty = 7.78 \times 10^3$). Using Equations (5.90) to (5.93), we find: $a = -1.574$, $m = 7.93$, $f_L = 0.2045$, $f_T = 0.00491$, $f = 0.205$. Thus, the above equation gives $-w\dot{m} = 3860$ kW (5170 hp).

5.5.6 Fitting Losses

The loss coefficient for pipe is related to the Fanning friction factor by

$$K_f = \frac{4fL}{D} \tag{5.93}$$

For other “loss elements” (e.g., fittings, valves, constrictions, expansions, contractions, etc.), a variety of methods exist for determining K_f. These include the “constant K_f” (a rough estimate), the $(L/D)_{\mathrm{eq}}$ method (a better, but limited, estimate), the Crane (1991) method (a good estimate for fully turbulent flow), and the 2-*K* (Hooper, 1981, 1988) and 3-*K* (Darby, 2001) methods. The latter two methods provide good values over the greatest range of fitting sizes and Reynolds numbers, and are presented below, with the 3-*K* method being the most accurate.

5.5.6.1 2-*K* (Hooper) Method

Hooper (1981, 1988) correlated loss coefficients for a variety of fittings as a function of Reynolds number and diameter by the equation

$$e_f = \frac{K_f V^2}{2} \quad \text{where} \quad K_f = \frac{K_1}{N_{\mathrm{Re}}} + K_\infty\left(1 + \frac{1}{ID_{in}}\right) \tag{5.94}$$

where ID_{in} is the internal diameter in inches of the pipe that contains the fitting. This correlation is valid over a wide range of Reynolds numbers and a limited range of fitting sizes. Tables 5.5 and 5.6 give values of K_1 and K_∞ for various contractions and expansions and for entrance and exit losses.

5.5.6.2 3-*K* Method

Although the 2-*K* method applies over a wide range of Reynolds numbers, the scaling term (e.g., 1/ID) works best for relatively small fittings. A more accurate scaling law based on data for a wider range of valve and fitting sizes from a variety of sources has been given by Darby (1991, 2001) based on data for various valves, tees, and elbows and is represented by the *3-K* equation

$$K_f = \frac{K_1}{N_{\mathrm{Re}}} + K_i\left(1 + \frac{K_d}{D_{n.in}^{0.3}}\right) \tag{5.95}$$

where $D_{n,in}$ is the pipe nominal diameter in inches. Values of the 3 *K*’s (K_1, K_i, and K_d are given in Table 5.7 for various valves, tees, and elbows. (For comparison, typical values of $(L/D)_{eq}$ for these fittings are also included.) All of the *K*’s are dimensionless except for K_d, which has units of in.$^{0.3}$. If units of millimeters are used for the diameter, the values of K_d in Table 5.7 should be multiplied by 2.64. This method is based on a wide range of observations from different sources (Darby, 2001), and is recommended as providing the best values over the widest range of Reynolds numbers and fitting sizes.

The definition of K_f (i.e., $K_f = 2e_f/V^2$) involves the kinetic energy of the fluid, $V^2/2$. For sections in which the flow area changes (e.g., pipe entrance, exit, expansion, contraction, etc.), the entering and leaving velocities will be different. Since the value of the velocity used with the definition of K_f is arbitrary, it is very important to know which velocity is implied when values of the loss coefficient are used from various sources (e.g., handbooks, manuals, texts, etc.). In most cases it is the largest velocity, through the smallest flow area, but the values in Table 5.6 for contractions and expansions are all used with the upstream velocity.

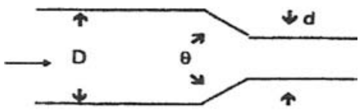
5.5.6.3 Non-Newtonian Fluids

There are insufficient data in the literature to enable reliable correlation or prediction of friction loss in valves and fittings for non-Newtonian fluids. As a first approximation, however, it may be assumed that a correlation analogous to the 2-*K* or 3-*K* method should apply to non-Newtonian

TABLE 5.5
Loss Coefficients for Expansions and Contractions

K_t to be used with upstream velocity head, $V_1^2/2$. $\beta = d/D$

Contraction



$\theta < 45°$

$N_{\mathrm{Re},1} < 2500$:

$$K_t = 1.6\left[1.2 + \frac{160}{N_{\mathrm{Re},1}}\right]\left[\frac{1}{\beta^4} - 1\right]\sin\frac{\theta}{2}$$

$N_{\mathrm{Re},1} > 2500$:

$$K_t = 1.6[0.6 + 1.92 f_1]\left[\frac{1-\beta^2}{\beta^4}\right]\sin\frac{\theta}{2}$$

$\theta > 45°$

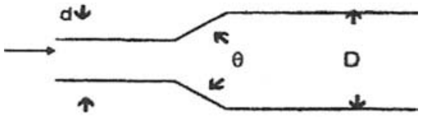
$N_{\mathrm{Re},1} < 2500$:

$$K_t = \left[1.2 + \frac{160}{N_{\mathrm{Re},1}}\right]\left[\frac{1}{\beta^4} - 1\right]\left[\sin\frac{\theta}{2}\right]^{1/2}$$

$N_{\mathrm{Re},1} > 2500$:

$$K_t = [0.6 + 1.92 f_1]\left[\frac{1-\beta^2}{\beta^4}\right]\left[\sin\frac{\theta}{2}\right]^{1/2}$$

Expansion



$\theta < 45°$

$N_{\mathrm{Re},1} < 4000$:

$$K_t = 5.2(1-\beta^4)\sin\frac{\theta}{2}$$

$N_{\mathrm{Re},1} > 4000$:

$$K_t = 2.6(1 + 3.2 f_1)(1-\beta^2)^2\sin\frac{\theta}{2}$$

$\theta > 45°$

$N_{\mathrm{Re},1} < 4000$:

$$K_t = 2(1-\beta^4)$$

$N_{\mathrm{Re},1} > 4000$:

$$K_{t1} = (1 + 3.2 f_1)(1-\beta^2)^2$$

fluids if the (Newtonian) Reynolds number is replaced by a single corresponding dimensionless group that adequately characterizes the influence of the non-Newtonian properties. For the power law model, the appropriate Reynolds number was derived for pipe flow:

$$N_{\mathrm{Re}PL} = \frac{2^{7-3n}\rho Q^{2-n}}{m\pi^{2-n}D^{4-5n}}\left[\frac{n}{3n+1}\right]^n \tag{5.96}$$

For the Bingham plastic, a corresponding expression for the Reynolds number based on the ratio of inertial to viscous momentum flux is

$$N_{ReBP} = \frac{4Q\rho}{\pi D\mu_\infty(1+\pi D^3\tau_o/24Q\mu_\infty)} = \frac{N_{Re}}{1+N_{He}/(6N_{Re})} \tag{5.97}$$

5.5.7 Pipe Flow Analysis

Pipe flow analyses may require the determination of either the driving force, flow rate, or pipe diameter. The procedures for these analyses for Newtonian and non-Newtonian fluids are similar, utilizing the engineering Bernoulli equation and the dimensionless expressions for the Fanning friction factor. For these purposes, the engineering Bernoulli equation can be written as

$$DF = \sum_i e_{fi} + \frac{1}{2}(\alpha_2 V_2^2 - \alpha_1 V_1^2) \tag{5.98}$$

where

$$DF = -\left(\frac{\Delta P}{\rho} + g\Delta z + w\right) \tag{5.99}$$

is the net "driving force" for moving the fluid, and

$$\sum_i e_{fi} = \frac{1}{2}\sum_i (V^2 K_f)_i = \frac{8Q^2}{\pi^2}\sum_i \left(\frac{K_f}{D^4}\right)_i \qquad (5.100)$$

where the summation is over each fitting and segment of pipe (of diameter D_i) in the system. The loss coefficients for the pipe and fittings are given by the Fanning friction factor in the 3-*K* formula:

$$K_{pipe} = \frac{4fL}{D}, \; K_{fit} = \frac{K_1}{N_{\text{Re}}} + K_i\left(1 + \frac{K_d}{D_{n,in}^{0.3}}\right) \tag{5.101}$$

In many applications the kinetic energy terms in Equation (5.98) are negligible (or cancel out), although this should be verified for each situation. The loss coefficients are a function of the Reynolds number, which for Newtonian fluids is

$$N_{\text{Re}} = \frac{4Q\rho}{\pi D\mu} \tag{5.102}$$

as well as the relative roughness if Newtonian, or the flow index (n) if power law, or the Hedstrom number if Bingham plastic. The Bernoulli equation can thus be written as

$$DF = \frac{8Q^2}{\pi^2}\left[\sum_i \left(\frac{K_f}{D^4}\right)_i + \frac{\alpha_2}{D_2^4} - \frac{\alpha_1}{D_1^4}\right] \tag{5.103}$$

where the α's are the kinetic energy correction factors at the upstream (1) and downstream (2) points ($\alpha = 2$ for laminar flow and $\alpha = 1$ for turbulent flow of a Newtonian fluid). This equation can be solved directly for either DF, or Q, or D provided all the loss coefficients (K_f's) are known. If DF is to be determined, the Reynolds number and hence all of the K_f's can be calculated directly, so the procedure is straightforward. If Q or D are to be determined, it is necessary to start with an estimate of each of the K_f's, use this to calculate Q or D, and use the result to calculate the Reynolds number and hence to verify (or revise) the K_f values. For the unknown diameter case, only one diameter $D = D_i$ can be determined. The procedure is the same for non-Newtonian as for Newtonian fluids.

5.5.8 Economical Diameter

When installing a piping system, both the "best" pipe and the "best" pump must usually be selected to deliver a prescribed flow. The term "best" in this case refers to that combination of pipe and pump that will minimize the total system cost, including both the capital cost of the pipe and pump stations as well as operating (energy) cost, i.e.,

Capital cost of pipe (CCP)
Capital cost of pump stations (CCPS)
Energy cost to power pumps (EC)

Since energy cost is continuous and capital costs are "one time," it is assumed that the capital costs are amortized over a period of Y years, the "economic lifetime" of the pipeline. The reciprocal of this ($X = 1/Y$) is the fraction of the total capital cost charged off per year. The capital cost and the energy cost per year combine to give the total cost. (There are other costs, such as maintenance, etc., but these are minor and will not materially influence the result.)

Data on the cost of typical pipelines of various sizes can be represented by (Darby and Melson, 1982)

$$CCP = aD_{ft}^{p}L \tag{5.104}$$

where D_{ft} is the pipe ID in feet, and the parameters a and p depend upon the grade of steel in the pipe, as shown in Table 5.8. Likewise, the capital cost of (installed) pump stations (for 370 kW (500 hp) and over) is a linear function of the pump power (see Figure 5.8):

TABLE 5.8
Cost of Pipe (1980 \$)

	Pipe Cost Correlation Parameters[b]				
Pipe Grade[a]	**ANSI 300#**	**ANSI 400#**	**ANSI 600#**	**ANSI 900#**	**ANSI 1500#**
a	23.1	23.9	30.0	38.1	55.3
p	1.16	1.22	1.31	1.35	1.39

[a] ANSI grades correspond roughly to Schedules 20, 30, 40, 80, and 120, respectively.
[b] Pipe cost: \$/ft = $a(ID_{ft})^P$, \$/m = $3.28 \times a(0.3048\ ID_m)^P$

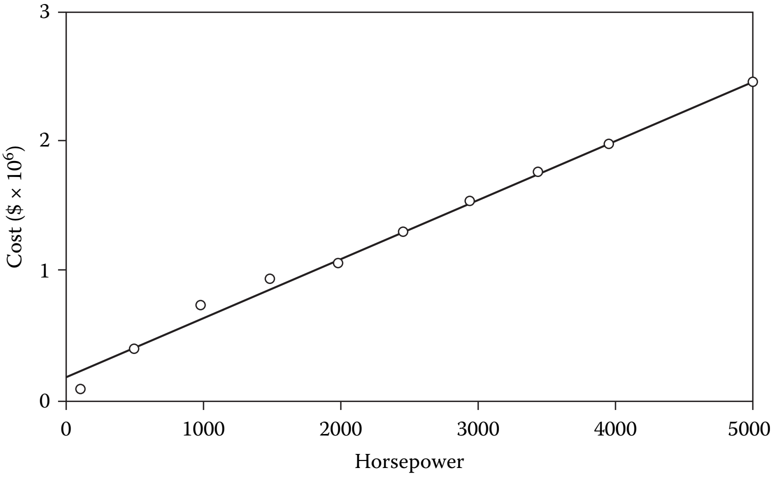

FIGURE 5.8 Cost of pump stations (1980 \$).

$$CCPS = A + BHP / \eta_e \tag{5.105}$$

where A = \$172,800, B = \$605/kW (\$450.8/hp) (in 1980 \$), and HP/η_e is the power rating of the pump.

The energy cost is determined from the pumping power requirement, as calculated from the Bernoulli equation:

$$HP = -w\dot{m}\left[\frac{2fLV^2}{D} + \frac{\Delta\Phi}{\rho}\right] = \frac{32fL\dot{m}^3}{\pi^2\rho^2D^5} + \dot{m}\frac{\Delta\Phi}{\rho} \tag{5.106}$$

and the total energy cost per year is

$$EC = \frac{CHP}{\eta_e} \tag{5.107}$$

where C is the unit energy cost (e.g., \$/hp·yr, \$/kW·h, etc.) and η_e is the pump efficiency. The total annual cost of the pipeline is the sum of the capital and energy costs. The pipe diameter that minimizes this total cost (i.e., D_{ec}) is given by

$$D_{ec}\left[\left(\frac{B+CY}{ap\eta_e}\right)\left(\frac{160 f\dot{m}^3}{\pi^2\rho^2}\right)\right]^{1/(p+5)} \tag{5.108}$$

where $Y = 1/X$. Since this equation is implicit (i.e., f depends on D_{ec}), it is best solved by iteration, starting with an assumed value for f, calculating the corresponding value of D_{ec}, and using this to evaluate N_{Re} and hence verify (revise) f. The same procedure can be used for non-Newtonian as for Newtonian fluids. Note that the cost data in Figure 5.8 are circa 1980. These data can be used with an appropriate inflation factor to apply to current costs, or the energy cost as of 1980 can be used with these values, since all of the cost factors in Equation (5.108) appear as a ratio, so that any inflation factor will cancel out when applied to both capital and energy costs.

5.5.9 Noncircular Conduits

Application of the conservation of momentum to the steady flow of a fluid in a uniform conduit with any arbitrary cross-sectional shape results in an expression for the momentum due to wall drag (or the equivalent frictional energy dissipation) of the form

$$e_f = \frac{\tau_w}{\rho}\left(\frac{4L}{D_h}\right) \tag{5.109}$$

where

$$D_h = 4\frac{A}{W_p} \tag{5.110}$$

Here, A is the cross-sectional area of the conduit, and W_p is the "wetted perimeter" (i.e., the length of the solid boundary in the cross section that is wetted by the fluid). For a circular pipe filled with liquid, $D_h = D$, the pipe diameter. Thus, D_h is the geometric parameter that is equivalent to the diameter of a circular pipe and is called the *hydraulic diameter*.

This result can be used to apply the previous equations for circular pipes to conduits of any other shape, by replacing D in the appropriate equation with D_h for the noncircular conduit. This gives excellent results for turbulent flows, for which the boundary layer is generally thin relative to the flow area dimensions, since the wall resistance (i.e., friction loss) is confined to a region very near the wall and, consequently, is not very sensitive to the shape of the cross section.

For laminar flows, the "laminar sublayer" fills the entire cross section. Thus, the effect of wall drag is influenced to a greater extent by the shape of the cross section. For many noncircular conduits with laminar flows, either theoretical analyses (similar to the Hagen-Poiseuille equation) or numerical analyses for the pressure-flow relation have been conducted. The results can be expressed in dimensionless form as

$$fN_{\text{Re}h} = K \tag{5.111}$$

similar to the dimensionless form of the Hagen-Poiseuille equation (5.64), for which $K = 16$. Table 5.9 shows the results in terms of the value of K for a variety of noncircular cross sections. It is

important to note that the proper definitions of the fanning friction factor (f) and the hydraulic Reynolds number be used in these expressions, i.e.,

$$f = \frac{e_f}{(4L/D_h)(V^2/2)} \tag{5.112}$$

$$N_{\mathrm{Re}h} = \frac{D_h V \rho}{\mu} \tag{5.113}$$

The velocity in these equations can be replaced by Q/A (where A can be expressed in terms of D_h for the geometry of interest). However, *do not* use $V = 4Q/\pi D^2$, since this is for circular pipes only.

For turbulent flows in noncircular conduits, the Moody diagram or Churchill equation can be used with good results, if the relative roughness is taken as ε/D_h.

5.5.10 Turbulent Drag Reduction

A phenomenon known as *turbulent drag reduction* (or the *Toms effect*) occurs in solutions of a variety of very high polymers. As much as 85% *less* energy may be required to pump solutions of certain high polymers at concentrations of 100 ppm or less through a pipe, when compared with the energy required to pump the solvent alone at the same flow rate through the same pipe. Although the mechanism is still under debate, the model of Darby and Chang (1984) as modified by Darby and Pivsa-Art (1991), based on energy storage by the elastic properties of the polymers, shows that, for smooth tubes, the friction factor vs. Reynolds number relation for Newtonian fluids (e.g., the Colebrook or Churchill equation) may also be used for drag-reducing flows, provided that: (a) the Reynolds number is defined using the properties (e.g., viscosity) of the Newtonian solvent, and (b) the Fanning friction factor is modified as follows:

$$f_p = \frac{f_s}{\sqrt{1 + N_{De}^2}} \tag{5.114}$$

Here, f_s is the Fanning friction factor for the Newtonian solvent, as predicted using the (Newtonian) Reynolds number; f_p is a "generalized" Fanning friction factor that applies to polymer (e.g., drag reducing) solutions as well as Newtonian fluids; and N_{De} is the dimensionless Deborah number, which reflects the fluid viscoelastic properties and accounts for the storage of energy by the elastic deformations (for Newtonian fluids, $N_{De} = 0$). This correlation collapses data for a wide range of polymers at various concentrations in a wide range of tube sizes all on the same line for f_p vs. N_{Re}, which can be represented by the classic Colebrook equation (for Newtonian fluids in smooth tubes).

The complete expression for N_{De} is given by Darby and Pivsa-Art (1991) in terms of the viscoelastic properties of the fluid. These properties are complex, and cannot be predicted accurately from first principles or other basic properties, and must be measured for each polymer solution. However, a simplified expression has been given by Darby and Pivsa-Art (1991), in which these rheological parameters are contained within two "constants," k_1 and k_2, which depend only on the specific polymer solution and its concentration:

$$N_{De} = k_2 \left(\frac{8\mu_s N_{\mathrm{Re}s}}{\rho D^2} \right)^{k_1} N_{\mathrm{Re}s}^{0.34} \tag{5.115}$$

Values of k_1 and k_2 for various polymer/tube systems are given in Table 5.10. (Values of k_1 and k_2 can be determined for a given polymer solution from laboratory measurements of pressure drop in smooth tubes at two flow rates in the turbulent range.) These values can be used with the model to predict friction loss for that solution at any Reynolds number in any size pipe. If the Colebrook equation for smooth tubes is used, the appropriate generalized expression for the friction factor is

TABLE 5.10

5.5.11 Compressible Flows

For gases, the dependence of density upon pressure and temperature has a significant effect on the flow behavior when the change in pressure is significant (e.g., 20% or more) relative to the absolute pressure in the system. At low velocities (relative to the speed of sound), the relative change in pressure and associated effects are often small, and the assumption of constant density (evaluated

at an average pressure) is usually reasonable. However, when the gas velocity approaches the speed of sound, the effects of compressibility become the most significant.

Under most conditions, the gas properties can be described adequately by the ideal gas law, i.e.,

$$\rho = \frac{PM}{RT} \tag{5.117}$$

In general, the further the temperature and pressure are from the critical temperature and pressure of the gas (i.e., the higher the temperature and lower the pressure), the better the properties are represented by the ideal gas law.

For a steady flow of an incompressible fluid in a uniform pipe, the only property that varies along the pipe is pressure. However, for a compressible fluid when the pressure varies (i.e., drops), the density also drops, which means that the velocity must increase for a given mass flow. The kinetic energy thus increases, which results in a decrease in the internal energy and the temperature. This process is usually described as adiabatic, or locally isentropic, with the effect of friction loss included separately. A limiting case is the isothermal condition, although special means are usually required to achieve constant temperature. Under *isothermal* conditions for an ideal gas,

$$\frac{P}{\rho} = constant = \frac{P_1}{\rho_1} = \frac{P_2}{\rho_2} \ldots \text{ etc.} \tag{5.118}$$

whereas for *isentropic* conditions,

$$\frac{P}{\rho^k} = constant = \frac{P_1}{\rho_1^k} = \frac{P_2}{\rho_2^k} \ldots \text{ etc.} \tag{5.119}$$

where $k = c_p/c_v$ is the “isentropic exponent.” For an ideal gas, $c_p = c_v + R/M$, and for diatomic gases $k \approx 1.4$, whereas for triatomic and higher gases, $k \approx 1.3$. Table 5.11 lists some properties of various gases, including the isentropic exponents. As the downstream pressure drops, the velocity in the pipe increases until it reaches the speed of sound at the pipe exit. At this point, no further increase in velocity is possible by reducing pressure downstream, since pressure changes are transmitted at the speed of sound, and the flow is said to be “choked.” The speed of sound in any medium is given by

$$c = \sqrt{\frac{K}{\rho}} \tag{5.120}$$

where K is the bulk modulus of the material. For gases,

$$K = \rho\left(\frac{\partial P}{\partial \rho}\right)_s = \rho k\left(\frac{\partial P}{\partial \rho}\right)_T \tag{5.121}$$

which for an ideal gas becomes

$$c = \sqrt{\frac{kP}{\rho}} = \sqrt{\frac{kRT}{M}} \tag{5.122}$$

Note: Weight density values were obtained by multiplying density of air by specific gravity of gas. For values at 60°F, multiply by 1.0154.

Natural gas values are representative only. Exact characteristics require knowledge of specific constituents.

[a] c_p= Specific heat at constant pressure.

[b] c_v = Specific heat al constant volume.

Source: Molecular weight, specific gravity, individual gas constant, and specific heat values were abstracted from, or based on, data in Table 24 of Mark's *Standard Handbook for Mechanical Engineers* (7th edition)

5.5.11.1 Isothermal Pipe Flow

For isothermal flow in a pipe, the mass flux ($G = \dot{m}/A$) can be determined by integrating the differential form of the Bernoulli to give

$$G = \sqrt{P_1\rho_1}\left[\frac{(1 - P_2^2/P_1^2)}{4fL/D - 2\ln(P_2/P_1)}\right]^{1/2} \tag{5.123}$$

Neglecting the logarithmic term in the denominator (which comes from the change in kinetic energy of the gas) gives the *Weymouth equation*. Furthermore, if the average density of the gas is used in the Weymouth equation, i.e.,

$$\bar{\rho} = \frac{(P_1 + P_2)M}{2RT} \quad \text{or} \quad \frac{M}{2RT} = \frac{\bar{\rho}}{P_1 + P_2} \tag{5.124}$$

the result is identical to the Bernoulli equation for an incompressible fluid in a straight, uniform pipe:

$$G = \left[\frac{\bar{\rho}(P_1 - P_2)}{2fL/D}\right]^{1/2} = \sqrt{P_1\bar{\rho}}\left[\frac{2(1 - P_1/P_2)}{4fL/D}\right]^{1/2} \tag{5.125}$$

The mass flux reaches a maximum (choked flow) when the velocity reaches the speed of sound. At this point, the mass flow rate is independent of any further decrease in the exit pressure but will still vary with changes in the upstream pressure. The equation for G is implicit, since the friction factor depends upon the Reynolds number, which depends on G. However, the Reynolds number under choked flow conditions is typically high enough that fully turbulent flow occurs, in which case the friction factor depends only on the relative pipe roughness, i.e.,

$$f = \frac{0.0625}{\left[\log\left(\frac{3.7}{\varepsilon/D}\right)\right]^2} \tag{5.126}$$

5.5.11.2 Adiabatic Flow

For adiabatic flow, the usual procedure is to assume "locally isentropic" conditions and include the friction loss to account for irreversibilities. In this case, the pressure, temperature, density, and velocity all change along the pipe. For an ideal gas under isentropic conditions,

$$T = T_1\left(\frac{P}{P_1}\right)^{(k-1)/k} \tag{5.127}$$

and the expression for the mass flux is

$$G = \sqrt{P_1\rho_1}\left[\frac{2\left(\frac{k}{k+1}\right)\left(1 - \left(\frac{P_2}{P_1}\right)^{(k+1)/k}\right)}{\frac{4fL}{D} - \frac{2}{k}\ln\left(\frac{P_2}{P_1}\right)}\right]^{1/2} \tag{5.128}$$

If the system contains fittings as well as straight pipe, the term ($2fL/D$) is replaced by $\Sigma(K_f/2)$, where ΣK_f represents the sum of all the loss coefficients in the system.

5.5.11.3 Choked Flow

The pressure at which choked flow occurs (P_2*) is determined by the conditions for sonic flow. For isothermal flow, the critical (choked) mass flux is given by

$$G^* = \sqrt{P_1\rho_1}\left(\frac{P_2^*}{P_1}\right)^{1/2} \tag{5.129}$$

and $P_2{}^*$ is determined from

$$\Sigma K_f = \left(\frac{P_1}{P_2{}^*}\right)^2 - 2\ln\left(\frac{P_1}{P_2{}^*}\right) - 1 \tag{5.130}$$

The pressure at the (inside of the) end of the pipe at which the flow becomes sonic ($P_2{}^*$) is a unique function of the upstream pressure (P_1) and the sum of the loss coefficients in the system (K_f). The equation is implict for $P_2{}^*$ and can be solved by iteration for given values of K_f and P_1. For adiabatic flow, the corresponding expressions are

$$G^* = \sqrt{P_1\rho_1}\left[k\left(\frac{P_2{}^*}{P_1}\right)^{(k+1)/k}\right]^{1/2} \tag{5.131}$$

and

$$\Sigma K_f = \frac{2}{(k+1)}\left[\left(\frac{P_1}{P_2{}^*}\right)^{(k+1)/k} - 1\right] - \frac{2}{k}\ln\left(\frac{P_1}{P_2{}^*}\right) \tag{5.132}$$

5.5.11.4 Isentropic Nozzle Flow

The mass flux for the adiabatic flow of an ideal gas flowing through a frictionless conduit or a constriction (such as an orifice, valve, etc.) for which $A_1 >> A_2$ (i.e., $V_1 << V_2$) is given by

$$G = \sqrt{P_1\rho_1}\left[\left(\frac{2k}{k-1}\right)\left(\frac{P_2}{P_1}\right)^{2/k}\left\{1-\left(\frac{P_2}{P_1}\right)^{(k-1)/k}\right\}\right]^{1/2} \tag{5.133}$$

The mass flow is a maximum when

$$\frac{P_2}{P_1} = \frac{P_2{}^*}{P_1} = \left(\frac{2}{k+1}\right)^{k/(k-1)} \tag{5.134}$$

which, for $k = 1.4$ (e.g., air), has a value of 0.528. Thus, if the downstream pressure is approximately one-half or less of the upstream pressure, the flow will be choked. The mass flow rate under adiabatic conditions is always somewhat greater than that under isothermal conditions, but the difference is normally <20%. In fact, for long piping systems ($L/D > 1000$), the difference is usually less than 5% (e.g., Holland, 1973).

5.5.11.5 Supersonic Flow

The conservation of mass, energy, and momentum equations can be written for the adiabatic flow of an ideal gas, and, when arranged in dimensionless form,

$$G^* = \sqrt{P_1\rho_1}\left(\frac{P_2{}^*}{P_1}\right)^{1/2} \tag{5.135}$$

shows that all flow variables can be expressed in terms of three dimensionless variables: the isentropic ratio, k; the Mach number, $N_{Ma} = V/c$; and the dimensionless pipe length, L/D. An inspection of these equations shows that, for $N_{Ma} < 1$, as the distance down the pipe (dL) increases, V also increases, but P, ρ, and T will decrease. However, for $N_{Ma} > 1$, just the opposite is true, i.e., V and T decrease but P and ρ will increase with distance down the pipe. That is, a flow that is initially subsonic will approach (as a limit) sonic flow as L increases, while an initially supersonic flow will also approach sonic flow. Thus all flows, regardless of their starting conditions, will tend toward the speed of sound as the gas progresses down a uniform pipe. The only way that a subsonic flow can be transformed into a supersonic flow is through a converging-diverging nozzle, where the speed of sound is reached at the nozzle throat. Supersonic flow relations are found in many fluid mechanics books (e.g., Hall, 1951; Shapiro, 1953).

Example 5.7

Oxygen must be fed to a reactor at a constant rate of 4.55 kg/s (10 lb_m/s) from a storage tank in which the pressure is 791 kPa (100 psig) at a temperature of 21°C (70°F). The pressure in the reactor fluctuates from 115 to 170 kPa (2 to 10 psig), so you want to insert a choke in the line to maintain a constant flow rate. If the choke is a 0.61-m (2-ft) length of tubing, what should the diameter of the tubing be?

Solution

For the flow to be independent of the downstream pressure, it must be choked. Assuming adiabatic flow, Equation (5.132) gives the total loss coeffieient for the system when the downstream pressure is $P_2 \le P_2^*$, where P_{2max} = 170 kPa (10 psig = 24.7 psia). The mass flux under choked conditions (G^*) is given by Equation (5.131), which depends on P_2^*/P_1 (where P_1 = 791 kPa) as well as the tube diameter. Thus the solution is iterative, in accordance with the following procedure:

1. Assume a value for (P_2^*/P_1) and solve Equation (5.132) for ΣK_f and Equation (5.126) for G^*.
2. Determine the tube diameter from $A = \dot{m}/G^*$, and $D = \sqrt{4A/\pi}$, where $\dot{m}$ = 4.55 kg/s = 10 lb_m/s.
3. Calculate $N_{Re} = (\dot{m}/\pi D\mu)$, using μ = 0.02 cP.
4. Assuming ε = 0.0455 mm (0.0018 in.), determine f (from, for example, the Churchill equation) and $K_f = 4fL/D$.
5. If other losses in the line are small relative to that of the tubing, then $K_f = \Sigma K_f$, which was determined in step 1.
6. Repeat steps 1 to 5 until the values of K_f agree. The proper tube diameter is then determined from step 2.

Following this procedure gives: (P_2^*/P_1) = 0.66, P_2^* = 522 Pa (75.7 psia), D = 0.0485 m (0.159 ft), G^* = 2470 kg/s·m^2 (504 lb_m/s·ft^2), $N_{Re} = 5.96 \times 10^6$, and f = 0.00485.

5.6 PUMPS AND COMPRESSORS

5.6.1 Pump Types

There are a wide variety of pumps, but most can be broadly classified as either positive displacement or centrifugal. Positive-displacement pumps include piston, plunger, diaphragm, screw, gear, progressing cavity pumps, etc., and operate at a fixed volumetric flow rate under varying head or load requirements. Consequently, the discharge line from the pump should never be closed without allowing for recycle around the pump, or damage to the pump could result. Such pumps have limited flow capacity, but are capable of relatively high pressures, and are appropriate for high-

pressure requirements, very viscous fluids, and applications where precisely controlled or metered flow rate is required.

Centrifugal pumps operate by the transfer of energy (or angular momentum) from a rotating impeller to the fluid, normally inside a casing. The kinetic energy of the fluid is increased by the angular momentum imparted by the high-speed impeller, and is then converted to pressure energy (or head) in a diverging (volute) area. The developed head depends upon the pump design and the size, shape, and speed of the impeller, and the flow rate is determined by the fluid resistance of the system in which the pump is installed. Centrifugal pumps operate at approximately constant head over a wide range of flow rates (within limits). They can be operated in a "closed off" condition (i.e., closed discharge line), since the liquid will recirculate within the pump without causing damage. However, this condition should be avoided, because energy dissipation within the pump can result in excessive heating of the fluid or the pump, and cavitation or unstable operation could occur with adverse consequences. Centrifugal pumps are appropriate for "ordinary" liquids (i.e., low to moderate viscosity) and low to moderate pressures over a wide variety of flow conditions.

5.6.2 Centrifugal Pump Characteristics

The hydraulic work ($-w$) delivered per unit mass of fluid, the pressure (ΔP) developed by the pump, and the pump head (H_p) are related by

$$-w = \frac{\Delta P}{\rho} = gH_p \tag{5.135}$$

The pump efficiency, η_e, is the hydraulic work delivered to the fluid divided by the work delivered to the pump by the motor ($-w_m$):

$$\eta_e = \frac{-w}{-w_m} \tag{5.136}$$

The efficiency of a pump depends upon the pump and impeller design, the size and speed of the impeller, and the operating flow rate, and it is measured by the pump manufacturer.

When selecting a pump for a particular application, the flow capacity and required pump head must be specified. Although a variety of different pumps might satisfy the given specifications, the best pump is generally the one that requires the least power to operate at the specified conditions. The horsepower required for the pump-driving motor is determined by

$$HP = -w_m\dot{m} = \frac{\Delta PQ}{\eta_e} = \frac{\rho gH_pQ}{\eta_e} \tag{5.137}$$

The motor power is also related to the motor torque (Γ) and speed (ω) by

$$HP = \Gamma\omega = \frac{\rho gH_pQ}{\eta_e} \tag{5.138}$$

The angular momentum balance provides a relation for the required motor torque:

$$\Gamma = \dot{m}\omega R_i^2 = \rho Q\omega R_i^2 \tag{5.139}$$

where R_i is the impeller radius. Eliminating Γ from Equations (5.138) and (5.139) shows that

$$H_p = \frac{\eta_e \omega^2 R_i^2}{g} \tag{5.140}$$

That is, the pump head is determined primarily by the size and speed of the impeller and the pump efficiency, independent of the flow rate and fluid density. This is approximately correct for most centrifugal pumps over a wide range of flow rates. However, there is a limit to the flow that a given pump can handle, and the head will drop off significantly as the flow rate approaches this limit, which is typically near the maximum or "best" efficiency point (BEP). Pump characteristic curves are determined by the pump manufacturer. Figure 5.9 shows a typical set of curves for a given pump with various impeller diameters at a specific motor speed. (To convert H_p from feet to meters, multiply by 0.3048, and to convert Q from gallons per minute (gpm) to cubic meters per second (m^3/s), multiply by 6.31×10^{-5}.) Curves for constant efficiency and NPSH (net positive suction head) are also shown on the plot. Operation at conditions on the right branch of the efficiency contours (to the right of the "maximum normal capacity" line) should be avoided, since this could result in unstable operation. Pump curves are normally determined by measurements using water. Although the pump head is independent of fluid density, the power is proportional to the fluid density so that the power (HP) curves are the motor horsepower required to pump water at 16°C (60°F) (multiply the values of HP by 0.746 to convert from horsepower to kilowatts). These must be corrected for density when operating with other fluids or temperatures. The curves labeled "minimum NPSH" refer to the cavitation characteristics of the pump (see below).

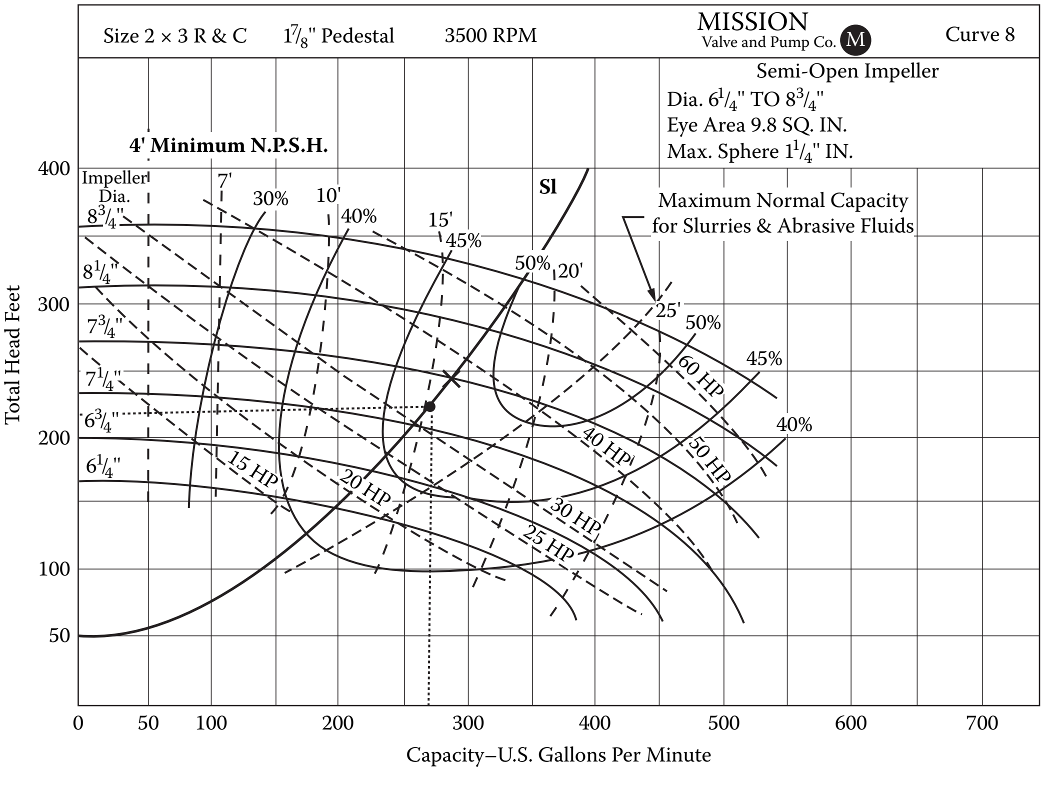

FIGURE 5.9 Typical centrifugal pump characteristic curves. (From TRW Mission Pump Brochure.)

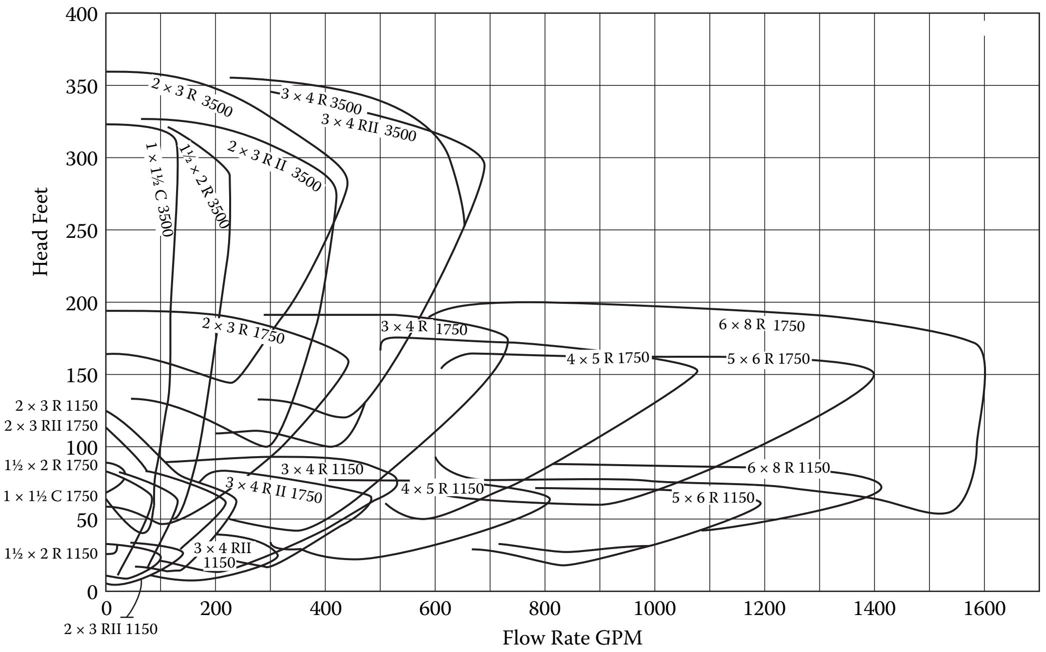

FIGURE 5.10 Typical centrifugal pump composite curves. (From TRW Mission Pump Brochure [manufacturer's catalog].)

5.6.2.1 Required Head

A typical application involves specifying a pump for a specified flow rate and given fluid properties. The piping system with the necessary valves, fittings, etc., should be sized for the most economical pipe size. Application of the energy balance (Bernoulli equation) to the pipeline determines the required pump head:

$$H_p = \frac{P_2 - P_1}{\rho g} + (z_2 - z_1) + \frac{8Q^2}{g\pi^2} \sum_i \left(\frac{K_f}{D^4} \right)_i \tag{5.141}$$

For highly turbulent flow (i.e., constant K_f's), the required pump head H_p is a quadratic function of the flow rate Q. This relation, which is superimposed on the pump characteristic curves (see line Sl in Figure 5.9), is the *operating line* for the system. The actual pump head and the resulting flow rate are determined by the intersection of the operating line and the pump impeller characteristic curve. For the specified flow rate, the best (least cost) pump/impeller/motor combination that will provide this flow rate should be selected.

5.6.2.2 Composite Curves

Composite curves such as those shown in Figure 5.10 are provided by most pump manufacturers, and can be used to quickly identify the operating range of various pumps. Once a pump that can deliver the specified head and flow rate is identified, the individual pump characteristic curves for that pump should then be consulted and the impeller diameter selected that will produce the required head or greater. This can be repeated for various pump, impeller, and speed combinations to determine the combination that results in the least power requirement.

5.6.2.3 Cavitation and NPSH

The fluid velocity in and around the pump impeller is much higher than the velocity entering or leaving the pump, and the pressure is lowest where the velocity is highest. If the minimum pressure in the pump is lower than the fluid vapor pressure, then vaporization or *cavitation* will occur. The pump head is the same if it is filled with gas or liquid, but the pump pressure, which is proportional to the fluid density, can be several orders of magnitude lower for a gas than a liquid at the same head (this condition is known as *vapor lock*). Cavitation can result in serious damage to a pump or impeller. To prevent cavitation, it is necessary that the pressure at all points within the pump be greater than the fluid vapor pressure. This will be true if the pump suction pressure is sufficiently higher than the fluid vapor pressure. The difference between the suction pressure and the minimum pressure in the pump depends upon the pump design, impeller size and speed, and flow rate. The minimum suction pressure relative to the fluid vapor pressure at which cavitation will not occur is called the *minimum required NPSH* (net positive suction head). The NPSH values are shown on the pump characteristic curves (e.g., Figure 5.9). The NPSH is almost independent of impeller diameter at low flow rates and increases with flow rate as well as with impeller diameter at higher flow rates. A distinction is sometimes made between the NPSH "required" to prevent cavitation (NPSHR) and the actual head (e.g., pressure) "available" at the pump suction (NPSHA), i.e., H_s. A pump will *not* cavitate if (NPSHA = H_s) > (*NPSHR* + Vapor Pressure Head), i.e.,

$$H_s = \frac{P_s}{\rho g} \geq NPSH + \frac{P_v}{\rho g} \tag{5.142}$$

where P_v is the liquid vapor pressure. The NPSH at the operating point determines where the pump can be installed in a piping system to avoid cavitation. If the pressure at the upstream entrance to the suction line is P_1, the maximum distance above this point that the pump can be located without cavitating (i.e., the maximum suction lift) is determined by Bernoulli's equation applied from P_1 to P_s:

$$h_{\max} = \frac{P_1 - P_v}{\rho g} - NPSH + \frac{V_1^2 - V_s^2}{2g} - \frac{\sum (e_f)_s}{g} \tag{5.143}$$

where V_1 is the velocity entering the suction line, V_s is the velocity at the pump inlet (suction), and $\Sigma(e_f)_s$ is the total friction loss in the suction line from the upstream entrance (point 1) to the pump inlet, including all pipe, fittings, etc. If the maximum suction lift ($h_{\max}$) is negative, the pump must be located below the upstream entrance to the suction line to prevent cavitation. It is best to be conservative when interpreting the suction head required to prevent cavitation. The minimum required NPSH on the pump curves is normally determined using water at 16°C (60°F) with the discharge line fully open. Even though a centrifugal pump will run with a closed discharge line and no bypass, the recirculation within the pump will increase the dissipative heating, which, in turn, increases the minimum required NPSH. This is especially true with high-efficiency pumps, which have close clearances.

Example 5.8

Determine the pump specifications required to transfer water at 30°C (86°F) from an open pond to an open tank located 61 m (200 ft) above the pond, at a rate of 0.0126 m^3/s (200 gpm). The pipe is 3 in. sch 40 (ID = 77.93 mm) commercial steel (ε = 0.0457 mm [0.0018 in.]) and is 67 m (220 ft) long, and includes four flanged elbows. There is 3.05 m (10 ft) of horizontal pipe in both the pump suction and discharge lines. If the pump has the characteristics shown in Figure 5.9,

determine: (a) the required pump head (in meters); (b) the proper impeller diameter to use; (c) the pump efficiency and NPSH at the operating point; (d) the power of the motor required to drive the pump; and (e) the maximum height above the pond that the pump can be located without cavitating. Fluid properties: $\rho = 996$ kg/m^3, $\mu = 0.798$ cP, $P_v = 31.824$ mm Hg.

Solution

The required pump head is calculated from Equation (5.141), with $P_1 = P_2$:

$$H_p = (z_2 - z_1) + \frac{8Q^2}{g\pi^2}\sum_i \left(\frac{K_f}{D^4}\right)_i$$

where

$$\sum_i K_f = 4K_{el} + \left(\frac{4fL}{D}\right)_{pipe}$$

and K_{el} is determined from the 3-*K* correlation:

$$K_{el} = \frac{800}{N_{Re}} + 0.091\left(1 + \frac{4.0}{D_{n,in}^{0.3}}\right)$$

The Reynolds number is

$$N_{Re} = \frac{4Q\rho}{\pi D\mu} = \frac{4(0.0126 \text{ m}^3/\text{s})(996 \text{ kg/m}^3)}{\pi(0.07793 \text{ m})(0.000798 \text{ Pa s})} = 2.57 \times 10^5$$

so that $K_{el} = 0.353$ ($4\ K_{el} = 1.41$). From the Churchill equation, $f = 0.00475$, which gives

$$K_{pipe} = \frac{4fL}{D} = \frac{4(0.00475)(67 \text{ m})(1000 \text{ mm/m})}{77.93 \text{ mm}} = 16.36$$

Inserting these values into the Bernoulli equation [Equation (5.141)] results in $H_p = 67.3$ m (221 ft). Referring to Figure 5.9, this pump will deliver a head of 220 ft (67.1 m) (which is close enough) at a flow rate of 200 gpm (0.0126 m^3/s) using an impeller with a diameter of 7-1/4 in. (184 mm). (Note that if the desired operating head and flow rate intersect at a point between the curves for available impeller diameters, the next larger impeller must be used, which will result in a pump head somewhat higher than necessary. This will result in a flow rate higher than desired, unless a valve is included in the line that can be adjusted to take the excess head as friction loss.)

From Figure 5.9 at the operating point, read $\eta_e = 0.42$ and NPSH = 11 ft (3.35 m). The required motor power is then given by

$$HP = \frac{\rho Q g H_p}{\eta_e} = \frac{(996 \text{ kg/m}^3)(0.0126 \text{ m}^3/\text{s})(9.81 \text{ m/s}^2)(67.3 \text{ m})}{0.42} = 19.8 \text{ kw (26.6 hp)}$$

The maximum suction lift for the pump that can be achieved without cavitation is given by Equation (5.144) as

$$h_{max} = \frac{P_1 - P_v}{\rho g} - NPSH + \frac{V_1^2 - V_s^2}{2g} - \frac{\sum (e_f)_s}{g}$$

where P_1 = 1 atm, V_1 = 0, V_s = 2.65 m/s (8.68 ft/s), and $\Sigma(e_f)_s$ is the total friction loss in the suction line, which is assumed to include two elbows, 3.05 m (10 ft) of horizontal pipe, and h_{max} m of vertical pipe:

$$\sum (e_f)_s = \left[\frac{4f(L + h_{max})_s}{D} + 4K_{el} \right] \frac{V_s^2}{2}$$

Note that h_{max} occurs on both sides of the equation. Solving this equation gives h_{max} = 5.55 m (18.2 ft). That is, the pump will cavitate if it is located more that 5.5 m (18 ft) above the pond. Conservative practice would be to locate the pump closer than this to the pond.

5.6.2.4 Specific Speed

The flow rate, head, and impeller speed at the best efficiency point (BEP) of the pump characteristic are used to define the pump *specific speed*:

$$N_s = \frac{N\sqrt{Q}}{H_p^{3/4}} \quad \text{or} \quad \frac{\text{rpm}\sqrt{\text{gpm}}}{\text{ft}^{3/4}} \tag{5.144}$$

Although N_s is dimensionless, it is common practice to use selected mixed units for the parameters in N_s. In English units, these are N (rpm), Q (gpm), and H_P (ft). For N (rpm), Q (m^3/s), and H_p (m), the corresponding value of N_s should be multiplied by 51.6 to give the same value of N_s determined using consistent English units. N_s represents roughly the ratio of the pump capacity to the head at the speed corresponding to the maximum efficient point (BEP), and depends primarily on the design of the pump and impeller. This can vary widely from almost pure radial flow to almost pure axial flow (e.g., a fan). Some examples of various types of impellers are shown in Figure 5.11. Radial-flow impellers have the highest head and lowest flow capacity (low N_s), whereas axial-flow impellers have a high flow capacity and low head characteristic (high N_s). Figure 5.12 indicates the range of flow rates and efficiencies for various impeller designs with corresponding values of N_s. The maximum efficiency occurs for mixed-flow impellers at a value of N_s of about 3000 (English units).

There are conflicting parameters in the proper design of a centrifugal pump. For example, the lower the suction velocity (V_s), the less the tendency to cavitate. This would dictate that the eye of the impeller should be as large as possible to minimize V_s. However, a large impeller eye means a large vane speed at the impeller inlet, which is destabilizing with respect to recirculation. Hence, it is advisable to design the impeller with the smallest eye diameter that is practicable.

5.6.3 Compressors

A compressor is basically a pump for a high-pressure compressible fluid. The compressibility properties of the fluid (gas) are normally significant when the pressure in a system changes by 30% or more. For small pressure changes, a fan or blower is an appropriate pump for a gas. Fan performance can be described using the incompressible flow equations, since the relative pressure change is small. Like pumps, compressors may be either positive displacement or centrifugal, the former being suitable for relatively high pressure ratios and low flow rates, while the latter are

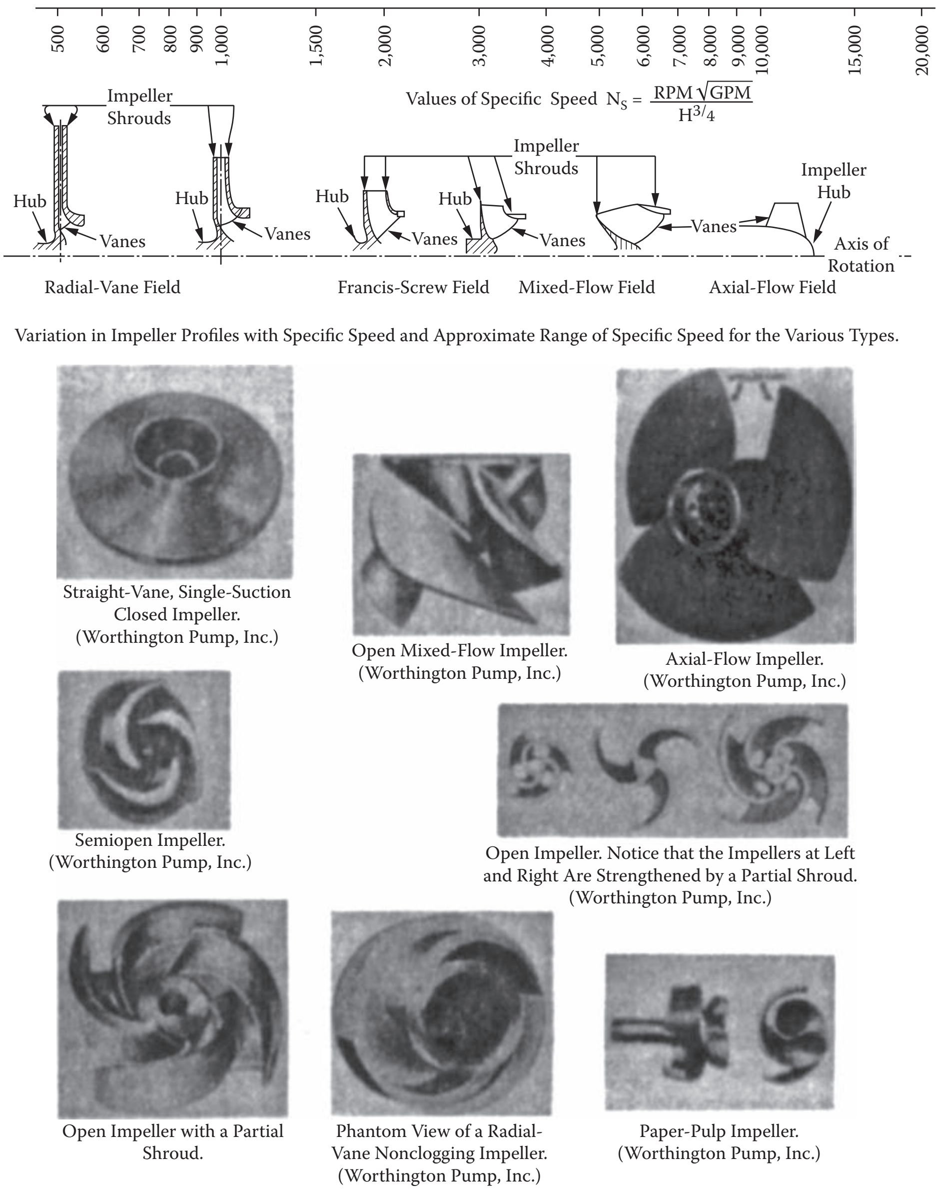

FIGURE 5.11 Impeller designs and specific speed characteristics. (From Karassik et al., 1976.)

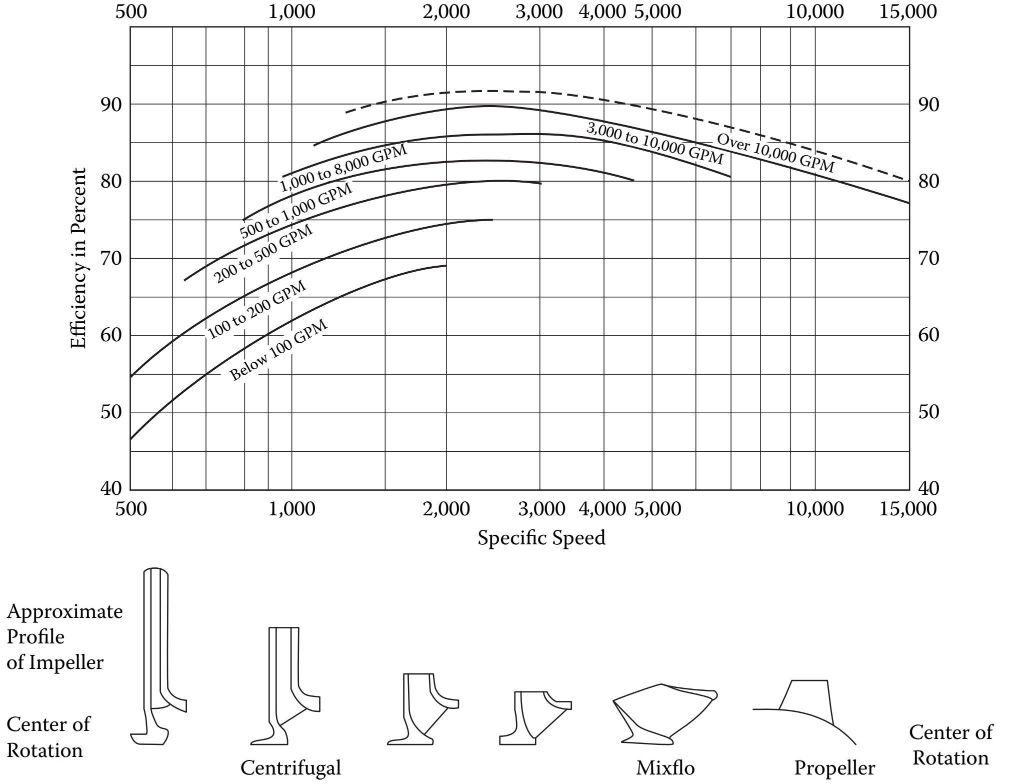

FIGURE 5.12 Correlation between impeller shape, specific speed, and efficiency. (From Drassik et al., 1976.)

more suited for higher flow rates but lower pressure ratios. The governing equations depend on whether the operation is isothermal or adiabatic. Expressions here assume that the ideal gas law applies, although this assumption can be modified by inclusion of a compressibility correction factor, as necessary. For an ideal (frictionless) compressor, the compression work is given by

$$-w = \int_{P_1}^{P_2} \frac{dP}{\rho} \tag{5.145}$$

and, for an ideal gas,

$$\rho = \frac{PM}{RT} \tag{5.146}$$

5.6.3.1 Isothermal, Isentropic, and Polytropic Operations

For isothermal conditions, Equation (5.145) becomes

$$-w = \frac{RT}{M} \ln r \tag{5.147}$$

where $r = P_2/P_1$ is the *compression ratio*.

For an ideal gas under adiabatic frictionless (i.e., isentropic) conditions,

$$\frac{P}{\rho^k} = \text{const}, \quad \text{where } k = \frac{c_p}{c_v} \text{ and } c_p = c_v + R/M \tag{5.148}$$

(Note that setting $k = 1$ reduces the isentropic state to the isothermal state). For isentropic compression,

$$-w = \frac{RT_1 k(r^{(k-1)/k} - 1)}{M(k-1)} \tag{5.149}$$

As ($k \to 1$), this expression reduces to Equation (5.148). For a given compression ratio, the isothermal work is always less than the isentropic work. However, most compressors operate under more nearly adiabatic conditions because of the relatively short residence time of the gas in the compressor. The temperature rise during an isentropic compression is

$$\frac{T_2}{T_1} = \left(\frac{P_2}{P_1}\right)^{(k-1)/k} = r^{k-1/k} \tag{5.150}$$

In reality, many compressor conditions are neither purely isothermal nor isentropic, but somewhere in between. This can be taken into account by using the isentropic Equation (5.149) and replacing the isentropic exponent k by a "polytropic" constant γ (where $1 < \gamma < k$), which is a function of the compressor design as well as the properties of the gas.

5.6.3.2 Staged Operation

Multiple compressor stages can be arranged in series to increase the overall compression ratio. To increase the overall efficiency, the gas is cooled between stages by "interstage coolers." As the number of stages increases, the total compression work for isentropic compression with interstage cooling to the initial temperature (T_1) approaches that of isothermal compression at T_1. The optimum compression ratio for each stage that minimizes the total compression work for any number of stages (n) with interstage cooling to the initial temperature is

$$r = \frac{P_2}{P_1} = \frac{P_3}{P_2} = \cdots = \frac{P_{n+1}}{P_n} = \left(\frac{P_{n+1}}{P_1}\right)^{1/n} \tag{5.151}$$

If there is no interstage cooling, or for interstage cooling to a temperature other than T_1, the optimum compression ratio for each stage (i) is related to the temperature entering that stage (T_i) by

$$T_i\left(\frac{P_{i+1}}{P_i}\right)^{(k-1)/k} = T_i r_i^{(k-1)/k} = \text{ constant } t \tag{5.152}$$

The above relations apply to ideal (frictionless) compressors. To account for friction losses, the ideal computed work is divided by the compressor efficiency, η_e, to get the total work that must be supplied to the compressor:

$$(-w)_{ideal} = \frac{(-w)_{ideal}}{\eta_e} \tag{5.153}$$

The energy "lost" due to friction is dissipated into thermal energy, which raises the temperature of the gas. This temperature rise is in addition to that due to the isentropic compression, so that the total temperature rise across an adiabatic compressor stage is

$$T_2 = T_1 r^{(k-1)/k} + \left(\frac{1-\eta_e}{\eta_e}\right)\left(\frac{-w_{ideal}}{c_v}\right) \tag{5.154}$$

Centrifugal compressors can operate at speeds from 9,000 to 50,000 rpm, with single-stage compression ratios from 1.2 to 9, and efficiencies from 30 to 85%, depending upon the specific design and application.

5.7 FLOW MEASUREMENT AND CONTROL

Some common methods for measuring flow rate in conduits, namely, the pitot tube, venturi, nozzle, and orifice meters, will be illustrated here. However, there are a great many other devices in use, such as turbine, vane, Coriolis, ultrasonic, and magnetic flow meters. The manufacturer or supplier of these devices should be consulted for their specifications and range of applicability.

5.7.1 Pitot Tube

The volumetric flow rate (Q) of a fluid through a conduit may be determined by integrating the local ("point") velocity over the cross section of the conduit. If the conduit cross section is circular,

$$Q = \int_0^{\pi R^2} V(r)d(\pi r^2) = 2\pi \int_0^R V(r)rdr \tag{5.155}$$

The pitot tube may be used to measure the local velocity $V(r)$ at a given position in the conduit, as illustrated in Figure 5.13. A differential pressure measuring device (e.g., a manometer, transducer, or DP cell) measures the pressure difference between two tubes, which is related directly to the local velocity:

$$V_1 = \sqrt{\frac{2(P_2 - P_1)}{\rho}} \tag{5.156}$$

The pitot-static tube includes an annular tube surrounding the stagnation tube, with holes in the sides through which the static pressure is measured. For this configuration, errors introduced by

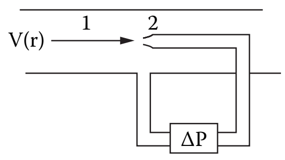

FIGURE 5.13 Pitot tube.

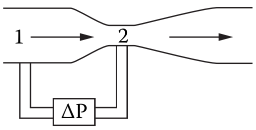

FIGURE 5.14 Venturi meter.

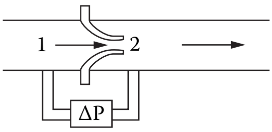

FIGURE 5.15 Nozzle.

the presence of the probe and the stem inserted into the flow are minimized if the probe length is 14 times the probe diameter, and the static pressure holes are six probe diameters from the end of the probe. Also, axial alignment of the probe is important for accurate measurement, and the probe should be located no closer than 100 pipe diameters from any bend or flow constriction. The total flow rate (Q) through the conduit can be determined by measuring a sufficient number of radial points across the conduit to enable accurate evaluation of the integral in Equation (5.155).

The pitot tube requires considerable effort and time to obtain an accurate value of the total flow rate. However, the probe offers minimal resistance to the flow and hence is very efficient from the standpoint of the resulting permanent pressure drop due to friction. It is also the only practical means for determining the flow rate in very large conduits (e.g., smokestacks). Errors increase as the ratio of the probe diameter to pipe diameter increases, and for accurate readings the probe diameter should be no larger than 2% of the tube diameter. This limits accurate application to pipes of about 40-cm diameter or larger.

5.7.2 Venturi and Nozzle

Other devices can be used to determine the flow rate from a single measurement. These are sometimes referred to as *obstruction meters*, since the basic principle involves introducing an "obstruction" (e.g., a constriction) into the flow channel and then measuring the pressure drop across this obstruction, which depends on the flow rate. Two such devices, the venturi meter and the nozzle, are illustrated in Figures 5.14 and 5.15, respectively. In both cases, the pressure drop from a point upstream of the meter to a point in a plane with the minimum flow area (A_2) is related to the velocity V_2 by the Bernoulli equation:

$$V_2 = C_v \sqrt{\frac{-2\Delta P}{\rho(1-\beta^4)}} \tag{5.157}$$

where C_v is the discharge coefficient for the venturi, which is a function of the conduit Reynolds number, as shown in Figure 5.16. The coefficient accounts for deviation from plug flow as well as irreversible effects. However, since the coefficient is not greatly different from 1.0 at high Reynolds numbers (having a value of about 0.985 at [pipe] Reynolds numbers, $N_{\mathrm{Re}D}$, above about 2×10^5), this indicates that these nonidealities are small. According to Miller (1983), for $N_{\mathrm{ReD}} > 4000$, the discharge coefficient for the venturi, as well as for the nozzle and orifice, can be described as a function of $N_{\mathrm{Re}D}$ and β by the general equation

$$C = C_\infty + \frac{b}{N_{\mathrm{Re}D}^n} \tag{5.158}$$

where the parameters C_∞, b, and n are given in Table 5.12 as a function of β (the ratio of the throat diameter to the pipe diameter). The range over which this equation applies and its approximate accuracy are given in Table 5.13. The pressure recovery in the venturi is relatively large, so that the net friction loss across the entire meter is a relatively small fraction of the measured pressure drop, as indicated in Figure 5.17.

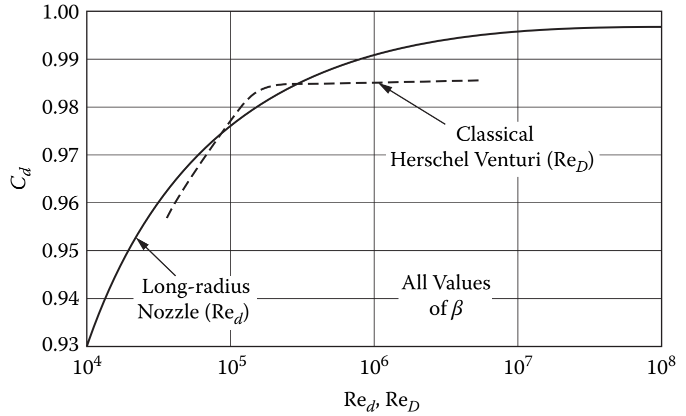

FIGURE 5.16 Venturi and nozzle discharge coefficient versus Reynolds number. (From White, F. M., *Fluid Mechanics*, 3rd ed., McGraw-Hill, New York (1994).)

For the orifice and nozzle, the flow, since the expansion area changes abruptly downstream, is uncontrolled, and considerable eddying occurs downstream. This dissipates more energy, resulting in a significantly higher net pressure loss and lower pressure recovery. The above equations assume that the device is horizontal, i.e., the pressure taps on the pipe are located in the same horizontal plane. Note that the Reynolds number used for the venturi coefficient in Figure 5.16 is based upon the pipe diameter (D), whereas the Reynolds number used for the nozzle coefficient is based upon the nozzle diameter (d) (also note that $N_{ReD} = \beta N_{Red}$). There are various "standard" designs for the nozzle, and the reader should consult the literature for details (e.g., Miller, 1983). The discharge coefficient for nozzles can also be described by Equation (5.158), with the appropriate parameters given in Table 5.12. International standard shapes for the nozzle and venturi are shown in Figure 5.18.

5.7.3 Orifice Meter

The orifice meter is illustrated in Figure 5.19. The flow equation is the same as for the venturi and nozzle, the major difference being the *vena contracta*, which is the contraction of the fluid stream just downstream of the orifice to an area that is approximately 60% of the orifice area. If the pipe diameter is D, the orifice diameter is d, and the diameter of the vena contracta is d_2, the contraction ratio for the vena contracta is defined as $C_c = A_2/A_o = (d_2/d)^2$. For highly turbulent flow, $C_c \approx 0.61$.

5.7.3.1 Incompressible Flow

For incompressible flow, the flow equation becomes

$$\dot{m} = C_o A_o \sqrt{\frac{2\rho\Delta P}{(1-\beta^4)}} \tag{5.159}$$

Figure 5.20 shows the orifice (discharge) coefficient C_o as a function of the orifice Reynolds number (N_{Red}) and $\beta = d/D$. There are a variety of "standard" orifice plate and pressure tap designs (e.g., Miller, 1983). The ASME specifications for the most common concentric square-edged orifices are shown in Figure 5.21. The various pressure tap locations are illustrated in Figure 5.22. Radius taps, for which the location is scaled to the pipe diameter, are the most reliable. Corner taps and flange taps are the most convenient, as they can be installed in the orifice flange and so do not require

additional taps through the pipe. Pipe taps measure essentially the total unrecovered pressure drop (friction loss), which is considerably lower than the maximum pressure drop across the orifice plate. Vena contracta taps are sometimes specified, with the upstream tap 1 D from the plate and the downstream tap at the vena contracta location, although the latter varies with the Reynolds number and beta ratio, and thus is not a fixed position (radius taps approximate this condition). The orifice coefficient shown in Figure 5.20 is valid to within 2–5% (depending upon the Reynolds number and β) for all pressure tap locations except pipe and vena contracta taps. More accurate values can be calculated from Equation (5.160) for high Reynolds numbers, with the parameter expressions given in Table 5.12 for the specific orifice and pressure tap arrangements.

5.7.3.2 Compressible Flow

For an ideal gas flowing through an orifice under adiabatic conditions, the flow equation is

$$\dot{m} = C_o A_o \sqrt{\frac{P_1 \rho_1}{1-\beta^4}} \left\{ \frac{2k}{k-1} \left(\frac{P_2}{P_1} \right)^{2/k} \left[\left(\frac{P_1}{P_2} \right)^{(k-1)/k} - 1 \right] \right\}^{1/2} \tag{5.160}$$

where the value of C_o is assumed to be the same as for a incompressible flow. The ratio of this equation to the incompressible equation is called the *expansion factor Y.* Thus,

$$\dot{m} = C_o A_o Y \sqrt{\frac{2\rho_1 \Delta P}{(1-\beta^4)}} \tag{5.161}$$

where the density ρ_1 is evaluated at the upstream pressure (P_1). Values of Y are shown as a function of $\Delta P/P_1$ and β for a square-edged orifice, nozzles, and venturi meters for values of $k = c_p/c_v$ of

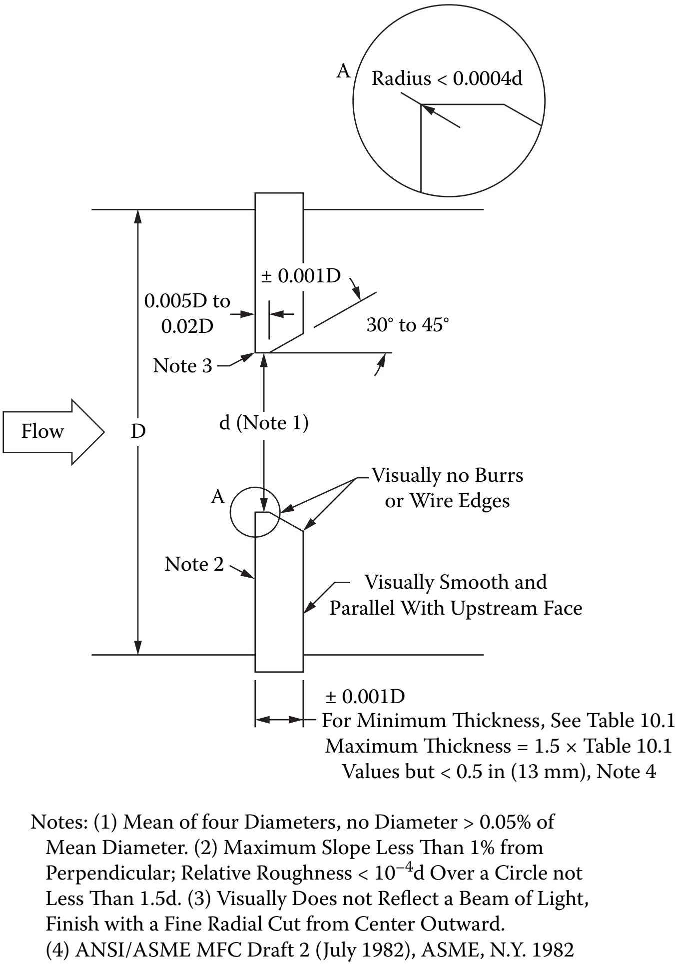

FIGURE 5.21 Concentric square-edged orifice specifications. (From Miller, R. W., *Flow Measurement Engineering Handbook*, McGraw-Hill, New York (1983).)

1.3 and 1.4 in Figure 5.23. The lines in Figure 5.23 for the orifice can be represented by the following equation for radius taps (Miller, 1983):

$$Y = 1 - \frac{\Delta P}{kP_1}(0.41 + 0.35\beta^4) \tag{5.162}$$

and for pipe taps by

$$Y = 1 - \frac{\Delta P}{kP_1}[0.333 + 1.145(\beta^4 + 0.7\beta^5 + 12\beta^{13})] \tag{5.163}$$

The "buttons" at the end of the lines in Figure 5.23 for the nozzle and venturi correspond to critical (choked) flow. Although there are no "buttons" shown on the lines for the orifice, choked flow does occur in orifices as well. However, the choked flow is not as reproducible for orifices because of the variable effects of the vena contracta.

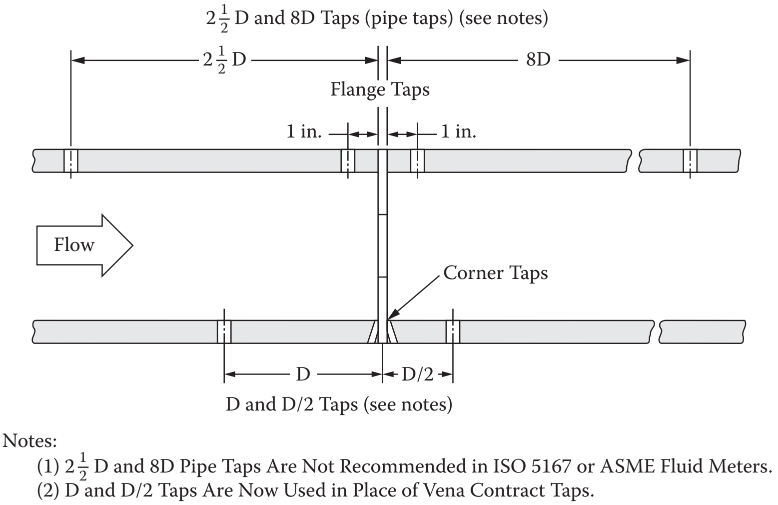

FIGURE 5.22 Orifice pressure tap locations. (From Miller, R. W., *Flow Measurement Engineering Handbook*, McGraw-Hill, New York (1983).)

5.7.3.3 Loss Coefficient

The total unrecovered pressure drop, i.e., the friction loss, (P_1 − P_3), in an orifice meter is characterized by the loss coefficient, K_f:

$$K_f = \frac{(1-\beta^4)(1-\beta^2)}{C_o^2\beta^4} \tag{5.164}$$

which is to be used with the pipe velocity (V_1). If K_f is based upon the velocity through the orifice (V_o) instead of the pipe velocity, the β^4 term in the denominator should be omitted.

5.7.3.4 Applications

Determining the flow rate for a given pipe/orifice geometry and known pressure drop from Equation (5.162) requires an iterative procedure, since the orifice coefficient C_o depends on the Reynolds number (e.g., Figure 5.20), which cannot be found until the flow rate is known. This procedure is usually simplified by initially assuming C_o = 0.61.

If the orifice diameter is to be determined for a specified value or range of flow rate and pressure drop in a given pipe, it is more convenient to rearrange Equation (5.162) for β as follows:

$$\beta = \left[\frac{X}{1+X}\right]^{1/4} \quad \text{where } X = \frac{8}{\rho_1 \Delta P}\left[\frac{\dot{m}}{\pi D^2 Y C_o}\right] \tag{5.165}$$

An iterative procedure for C_o is still required, since $C_o = fn(\beta)$, and this can be simplified as above by initially assuming C_o = 0.61.

5.8 CONTROL VALVES

A control valve is a specially designed globe valve that acts as a "variable resistance" in the line to control the flow rate. Closing down on the valve decreases the area between the plug and the

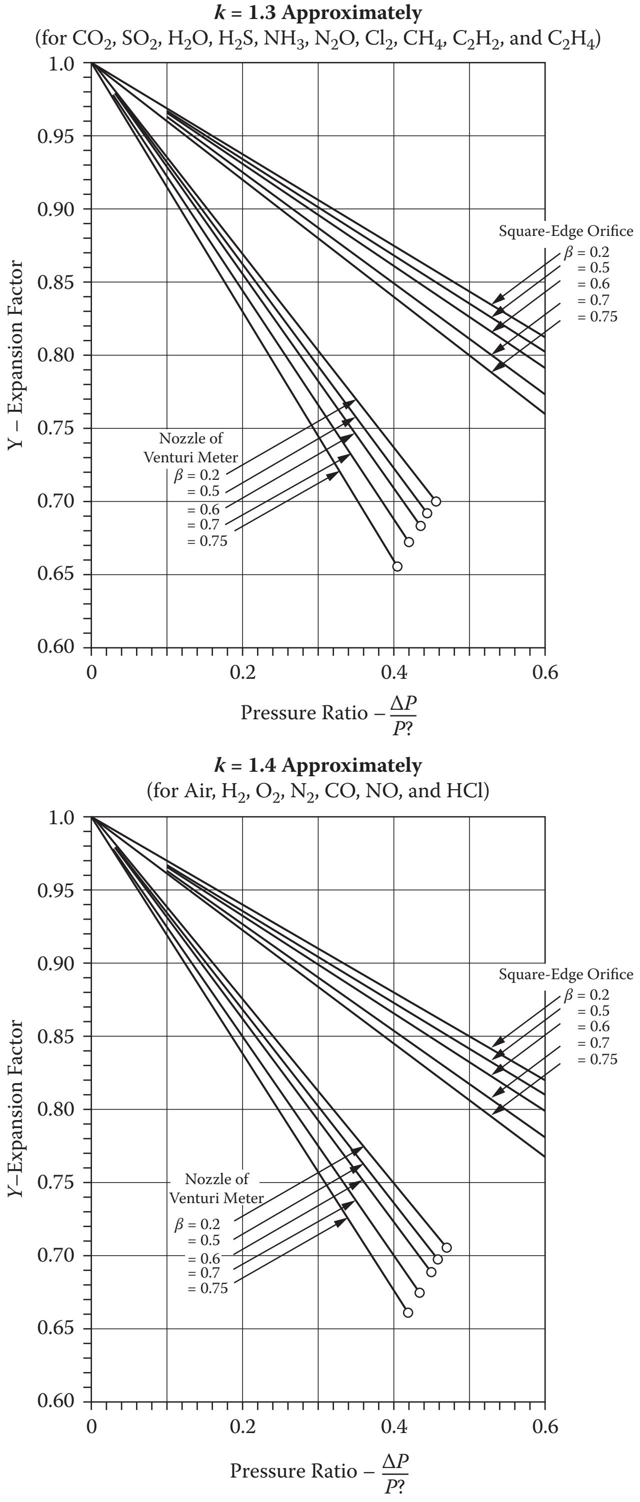

FIGURE 5.23 Expansion factor for square-edged orifice and nozzle or venturi meter; (a) $k = 1.3$, (b) $k = 1.4$. (From Crane Co., "Flow of Fluids through Valves, Fittings, and Pipe," Technical Manual 410, Crane Co., New York (1978).)

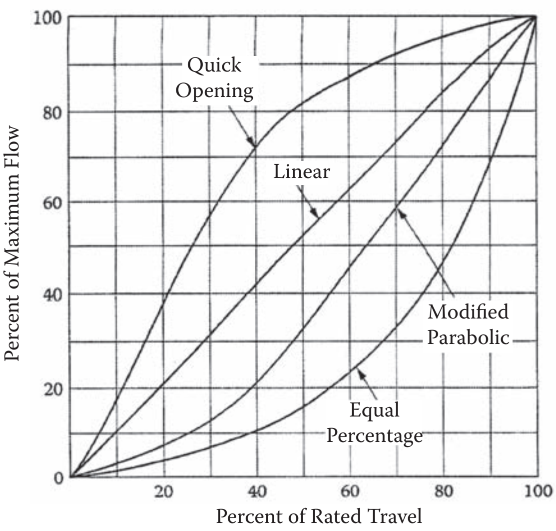

FIGURE 5.24 Control valve trim characteristics. (From Fisher Controls, Catalog 10, chap. 2, Fisher Controls, Marshalltown, IA (1987). With permission.)

seat, which increases the valve flow resistance (i.e., the K_f). The relation between the valve stem or plug position (which is the manipulated variable) and the flow rate through the valve (which is the controlled variable) is normally nonlinear to compensate for the nonlinear pressure-flow characteristics of the piping system, pump, etc., and is determined by the valve characteristic or "trim," i.e., the shape and design of the valve plug and the flow channel through the valve.

5.8.1 Valve Characteristics

Different shaped valve plugs or cages are available for a given valve that determine the valve response or trim characteristic as a function of the valve stem position. The valve trim is chosen to match the dynamic response of the piping system to give the desired response relation. Figure 5.24 illustrates typical trim characteristics (Fisher, 1987). The "quick opening" characteristic provides the maximum change in flow rate at low opening or stem travel, with a fairly linear relationship. As the valve approaches wide open, the change in flow with travel approaches zero. This is best suited for on-off control, but is also appropriate where a linear valve is desired. The "linear" flow characteristic has a constant "valve gain," i.e., the incremental change in flow rate with change in valve plug position is the same at all flow rates. This is a commonly desired property, particularly for liquid level control. The "equal percentage" flow trim provides the same percentage change in flow for equal increments of valve plug position. This characteristic is often used in pressure control applications and where a relatively small pressure drop across the valve is required relative to that in the rest of the system. The modified parabolic characteristic is intermediate to the linear and equal-percentage characteristics and can be substituted for equal-percentage valve plugs in many applications, with some loss in performance. However, the actual flow response to changes in stem position depends on the characteristics of the piping system as well as the valve, as described below.

5.8.2 Valve Sizing Equations—Incompressible Flows

For incompressible fluids, Bernoulli's equation relates the pressure drop across a valve and the flow rate through the valve in terms of the loss coefficient, K_f:

$$Q = AV = A\sqrt{\frac{2\Delta P}{\rho K_f}} \tag{5.166}$$

where A is an appropriate flow area, V is the velocity through that area, and $\Delta P = (P_1 - P_2)$ is the pressure drop across the valve. However, in a control valve the area (and hence V) is a variable, and the internal flow geometry can be quite complex. The pressure drop is not the maximum value (which would occur if P_2 were at the vena contracta, as for an orifice meter), but is the *net unrecovered* pressure loss corresponding to a point (P_2), which is far enough downstream that any possible pressure recovery has occurred. Combining the flow area and geometrical factors and the density of the reference fluid with the friction loss coefficient leads to the following equation for incompressible fluids:

$$Q = C_v\sqrt{\frac{\Delta P}{SG_v}} = C_v\sqrt{\rho_w g h_v} = 0.658\left[\sqrt{\text{psi/ft}}\right] C_v \left[\text{gpm}/\sqrt{\text{psi}}\right]\sqrt{h_v\ [\text{ft}]} \tag{5.167}$$

This equation defines the *flow coefficient*, C_v. Here, SG is the fluid specific gravity (relative to water), ρ_w is the density of water, and h_v is the head loss across the valve. Valve C_v's are determined by the manufacturer, and the values are different for each valve and also vary with the valve opening (or stem travel) for a given valve. Although Equation (5.167) is similar to the flow equation for flow meters, the flow coefficient C_v is *not dimensionless*, but has dimensions of $[L^3][L/M]^{1/2}$. More specifically, the "normal engineering" units for C_v are gpm/(psi)$^{1/2}$:

Q = volumetric flow rate (gpm for liquids or scfh for gas or steam)
SG = specific gravity (relative to water for liquids [62.3 $\text{lb}_\text{m}/\text{ft}^3$] or air at 60°F and 1 atm for gases [0.0764 $\text{lb}_\text{m}/\text{ft}^3$])
ρ_1 = density at upstream conditions ($\text{lb}_\text{m}/\text{ft}^3$)
P_1 = upstream pressure (psia)
ΔP = total (net) pressure drop across valve (psi)

Typical flow coefficient values are shown in Table 5.14, in which K_m applies to cavitating and flashing liquids and C_1 applies to critical (choked) compressible flow, as discussed below.

5.8.2.1 Matching Valve Trim and System Characteristics

Selection of the proper valve size and trim to be used for a given application requires matching the valve, piping system, and pump characteristics for the desired response (Darby, 1997). The operating point for a piping system depends upon the pressure-flow behavior of both the system and the pump. The control valve is part of the piping system and acts as a variable resistance in the system (the valve loss coefficient K_f increases as the discharge coefficient C_v decreases as the valve is closed). The operating point for the system is where the pump head (H_p) characteristic intersects the system head requirement (H_s):

$$H_s = \frac{\Delta P}{\rho g} + \Delta z + \frac{Q^2}{g}\left[\frac{8}{\pi}\sum\left(\frac{K_f}{D^4}\right) + \frac{1}{\rho_w C_v^2}\right] \tag{5.168}$$

where the last term is the head loss through the control valve, h_v (Equation (5.167)), and C_v depends upon the valve stem travel, X (see Figure 5.24), i.e.,

$$C_v = C_{v\max} f(X) \tag{5.169}$$

TABLE 5.14

This table lists The Km values for the Cv coefficients and the C1 values for the Cg and Cs coefficients at 100% total travel.

A typical pump and system curve is illustrated in Figure 5.25. The effect on the system curve of partially closing the valve is shown. Closing down on the valve (reducing X) decreases the valve C_v and increases the head loss through the valve, h_v. This shifts the system curve upward by an amount h_v at a given flow rate (h_v depends on flow rate). The range of possible flow rates (i.e., the "turndown" ratio) lies between the intersection on the pump curve of the system curve with a "fully open" valve (Q_{max}, corresponding to $C_{v,max}$) and the intersection of the system curve with the (partly) closed valve. The desired operating point should be as close as practical to Q_{max}, since this corresponds to an open valve with minimum flow resistance and is the most efficient region on the pump curve. Thus the flow is controlled by closing down on the valve (i.e., reducing X and C_v, and thus raising h_v). The minimum operating flow rate (Q_{min}) is established by the turndown ratio required for proper control. These limits set the size of the valve (e.g., the required $C_{v,max}$), and the head-flow-rate behavior of the system over the desired flow range determines the proper trim for the valve. The system curve is shifted by the amount h_v in response to closing the valve (i.e., reducing X), where

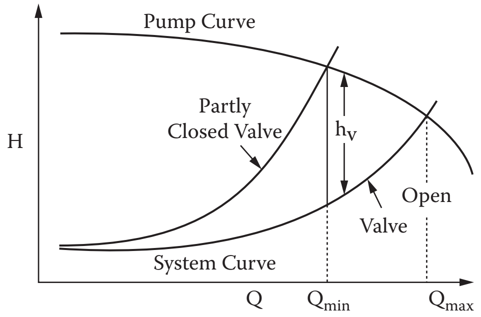

FIGURE 5.25 Effect of control valve on operating point.

$$h_v = \frac{Q^2}{\rho_w g C_{v\max}^2 f^2(X)} \tag{5.170}$$

where $f(X)$ represents the valve trim characteristic function.

The trim may be chosen to provide as sensitive a response between valve stem travel (X) and flow rate (Q) as possible, or to give a linear relation between X and Q. However, the piping resistance and pump head are nonlinear functions of the flow rate, and the flow through the control valve is a nonlinear function of the valve stem travel, X. Thus, the most appropriate valve trim for a given installation is best determined by evaluating Q as a function of X for various trim characteristics, and choosing the trim that provides the most sensitive or most linear response over the operating range. For a given valve (e.g., $C_{v,\max}$) and a given flow system, this can be done by calculating the valve position (X) for various flow rates (Q) for a given trim function $f(X)$ from the system and valve equations (Equations (5.168) to (5.171)). The trim that gives the most linear (or most sensitive) relation between X and Q is then chosen. This process can be aided by fitting the trim curves by an empirical equation of the form

$$\text{Linear trim: } f(X) = X \tag{5.171}$$

$$\text{Parabolic trim: } f(X) = X^2 \text{ or } X^n \tag{5.172}$$

$$\text{Equal-percentage trim: } f(X) = \frac{\exp(aX^n) - 1}{\exp(a) - 1} \tag{5.173}$$

$$\text{Quick-opening trim: } f(X) = 1 - [a(1 - X) - (a - 1)(1 - X)^n] \tag{5.174}$$

where a and n are parameters that can be adjusted to give the best fit to the trim curves. It is also often possible to fit the pump characteristic curves by a parabolic equation of the form

$$H_p = H_o + aQ + bQ^2 \tag{5.175}$$

Example 5.9

Two tanks containing water at 15.6°C (60°F) are connected by a piping system that contains 30.5 m (100 ft) of 3-in. sch 40 pipe (ID = 77.9 mm), four flanged elbows, two ball valves, and a control

valve with equal-percentages trim (with flow coefficients given in Table 5.14). The pressure in the upstream tank is 170 kPa (10 psig) and is atmospheric in the downstream tank, and the elevation of the downstream tank is 1.52 m (5 ft) lower than that in the upstream tank. Determine the flow rate of the water in the system if the valve position (X) is (a) fully open and (b) half-open.

Solution

The Bernoulli equation for the piping system can be solved for the flow rate (Q) to give

$$Q = \frac{\pi D^2}{2\sqrt{2}} \left[\frac{DF}{\sum K_f} \right]^{1/2}$$

where ΣK_f includes all losses in the pipe, fittings, and the control valve as well as all entrance and exit losses. Although the loss coefficients for the pipe and fittings are dependent upon the Reynolds number (hence on Q), a first estimate can be obtained by assuming fully turbulent flow. In this case, the fitting loss coefficients are determined by the 3-K correlation by omitting the K_m term. This gives (4 K_{el}) = 1.41 and (2 K_{bv}) = 0.132. For pipe in fully turbulent flow:

$$f = \frac{0.0625}{\left[\log\left(\frac{3.7D}{\varepsilon}\right)\right]^2} = 0.00433$$

so that $K_{pipe} = 4fL/D = 6.77$. From Equation (5.167), the loss coefficient for the control valve is related to the valve flow coefficient by

$$(K_f)_{CV} = 1.732 \frac{2A^2}{C_v^2 \rho_w}$$

where A is the pipe cross-section area. The factor 1.732 includes the conversion factors required for C_v in gpm/(psi)$^{1/2}$ (Table 5.14), A in mm^2, and ρ_w in kg/m^3. From Table 5.14, the value of C_v is 28.9 for the valve half-open, and 117 when fully open, giving $(K_f)_{cv}$ of 5.75 and 94.2, respectively. Setting $K_{entr} = 0.5$ and $K_{exit} = 1.0$ gives $\Sigma K_f = 15.6$ for the fully open valve and 104.2 for the half-open valve. Inserting these values into the equation for Q gives $Q = 0.0156$ m^3/s (248 gpm) for the open valve and 0.00606 m^3/s (96 gpm) for the half-open valve.

5.8.3 Compressible Flows

The minimum pressure in the valve (P_{vc}) generally occurs at the vena contracta, just downstream of the flow orifice. The pressure then rises downstream to P_2, with the amount of pressure recovery depending upon the valve design. If P_{vc} is less than the fluid vapor pressure (P_v), the liquid will partially vaporize, forming bubbles. If the pressure recovers to a value greater than P_v, these bubbles may collapse suddenly, setting up local shock waves, which can result in considerable damage. The result is *cavitation*, as opposed to *flashing*, which occurs if the recovered pressure remains below P_v and the bubbles do not collapse. After the first vapor cavities form, the flow rate will no longer be proportional to the square root of the pressure difference across the valve due to the decreasing density of the mixture. If sufficient vapor forms, the flow can become choked, at which point the flow rate will be independent of the downstream pressure as long as P_1 remains constant. The critical pressure ratio ($r_c = P_{2c}/P_v$) at which choking will occur is shown in Figure 5.26 for

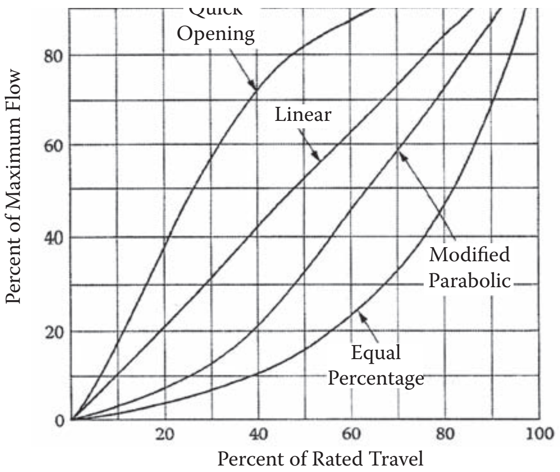

FIGURE 5.26 Critical pressure ratios for water. (From Fisher Controls, Catalog 10, chap. 2, Fisher Controls, Marshalltown, IA (1987).)

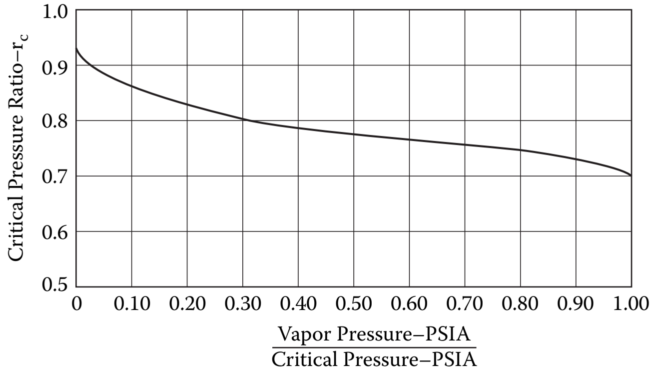

FIGURE 5.27 Critical pressure ratio for cavitating and flashing liquids. (From Fisher Controls, Catalog 10, chap. 2, Fisher Controls, Marshalltown, IA (1987).)

water and Figure 5.27 for other liquids, as a function of the liquid vapor pressure (P_v) relative to the fluid thermodynamic critical pressure (P_c). Table 5.15 lists the critical pressure values for some common fluids. An equation that represents the critical pressure ratio, r_c, with acceptable accuracy (Fisher Controls, 1977) is

$$r_c = 0.96 - 0.28\sqrt{\frac{P_v}{P_c}} \tag{5.176}$$

With r_c known, the allowable pressure drop across the valve at which cavitation occurs is given by

$$\Delta P_c = K_m(P_1 - r_c P_v) \tag{5.177}$$

where K_m is the valve recovery coefficient (which is a function of the valve design). The recovery coefficient is defined as the ratio of the overall net pressure drop ($P_1 - P_2$) to the maximum pressure drop from upstream to the vena contracta ($P_1 - P_{vc}$):

$$K_m = \frac{P_1 - P_2}{P_1 - P_{vc}} \tag{5.178}$$

Values of K_m for the Fisher Controls Example valve are given in the last column of Table 5.14, and representative values for other valves at the fully open condition are given in Table 5.16. If $\Delta P > \Delta P_c$, the value of ΔP_c is used as the pressure drop in the standard liquid sizing equation to determine Q; otherwise, the value of $(P_1 - P_2)$ is used:

$$Q = C_v\sqrt{\Delta P_c / SG} \tag{5.179}$$

The notation used here is that from the Fisher Controls literature (e.g., Fisher Controls, 1990). The ANSI/ISAS 75.01 standard for control valves (e.g., Baumann, 1991; Hutchison, 1971) gives the same equations with the notation $F_L = (K_m)^{1/2}$ and $F_F = r_c$ in place of the factors K_m and r_c.

For relatively low pressure drops, the effect of compressibility is negligible, and the general flow equation (Equation (5.167)) applies. Including conversion factors for flow rate in *scfh* and the density of air at standard conditions (1 atm, 520°R), this equation is

$$Q_{scfh} = 1362 C_v P_1 \sqrt{\frac{\Delta P}{P_1 (SG) T_1}} \tag{5.180}$$

TABLE 5.16
Representative Values of Fully Open K_m for Various Valves

Body Type	K_m
Globe: single port, flow opens	0.70–0.80
Globe: double port	0.70–0.80
Angle: flow closes	
Venturi outlet liner	0.20–0.25
Standard seat ring	0.50–0.60
Angle: flow opens	
Maximum orifice	0.70
Minimum orifice	0.90
Ball Valve:	
V-Notch	0.40
Conventional	0.30
Butterfly valve:	
60° open	0.55
90° open	0.30

Source: Hutchison, J. W., *ISA Handbook of Control Valves*, Instrument Society of America, Research Triangle Park, NC (1971).

The effect of variable density can be accounted for by an expansion factor *Y*, as is done for flow in pipes and meters, in which case Equation (5.181) can be written as

$$Q_{scfh} = 1362 C_v P_1 Y \sqrt{\frac{X}{(SG)T_1}} \tag{5.181}$$

where

$$X = \frac{\Delta P}{P_1} = \frac{P_1 - P_2}{P_1} \tag{5.182}$$

Deviations from the ideal gas law may be incorporated by multiplying T_1 in Equation (5.180) or (5.182) by the compressibility factor, *Z*, for the gas. The expansion factor *Y* depends upon the pressure drop *X*, the dimensions (clearance) in the valve, the gas-specific heat ratio *k*, and the Reynolds number (the effect of which is often negligible). The expansion factor for a given valve can be represented, to about ±2%, by the expression (Hutchison, 1971)

$$Y = 1 - \frac{X}{3X_T} \tag{5.183}$$

where X_T depends upon the specific valve, as illustrated in Figure 5.28. The value of X_T can be determined from Figure 5.28 as the value of *X* where $Y = 2/3 \times 1.4/\text{k}$.

When the gas velocity reaches the speed of sound, choked flow occurs and the mass flow rate reaches a maximum. From Equation (5.184), this is equivalent to a maximum in $Y\sqrt{X}$, which occurs at $Y = 0.667$. This corresponds to the terminus of the lines in Figure 5.29, i.e., X_T is the

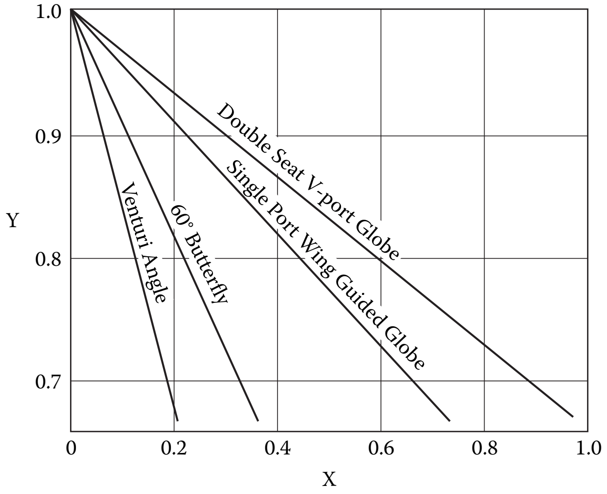

FIGURE 5.28 Expansion factor (Y) as a function of pressure drop ratio (X) for four different types of control valves. (From Hutchison, J. W., *ISA Handbook of Control Valves*, Instrument Society of America, Research Triangle Park, NC (1971).)

pressure ratio across the valve at which choking occurs, and any further increase in X (e.g., ΔP) due to lowering P_2 can have no effect on the flow rate.

The flow coefficient C_v is determined by calibration with water, and it is not entirely satisfactory for predicting the flow rate of compressible fluids under choked flow conditions. This has to do with the fact that different valves exhibit different pressure recovery characteristics with gases and hence will choke at different pressure ratios, which is not significant for liquid flows. For this reason, another flow coefficient, C_g, is often determined by calibration with air under critical flow conditions (Fisher Controls, 1977). The corresponding flow equation for gas flow is

$$Q_{critical} = C_g P_1 \left(\frac{520}{SGT} \right)^{1/2} \tag{5.184}$$

Equation (5.181), which applies at low pressure drops, and Equation (5.185), which applies to critical (choked) flow, have been combined into one general "universal" empirical equation by Fisher (1977), by using a sine function to represent the transition between the limits of both of these states:

$$Q_{scfh} = C_g \sqrt{\frac{520}{(SG)T_1}} P_1 \sin\left[\frac{3417}{C_1} \sqrt{\frac{\Delta P}{P_1}} \right]_{degrees} \tag{5.185}$$

Here, $C_1 = C_g/C_v$ and is determined by measurements on air. Values of C_1 are listed in the last column in Table 5.14 for the valve illustrated. C_1 is also approximately equal to $40\sqrt{X_T}$ (Hutchison, 1971). For steam or vapor at any pressure, a corresponding equation is

$$Q_{\text{lb/hr}} = 1.06 C_g \sqrt{P_1 \rho_1} \sin\left[\frac{3417}{C_1} \sqrt{\frac{\Delta P}{P_1}} \right]_{degrees} \tag{5.186}$$

where ρ_1 is the density of the gas at P_1, in lb_m/ft^3. When the argument of the sine term (in brackets) in Equation (5.185) or (5.186) is equal to 90° or more, the flow has reached critical flow conditions (choked) and cannot increase above this value without increasing P_1. Under these conditions, the sine term is equal to unity for this and all larger values of ΔP.

The flow coefficients referred to above are determined by calibration with air. For applications with other gases, the difference between the properties of air and those of the other gas must be considered. The gas density can be incorporated into the equations, but a correction must be made for the specific heat ratio ($c_p/c_v = k$) as well. This can be done by considering the expression for the ideal (isentropic) flow of a gas through a nozzle, which can be written (in "engineering units") as follows:

$$Q_{scfh} = \frac{3.78\times 10^5 A_2 P_1}{SG\sqrt{RT}}\sqrt{\frac{k}{k-1}\left[\left(\frac{P_2}{P_1}\right)^{2/k} - \left(\frac{P_2}{P_1}\right)^{(k+1)/k}\right]} \tag{5.187}$$

Critical (choked) flow will occur in the nozzle throat when the pressure ratio is

$$r = \frac{P_2}{P_1} = \left(\frac{2}{k+1}\right)^{k/(k-1)} \tag{5.188}$$

Thus, for choked flow, Equation (5.188) becomes

$$Q_{scfh} = \frac{3.78\times 10^5 A_2 P_1}{SG\sqrt{RT}}\sqrt{\left(\frac{k}{k+1}\right)\left(\frac{2}{k+1}\right)^{2/(k-1)}} \tag{5.189}$$

The quantity in the radical, which is a function only of $k[fn(k)]$, represents the dependence of the flow rate on the gas property. This may be used to define a correction factor, C_2, that can be used as a multiplier to correct the flow rate for air to that for any other gas:

$$C_2 = \frac{fn(k)_{gas}}{fn(k)_{air}} = \frac{\sqrt{\left[\frac{k}{k+1}\right]\left[\frac{2}{k+1}\right]^{2/(k-1)}}}{0.4839} \tag{5.190}$$

A plot of C_2 versus k from Equation (5.190) is shown in Figure 5.29.

5.8.4 Viscosity Correction

A correction for fluid viscosity must be applied to the flow coefficient (C_v) for liquids other than water. This correction factor (F_v) is obtained from Figure 5.30 by the following procedure, depending upon whether the objective is to find the valve size for a given Q and ΔP, to find Q for a given valve and ΔP, or to find ΔP for a given valve and Q.

To determine the valve size for a given Q and ΔP, calculate the required C_v as follows:

$$C_v = \frac{Q}{\sqrt{\Delta P / SG}} \tag{5.191}$$

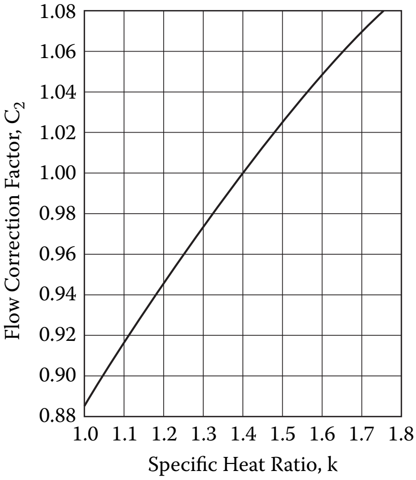

FIGURE 5.29 Correction factor for gas properties.

Then determine the Reynolds number for the valve from

$$N_{\text{Re}} = \frac{17250Q}{\sqrt{C_v}\,\nu_{cs}} \tag{5.192}$$

where Q is in gpm, ΔP is in psi, and ν_{cs} is the fluid kinematic viscosity (μ/ρ) in centistokes. The viscosity correction factor, F_v, is then read from the middle line on Figure 5.30 and used to calculate a corrected value of C_v as follows:

$$C_{v_c} = C_v F_v \tag{5.193}$$

The proper valve size and percent opening are then found from the table for the valve flow coefficient (e.g., Table 5.14) at the point where the coefficient is equal to or higher than this corrected value.

To predict flow rate for a given valve (i.e., a given C_v) and given ΔP, the maximum flow rate (Q_{max}) is determined as

$$Q_{\text{max}} = C_v\sqrt{\Delta P / SG} \tag{5.194}$$

The Reynolds number is then calculated from Equation (5.192), and the viscosity correction factor, F_v, is read from the bottom curve in Figure 5.30. The corrected flow rate is then

$$Q_c = \frac{Q_{\text{max}}}{F_v} \tag{5.195}$$

To predict pressure drop for a given valve (C_v) and given flow rate (Q), calculate the Reynolds number as above and read the viscosity correction factor, F_v, from the top line of Figure 5.30. The predicted pressure drop across the valve is then

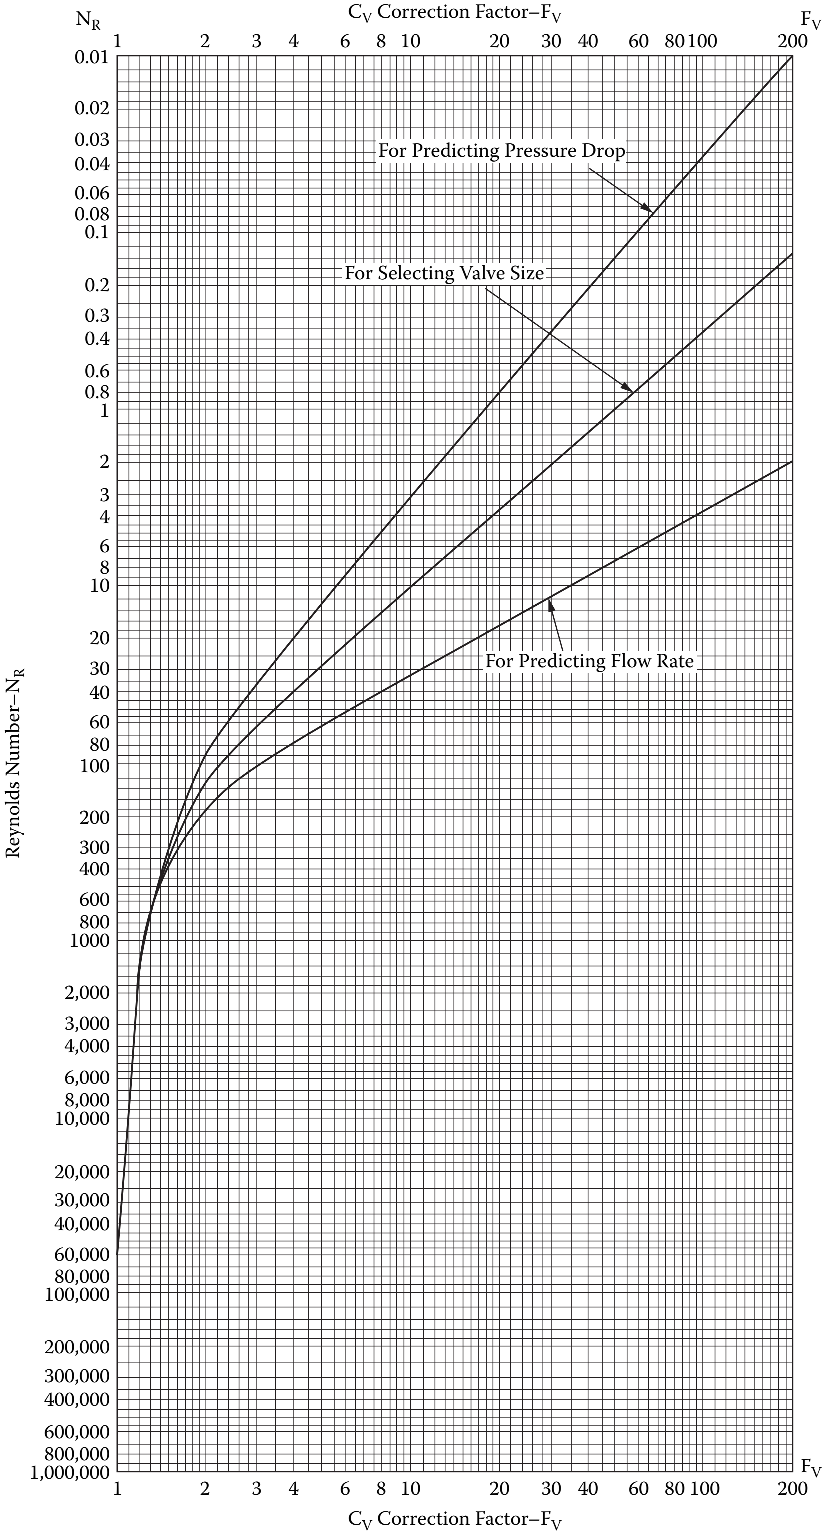

FIGURE 5.30 Viscosity correction factor for C_v. (From Fisher Controls, 1977.)

$$\Delta P = SG\left(\frac{QF_v}{C_v}\right)^2 \tag{5.196}$$

6.1 INTRODUCTION

This chapter deals with the transfer of heat in systems likely to be of interest to chemical engineers. These situations include transfer within a single phase (especially between two surfaces of a solid), between a solid surface and a fluid, between fluids separated by a solid surface, and between surfaces of neighboring bodies. The basic heat-transfer processes discussed include conduction, single-phase convection, vaporization, and condensation. These processes are described physically, and representative equations are given for calculating the rate at which heat is transferred.

The fundamental relationships are then extended to the design of heat exchangers, including a description of the most important types of heat exchangers and their areas of application.

The literature on both the fundamental processes and the applications to practical heat-transfer devices is immense, and only the most important references are given here. The *Heat Exchanger Design Handbook* [1] is a particularly useful source, being both comprehensive and giving special attention to design and application of heat exchangers.

6.2 CONDUCTION HEAT TRANSFER

6.2.1 Mechanisms of Conduction and the Basic Equation

Heat in solid, liquid, or gaseous matter is the random kinetic energy of the electrons, atoms, or molecules present; temperature is a measure of the average kinetic energy possessed by the assembly of electrons, atoms, and molecules. In a solid, the atoms or molecules are on the average fixed in a given position, but vibrate about this position, moving more rapidly at higher temperatures. In metallic solids, free electrons (so called because they are not associated with a given atom but can move freely within the boundaries of the body) represent a substantial fraction of the total kinetic energy (or heat content) of the body. The electrons move faster on average in a hot metal than in a colder one.

Conduction in a nonmetallic solid occurs when higher-temperature, more rapidly vibrating atoms (or molecules) transfer some of their kinetic energy to their lower-temperature neighbors, and so on through the extent of the solid. The same mechanism also occurs in a metallic solid, but the energy transport by the free electrons is generally even more important. Since the free electrons are also responsible for the conduction of an electrical current through a metal, a relationship exists between the ability of a metal to conduct heat and to conduct electricity. Details of the conduction process are complicated. Fortunately, for the present purposes, all of the complexities may be bypassed and the problem handled in a very simple way: To a very good approximation, the heat flux, $\dot{q}/A$, in conduction is directly proportional to the temperature gradient, $-(\partial T / \partial x)$, and the constant of proportionality is termed the thermal conductivity, k:

$$\left(\frac{\dot{q}}{A}\right)_x = -k_x\left(\frac{\partial T}{\partial x}\right) \tag{6.1}$$

In Equation (6.1), the terms are subscripted x because certain solids (e.g., wood, single crystals, and some highly oriented materials like pyrolitic graphite) have different thermal conductivities in different directions, and the subscript indicates the direction of heat flow. Most engineering materials, however, may be treated as isotropic (properties independent of direction) and the subscript dropped. The minus (−) sign in Equation (6.1) arises from the fact that heat flows from a high temperature to a lower one, and therefore $(\partial T / \partial x)$ is inherently negative; hence, the thermal conductivity and the heat flux are positive.

Equation (6.1) also applies in principle to gases and liquids. The temperature difference (and therefore the density difference) in the fluid often results in natural convection effects (discussed below), usually substantially enhancing the heat-transfer rate.

The thermal conductivity is experimentally determined, and appropriate values can be found in Part V of [1] or many other sources. Values can be sensitive to composition, (e.g., a small amount of alloying material usually significantly reduces k), to density, and to microstructure. The thermal conductivity is also a function of the temperature and hence varies with position in a conducting body. However, it is usually satisfactory to evaluate the conductivity at the arithmetic mean of the surface temperatures and use that value in the calculations.

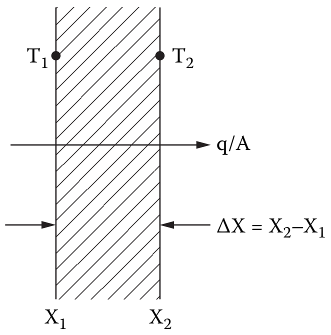

FIGURE 6.1 Conduction through a plane wall.

Equation (6.1) can be generalized to apply to three-dimensional, transient conduction with internal heat sources or sinks, but most chemical engineering applications can be treated as one- or two-dimensional, steady-state cases as described below. More advanced treatments are given in the literature [1–3].

6.2.2 One-Dimensional Steady-State Conduction

Equation (6.1) can be readily integrated for several important cases of one-dimensional steady-state conduction, including the following:

1. Plane slab of thickness Δx, with uniform temperatures on each surface (Figure 6.1). Integrating Equation (6.1) with $T = T_1$ on one surface (at $x = x_1$) and $T = T_2$ on the other surface (at $x = x_2$) gives

$$\frac{\dot{q}}{A} = \frac{k\left|(T_1 - T_2)\right|}{(x_2 - x_1)} = \frac{k\left|(T_1 - T_2)\right|}{\Delta x} \tag{6.2}$$

The vertical bars on the temperature difference indicate that the absolute value is to be used. It is assumed that the face dimensions Δy and Δz (where $\Delta y \Delta z = A$) either are large compared with Δx, or that the edges of the slab are well-insulated (adiabatic).

2. Multiple plane slabs in series with uniform temperatures on each surface (Figure 6.2). For two slabs of thicknesses Δx_1 and Δx_2 with thermal conductivities k_1 and k_2, and with $T = T_1$ on the front face of the first slab and $T = T_2$ on the rear face of the second slab, Equation (6.2) gives

$$\frac{\dot{q}}{A} = \frac{k_1\left|(T_1 - T^*)\right|}{\Delta x_i} = \frac{k_2\left|(T^* - T_2)\right|}{\Delta x_2} \tag{6.3}$$

where T^* is the temperature of the contact surface between the two slabs. This assumes no contact resistance between the two slabs; contact resistance is discussed in Section 6.2.3. T^* can be eliminated from Equation (6.3) to give

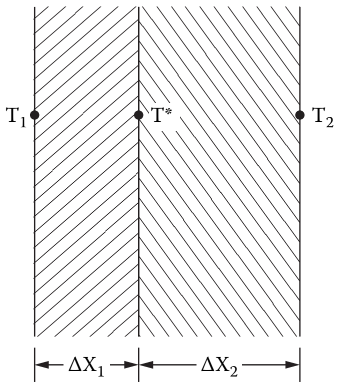

FIGURE 6.2 Conduction through two plane walls in series.

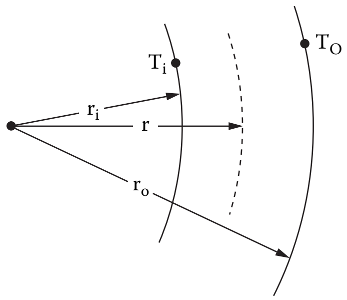

FIGURE 6.3 Conduction through a cylindrical wall.

$$\frac{\dot{q}}{A} = \frac{|(T_1 - T_2)|}{\dfrac{\Delta x_1}{k_1} + \dfrac{\Delta x_2}{k_2}} \tag{6.4}$$

Equation (6.4) can be extended to any number of plane slabs in series. Note that the right-hand side has the form of an overall driving force ($T_1 - T_2$), divided by the sum of the individual resistances ($\Delta x_i / k_i$). The interface temperature T^* can be found by substituting $\dot{q}/A$ back into Equation (6.3).

3. Cylindrical tube with wall thickness ($r_o - r_i$) and uniform temperatures on each surface (Figure 6.3). For this geometry, the area available for conduction increases from the inner wall to the outer according to the relationship $A(r) = 2\pi rL$, where r is the radius from the centerline of the tube and L is the length of the tube. Equation (6.1) may be rewritten

$$\frac{\dot{q}}{L} = -k(2\pi r)\left(\frac{dT}{dr}\right) \tag{6.5}$$

Integrating this equation with the conditions that $T = T_i$ at $r = r_i$ (inside surface of the tube) and $T = T_o$ at $r = r_o$ (outside surface) gives

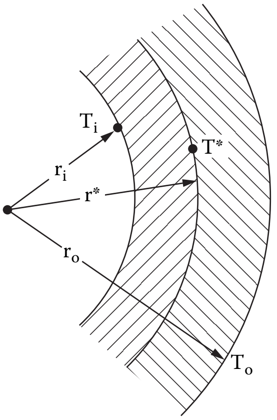

FIGURE 6.4 Conduction through a composite tube wall.

$$\frac{\dot{q}}{L} = \frac{2\pi k\left|(T_i - T_o)\right|}{\ln\left(\frac{r_o}{r_i}\right)} \tag{6.6}$$

The diametral ratio (D_o / D_i) can be used in the logarithmic term.
The heat flux, i.e., the heat-flow rate per unit area of heat-transfer surface, may be found from

$$\frac{\dot{q}}{A_i} = \frac{\dot{q}}{2\pi r_i L} = \frac{k\left|(T_i - T_o)\right|}{r_i \ln(r_o / r_i)} \tag{6.7}$$

for the inside surface area of the tube, and from

$$\frac{\dot{q}}{A_o} = \frac{\dot{q}}{2\pi r_o L} = \frac{k\left|(T_i - T_o)\right|}{r_o \ln(r_o / r_i)} \tag{6.8}$$

for the outside surface area. It is necessary to specify the area involved whenever a heat flux is given.

4. Multiple concentric cylinders with uniform temperatures on inside and outside surfaces (Figure 6.4), with zero contact resistance at the interface. Applying Equation (6.6) to each cylinder gives

$$\frac{\dot{q}}{L} = \frac{2\pi k_i\left|(T_i - T^*)\right|}{\ln\left(\frac{r^*}{r_i}\right)} = \frac{2\pi k_0\left|(T^* - T_0)\right|}{\ln\left(\frac{r_0}{r^*}\right)} \tag{6.9}$$

where k_i and k_o are the thermal conductivities of the inner and outer cylinders, respectively. Eliminating T^* gives

$$\frac{\dot{q}}{L} = \frac{|(T_i - T_0)|}{\dfrac{\ln(r^*/r_i)}{2\pi k_i} + \dfrac{\ln(r_0/r^*)}{2\pi k_0}} \tag{6.10}$$

The right-hand side is the overall driving force divided by the sum of the resistances, which can be extended to include additional concentric cylinders. The value of $(\dot{q}/L)$ found from Equation (6.10) can be inserted into Equation (6.9) to find T^*.

Example 6.1

Calculate the rate of heat transfer through a bimetallic tube consisting of an outer tube of low-carbon steel and an inner tube ("liner") of 347 stainless steel. The outer tube has an outside diameter of 31.8 mm (1.25 in.) and an inside diameter of 19.0 mm (0.75 in.). The liner has an outside diameter of 18.9 mm (0.75 in.) and a wall thickness of 20 BWG (= 0.889 mm = 0.035 in.), giving a nominal inside diameter of 17.3 mm (0.680 in.).

The inside wall temperature of the liner is 260°C (500°F) and the outside wall temperature of the outer tube is 100°C (212°F). Assume the liner and the outer tube are in perfect thermal contact.

Solution

Estimate that the average temperature of the outer tube is 150°C (302°F) and that of the liner is 230°C (446°F). (These estimates can be checked later.) Then the thermal conductivities are 49.1 W/m·K (28.4 Btu/h·ft·°F) for the low-carbon steel and 17.5 W/m·K (10.1 Btu/h·ft·°F) for the liner. Substituting into Equation (6.10) using diameters:

$$\frac{\dot{q}}{L} = \frac{260 - 100}{\dfrac{\ln(31.8/19.0)}{2\pi(49.1)} + \dfrac{\ln(19.0/17.3)}{2\pi(17.5)}} = \frac{160}{1.67\times10^{-3} + 8.52\times10^{-4}}$$

$$\frac{\dot{q}}{L} = 6.34\times10^{4}\ \text{W/m}\ (= 6.60\times10^{4}\ \text{Btu/ft})$$

The interface temperature can be calculated from Equation (6.9), rewritten, and using diameters:

$$T^* = T_i - \frac{(\dot{q}/L)\ln(D^*/D_i)}{2\pi k_i}$$

$$= 260 - \frac{(6.34\times10^{4})\ln(19.0/17.3)}{2\pi(17.5)} = 260 - 54.0 = 206°\text{C}\ (= 403°\text{F})$$

giving an average temperature of the stainless steel of 233°C (451°F) and of the low-carbon steel 153°C (307°F). These are close enough to the assumed temperatures and the corresponding thermal conductivities that no further calculations are required.

The heat fluxes on the inside and outside tube surfaces can now be calculated:

$$\frac{\dot{q}}{A_i} = \frac{\dot{q}}{\pi D_i L} = \frac{6.34\times10^{4}}{\pi(0.01714)} = 1.18\times10^{6}\ \text{W/m}^2 (= 3.74\times10^{5}\ \text{Btu/hr ft}^2)$$

for the inside surface area of the tube and

$$\frac{\dot{q}}{A_o} = \frac{\dot{q}}{\pi D_o L} = \frac{6.34 \times 10^4}{\pi(0.0315)} = 6.41 \times 10^5 \text{ W/m}^2 (= 2.03 \times 10^5 \text{ Btu/hr ft}^2)$$

for the outside surface of the tube.

6.2.3 Thermal Contact Resistance

When two solid surfaces, even finely machined ones, are placed in physical contact, there are still gaps between the two surfaces due to the inherent irregularities—roughness—of each surface. These gaps are usually filled with the ambient atmosphere, which usually has a lower effective thermal conductivity than the materials in contact. Heat transfer from one surface to another thus tends to be concentrated at those areas where the surfaces are in direct physical contact, which are also the areas on which the pressure forces act to keep the two surfaces in static equilibrium. The concentration of the heat-flow paths on only a part of the adjoining surfaces increases the local temperature gradients and in effect creates an additional resistance to heat transfer at the interface. This is termed the *thermal contact resistance*, and its possible effect in reducing the rate of heat transfer through composite materials (such as the bimetallic tube described above) must be considered.

Several factors determine the magnitude of the resistance, including

1. The roughnesses of the surfaces (height of surface irregularities)
2. The topology of the surfaces, e.g., whether the surfaces are grooved or randomly bumpy (grainy roughness), etc.
3. Hardness of the surface materials
4. Pressure exerted by one surface on the other
5. Thermal conductivities of the surface materials and the interstitial fluid
6. Other possible thermal transport mechanisms between the two surfaces, including radiation, natural convection, and free molecule transport at low pressures

The most generally applicable predictive method for contact resistance is ascribed to Irvine and Taborek in Section 2.4.6 of the *Heat Exchanger Design Handbook* [1]. Their method requires numerical values of the above properties, which usually do not have high accuracy, and the authors estimate about 25% mean error, with an error spread of a factor of 2 about the actual value. A typical thermal contact resistance is on the order of

$$1 - 2 \times 10^{-4} \frac{\text{m}^2\text{K}}{\text{W}} (6 - 12 \times 10^{-4} \text{ hr ft}^2 \text{ °F/Btu})$$

The contact resistance is also affected by differential thermal expansion when the surfaces are at elevated temperatures or with large temperature differences in the two materials. The problem is aggravated by thermal cycling, especially if one material is heated above its elastic behavior range, and must be considered with finned tubes in air-cooled heat exchangers.

Example 6.2

Recalculate the results of Example 6.1 assuming a thermal contact resistance of 2×10^{-4} m²·K/W at the interface between the low-carbon and stainless steels. Assume that the dimensions are unchanged.

Solution

The additional resistance may be added to the denominator of Equation (6.10):

$$\frac{\dot{q}}{L} = \frac{160}{\frac{\ln(31.8/19.0)}{2\pi(49.1)} + 2\times10^{-4} + \frac{\ln(19.0/17.3)}{2\pi(17.5)}}$$

$= 5.88 \times 10^4$ W/m (6.12×10^4 Btu/ft), a 7.5% reduction.

6.2.4 Extended Surfaces ("Fins")

6.2.4.1 Types of Extended Surface

It is sometimes advantageous to add heat-transfer area to a tube or other heat-transfer device by using extended surface or fins on the primary surface. These additional areas may be in the form of longitudinal or axial fins (Figure 6.5) or radial fins (Figure 6.6). The fins may be formed by extrusion or upsetting of the surface of a thick-walled tube (integral fins), or wrapped on the surface under tension ("tension-wound"), or welded or brazed to the tube. Studs or pin fins may also be used (Figure 6.7).

Using extended surfaces is addressed in several later sections on specific types and applications of heat exchangers. This section analyzes the efficiency of these surfaces, which is a problem of heat conduction, with the additional consideration of heat transfer to or from the surrounding fluid by convection.

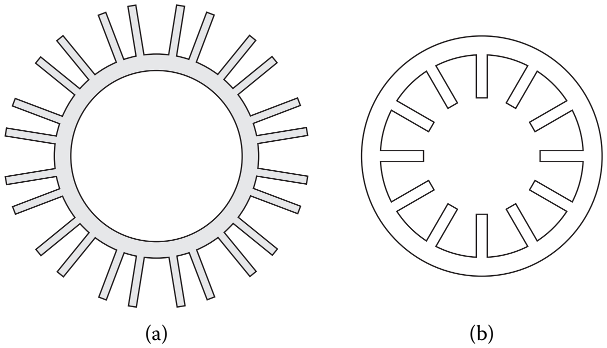

FIGURE 6.5 Longitudinal fins on a tube: (a) external, (b) internal.

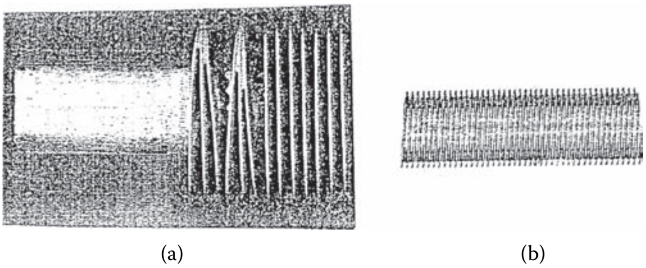

FIGURE 6.6 Radial fins on a tube: (a) high fin, (b) low fin.

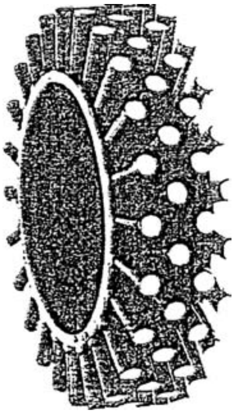

FIGURE 6.7 Studs or pin fins on a tube.

6.2.4.2 Convective Heat Transfer

Convection is the transfer of heat to or from, and within, flowing fluids. Section 6.3 of this chapter provides a more extensive treatment of convective heat transfer. For the analysis of heat-transfer fins, the rate of heat transfer to/from the fin surface from/to the ambient fluid is given by the equation

$$(\dot{q}/A)_{fin} = h_{fluid}\left|(T_{fluid} - T_{fin})\right| \quad (6.11)$$

where $(\dot{q}/A)_{fin}$ is the heat flux (W/m^2 or Btu/h·ft^2) to or from the fin, T_{fluid} is the bulk (mixed mean) temperature of the ambient fluid (K or °C or °F), and T_{fin} is the surface temperature of the fin (K or °C or °F). The film heat-transfer coefficient, h_{fluid} (W/m^2·K or Btu/h·ft^2·°F), is the constant of proportionality between the heat flux to/from the ambient fluid and the temperature differential for heat transfer to/from the fluid. The value of h_{fluid} depends upon the geometry of the system and the velocity and physical properties of the fluid. The relationship among the variables is in the form of empirical correlations, which are given in Sections 6.3 and 6.4 of this chapter.

6.2.4.3 Heat Transfer in Fins of Constant Cross Section

Fins such as those shown in Figures 6.5 and 6.7 usually have a constant cross-sectional area for conduction and are usually several times as high as they are thick. This allows the use of the one-dimensional conduction equation to calculate the temperature profile in the fin (Figure 6.8). It is also usually assumed that the film heat-transfer coefficient is uniform over the surface (nonconservative) and that the fin tip is adiabatic (i.e., no heat transfer, which is a slightly conservative assumption).

The temperature distribution is given by

$$\frac{T_{fin} - T_{fluid}}{T_{fin,b} - T_{fluid}} = \frac{\cosh N(X - x)}{\cosh N\ X} \quad (6.12)$$

where

$$N = \sqrt{\frac{2h_{fluid}}{Yk_{fin}}} \quad (6.13)$$

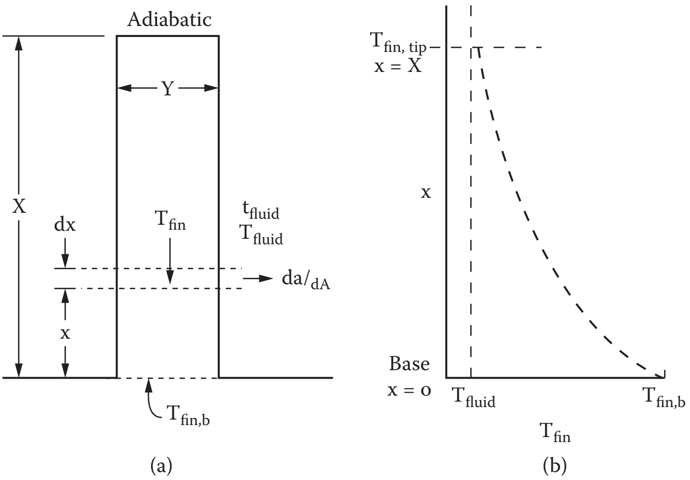

FIGURE 6.8 (a) Schematic for heat transfer in a constant cross-sectional fin, (b) typical temperature profile.

for the longitudinal fin, and

$$N = \sqrt{\frac{4h_{fluid}}{D_{stud}k_{fin}}} \tag{6.14}$$

for the stud fin.

In these equations, $T_{fin,\,b}$ is the temperature at the base of the fin, X is the height of the fin, Y is the thickness of the fin, D_{stud} is the diameter of the stud fin, and k_{fin} is the thermal conductivity of the fin material.

The fin efficiency, η_{fin}, is defined as the ratio of the actual amount of heat transferred by the fin to the amount that would be transferred if the fin material had an infinitely high thermal conductivity. For the longitudinal fin,

$$\eta_{fin} = \frac{\tanh\left[X\sqrt{\frac{2h_{fluid}}{Yk_{fin}}}\right]}{X\sqrt{\frac{2h_{fluid}}{Yk_{fin}}}} = \frac{\tanh(XN)}{XN} \tag{6.15}$$

and for the stud fin,

$$\eta_{fin} = \frac{\tanh\left[X\sqrt{\frac{4h_{fluid}}{D_{stud}k_{fin}}}\right]}{X\sqrt{\frac{4h_{fluid}}{D_{stud}k_{fin}}}} = \frac{\tanh(XN)}{XN} \tag{6.16}$$

Figure 6.9 shows η_{fin} as a function of XN.

The effective area for heat transfer from a finned surface is the sum of the "prime" area (the tube surface between the fins) and the finned area multiplied by the fin efficiency:

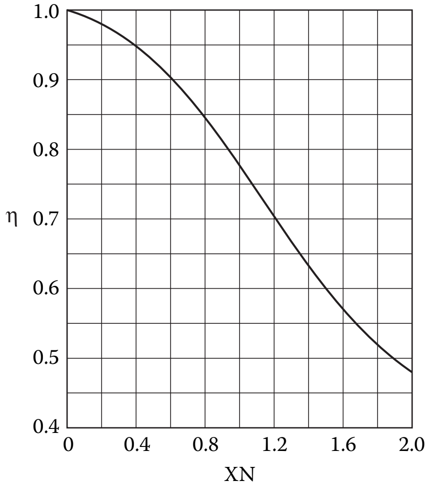

FIGURE 6.9 Fin efficiency for longitudinal and stud fins of constant cross-sectional area.

$$A_{eff} = A_{prime} + A_{fin}\eta_{fin} \tag{6.17}$$

In using the fin efficiency, the seemingly precise analytical solutions actually are premised upon several assumptions of unknown validity. Therefore, the resulting numerical values must be used cautiously and conservatively. And it must be remembered that, when using convective heat-transfer correlations for finned surfaces, the experimental data underlying these correlations were reduced using computed fin efficiencies.

Example 6.3

Twelve longitudinal low-carbon steel fins, each 15.8 mm (0.625 in.) high and 3.18 mm (0.125 in.) thick, are uniformly spaced around the outside surface of a 2-in. Schedule 40 (outside diameter = 6.033 cm = 2.375 in.) low-carbon steel pipe. The outside pipe wall temperature is 150°C (302°F), and it is cooled by a viscous oil flowing along the pipe at an average bulk temperature of 40°C (104°F). The oil has a film heat-transfer coefficient of 120 W/m^2·K (21.1 Btu/h·ft^2·°F), which is assumed constant over the outside surface of the pipe and the fins. The thermal conductivity of the steel is assumed constant at 49.1 W/m·K (28.4 Btu/h·ft·°F). Find the rate of heat transfer from the finned pipe per unit length and compare this with the heat transfer from the same length of unfinned pipe.

Solution

The heat-transfer area of the fins per meter of finned pipe (neglecting the fin tips) is

$$\frac{A_{fin}}{L} = 12(2)(15.8\times10^{-3}) = 0.379\ \text{m}^2/\text{m}\ (= 1.25\ \text{ft}^2/\text{ft})$$

The outside surface area of the pipe, excluding the area covered by the bases of the fins, A_{prime}, is

$$\frac{A_{prime}}{L} = \pi(6.033\times10^{-2}) - 12(3.18\times10^{-3})$$

$$= 0.1514\ \text{m}^2/\text{m}\ (= 0.497\ \text{ft}^2/\text{ft})$$

The fin efficiency is found from Equation (6.15):

$$X\sqrt{\frac{2h_{fluid}}{Yk_{fin}}} = 15.8\times 10^{-3}\sqrt{\frac{2(120)}{3.18\times 10^{-3}(49.1)}} = 0.619$$

Since this quality is dimensionless, the same value would be found for any set of consistent units:

$$\eta_{fin} = \frac{\tanh(0.619)}{0.619} = 0.890$$

The effective area is

$$\frac{A_{eff}}{L} = 0.1514 + 0.379(0.890) = 0.489\ \text{m}^2/\text{m}\ (= 1.603\ \text{ft}^2/\text{ft})$$

The heat transfer from the finned pipe is

$$\frac{\dot{q}}{L} = h_{fluid}\left(\frac{A_{eff}}{L}\right)(T_{pipe} - T_{fluid})$$

$$= 120(0.489)(150 - 40)$$

$$= 6.45\times 10^3\ \text{W/m}\ (= 6.70\times 10^3 (\text{Btu/hr})/\text{ft})$$

By comparison, the heat transfer from the plain pipe is

$$\left(\frac{\dot{q}}{L}\right)_{plain} = h_{fluid}(\pi D_o)(T_{pipe} - T_{fluid})$$

$$= 120(\pi)(6.033\times 10^{-2})(150 - 40)$$

$$= 2.50\times 10^3\ \text{W/m}\ (= 2.60\times 10^3\ (\text{Btu/hr})/\text{ft})$$

6.2.4.4 Heat Transfer in Radial (Spiral) Fins

The analysis of fin efficiency in radial, or spiral, fins (Figure 6.6) is substantially more complex because of the changing areas for both conduction and convection heat transfer. Again assuming a uniform heat-transfer coefficient, constant fin thickness, and adiabatic fin tip, Gardner [4] obtained the results shown in Figure 6.10, where D_o and D_i are the outside (tip) and inside (root) diameters of the fin, respectively.

Example 6.4

A low-carbon steel tube with a 25.4 mm (1 in.) outside diameter is radially finned with an aluminum (Alloy 1100) strip 15.8 mm (0.625 in.) high and 0.483 mm (0.019 in.) average thickness uniformly spaced at 400 fins/m (10.2 fins/in.). The outside surface of the steel tube is 80°C (176°F), and the tube is cooled by air in cross flow, with a bulk air temperature of 30°C (86°F) with a film heat-transfer coefficient of 70 W/m^{2}K (12.3 Btu/h·ft^2·°F), assumed uniform over the entire outside surface

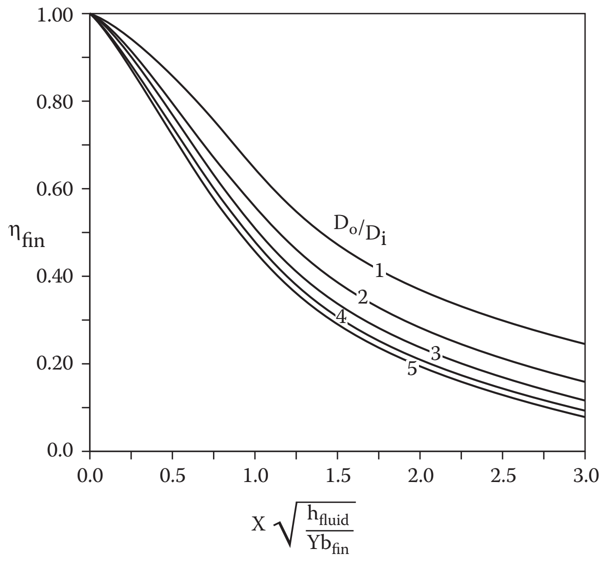

FIGURE 6.10 Fin efficiency for radial fins of constant thickness.

of the tube and fins. Assume negligible contact resistance. The thermal conductivity of Alloy 1100 is 218 W/m·K (126 Btu/h·ft·°F).

Calculate the heat-transfer rate per unit length of tube and compare that result with the unfinned tube under the same conditions.

Solution

The total fin area per unit length of tube is

$$\frac{A_{fin}}{L} = \frac{\pi}{4}(D_{fin}^2 - D_{root}^2)(2)(400)$$

$$= \frac{\pi}{4}[(0.0570)^2 - (0.0254)^2](2)(400)$$

$$= 1.636 \text{ m}^2/\text{m} \ (= 5.38 \text{ ft}^2/\text{ft})$$

The prime tube outside area (that area not covered by the fin bases) is

$$\frac{A_{prime}}{L} = \pi(0.0254)[1 - 400(0.483 \times 10^{-3})]$$

$$= 6.44 \times 10^{-2} \text{ m}^2/\text{m} \ (= 0.211 \text{ ft}^2/\text{ft})$$

The fin efficiency is found from

$$X\sqrt{\frac{h_{fluid}}{Yk_{fin}}} = 15.8 \times 10^{-3}\sqrt{\frac{70}{(0.483 \times 10^{-3})(218)}} = 0.407$$

$$\frac{D_{fin}}{D_{root}} = \frac{25.4 + 2(15.8)}{25.4} = 2.24$$

From Figure 6.10,

$$\eta_{fin} = 0.83$$

Then,

$$\frac{A_{eff}}{L} = 6.44 \times 10^{-2} + 0.83(1.636)$$

$$= 1.42 \text{ m}^2/\text{m} \ (= 4.67 \text{ ft}^2/\text{ft})$$

and, from Equation (6.11),

$$\frac{\dot{q}}{L} = 70(1.42)(80 - 30)$$

$$= 4.97 \times 10^3 \text{ W/m} \ (= 5.17 \times 10^3 \text{ (Btu/hr)/ft})$$

By comparison, the bare tube without fins has an outside area of

$$\frac{A_0}{L} = \pi D_0 = \pi(25.4 \times 10^{-3})$$

$$= 7.98 \times 10^{-2} \text{ m}^2/\text{m} \ (= 0.2618 \text{ ft}^2/\text{ft})$$

and a heat-transfer rate of

$$\frac{\dot{q}}{L} = 70(7.98 \times 10^{-2})(80 - 30)$$

$$= 279 \text{ W/m} \ (= 290 \text{ (Btu/hr)/ft})$$

In this case, the finned tube transfers 16.7 times as much heat per unit length as the plain tube.

6.2.4.5 Other Extended Surface Geometries

A wide variety of other geometrical configurations have been proposed for enhancing heat transfer in single-phase, condensing, and vaporizing systems. Extended treatments of many of these geometries are available in the literature [5–7].

6.2.5 Two- and Three-Dimensional Steady-State Conduction: Shape Factors

Many conduction problems involving one-, two-, and three-dimensional steady-state heat flows employ a "shape factor" S, defined by Equation (6.18):

$$S = \frac{\dot{q}}{k\Delta T} \tag{6.18}$$

where $\dot{q}$ is the rate of heat flow (W or Btu/h), k is the thermal conductivity of the conducting medium, and ΔT is the temperature difference between the heat source and the heat sink (both of which are assumed to be isothermal).

The shape factor may be found by one of two primary methods: analytical solution of the fundamental equations, or numerical solution in generalized dimensions presented in simple empirical equations to a sufficient degree of accuracy.

A solution of useful shape factors is given in Figure 6.11, taken from Parker et al. [8].

Example 6.5

A rectangular steel cold box with 4.76 mm (3/16 in.) thick walls has interior dimensions of 1.0 m by 1.25 m by 2.0 m (3.28 ft by 4.10 ft by 6.56 ft). It is insulated on all sides by a 10 cm (3.94 in.) thick layer of rock wool with a thermal conductivity of 0.040 W/m·K (0.023 Btu/h·ft·°F). The interior wall temperature is –20°C (–4°F), and the exterior surface of the insulation is at 40°C (104°F).

Calculate the heat-transfer rate from the surrounding atmosphere to the interior of the box.

Solution

The thermal resistance of the steel wall is negligible compared with that of the insulation. Assume zero contact resistance between the wall and the insulation.

Refer to the last diagram in Figure 6.11:

$$\sum L = 4(1.0) + 4(1.25) + 4(2.0) = 17.0 \text{ m } (= 55.8 \text{ ft})$$

$$\Delta X = 0.10 \text{ m } (= 0.328 \text{ ft})$$

$$A = 2\ (1.0)\ (1.25) + 2\ (1.0)\ (2) + 2\ (1.25 \times 2.0) = 11.5 \text{ m}^2 \ (= 124 \text{ ft}^2)$$

$$S = \frac{11.5}{0.10} + 0.54(17.0) + 1.2(0.1) = 124.3 \text{ m } (= 408 \text{ ft})$$

$$\dot{q} = (124.3 \text{ m})\left(0.040 \frac{\text{W}}{\text{m} \cdot \text{K}}\right)(40 - (-20))°\text{C}$$

$$\dot{q} = 298 \text{ W } (= 1020 \text{ Btu/hr})$$

Note that this calculation does not consider the convective heat transfer on either side of the insulated surface. An average temperature difference between the outside atmosphere and the outer surface could be obtained by using

$$\dot{q} = \bar{h} A_{outside}(T_{atm} - T_{surface})$$

where $\bar{h}$ is an appropriate film heat-transfer coefficient (Section 6.3), A_{outside} is the outside area of the box, and T_{atm} and T_{surface} are the temperatures of the atmosphere and the outside surface of the box, respectively. This assumes that the entire outside area of the box is exposed to the atmosphere and that $\bar{h}$ is constant and uniform.

6.2.6 Transient Conduction in Simple Solids

The analytical solutions for transient conduction in plates, cylinders, and spheres have been obtained by Heisler [9] and the solutions represented graphically for more convenient use. These solutions are for the case of a solid of initially uniform temperature T_0 exposed at time zero to a surrounding fluid medium at a constant temperature T_∞. The surface of the solid is cooled or heated by the fluid with a constant convective heat-transfer coefficient $\bar{h}$. The solid is assumed to have a constant thermal conductivity k_s and a constant thermal diffusivity α, defined as

$$\alpha = \frac{k_s}{\rho c_p} \tag{6.19}$$

where ρ is the density and c_p is the specific heat of the solid.

The charts for the flat plate of infinite length and width are given in Figures 6.12a and 6.12b, charts for infinitely long cylinders in Figures 6.13a and 6.13b, and for the sphere in Figures 6.14a and 6.14b. The first chart in each pair relates the dimensionless temperature at the center of the solid,

$$\frac{T_M - T_\infty}{T_o - T_\infty} \tag{6.20}$$

to the dimensionless time, expressed as the Fourier number

$$Fo = \frac{\alpha t}{L^2} \tag{6.21}$$

for the plane, and

$$Fo = \frac{\alpha t}{R^2} \tag{6.22}$$

for the cylinder and sphere.

In the Fourier number, α is the thermal diffusivity (Equation (6.19)), t is the time, L is the half-thickness of the plane, and R is the radius of the cylinder or sphere.

The reciprocal Biot number ($1/Bo$) is the parameter incorporating the convection. It is given as

$$\frac{1}{Bo} = \frac{k_s}{\bar{h}L} \tag{6.23}$$

for the plane, and

$$\frac{1}{Bo} = \frac{k_s}{\bar{h}R} \tag{6.24}$$

for the cylinder and sphere. The Biot number is a measure of the ability of an object to transfer heat to/from an external fluid compared with its ability to conduct heat internally. *Fo* and $1/Bo$ are dimensionless.

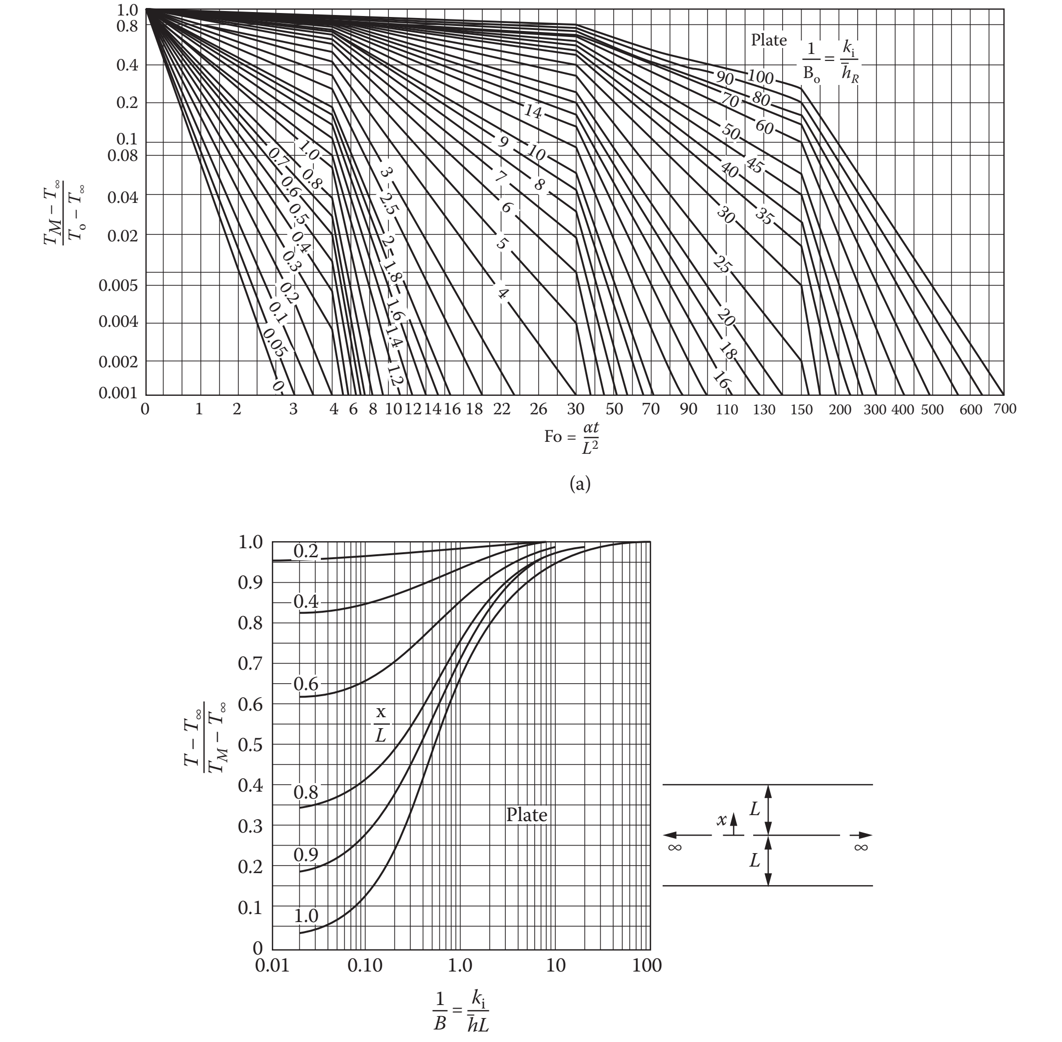

FIGURE 6.12 (a) Variation of the midplane temperature of a plane solid with dimensionless time. (b) Variation of temperature in a plane solid as a function of position.

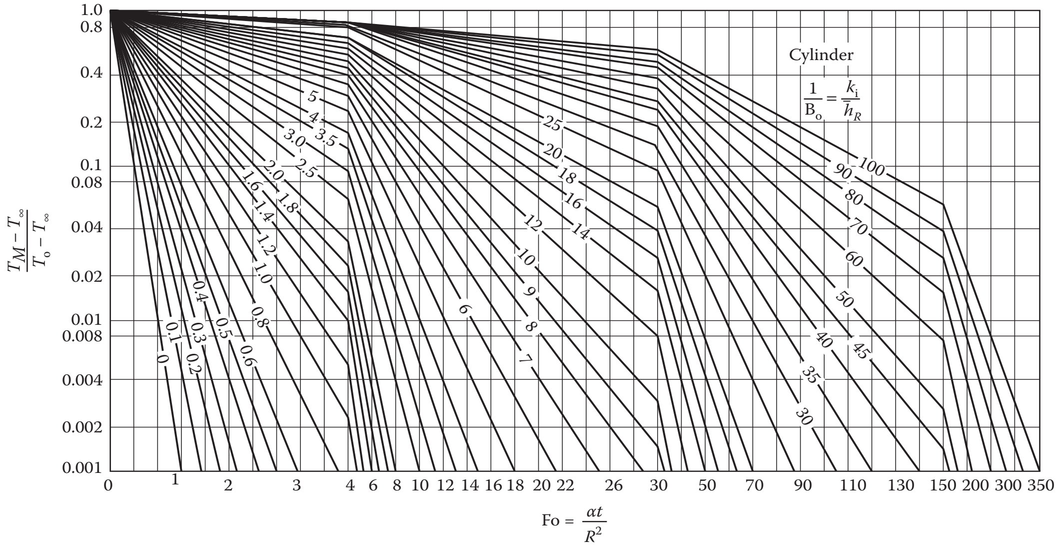
The second chart in each pair (Figures 6.12b, 6.13b, and 6.14b) relates the temperature at any position in the solid to the temperature at the center at any given time, using as parameters $1/Bo$ and the relative position in the solid between the center and the surface.

A property of these solutions is that they may be combined to give the solution to additional cases. For example, consider the case of a rectangular solid having dimensions X, Y, Z. The temperature at a given position within that solid at a given time $T(x,y,z,t)$ is given by

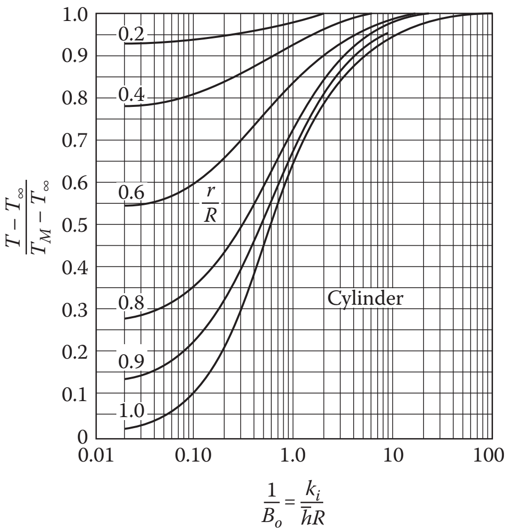
$$T(x,y,z,t) = T(x,t)T(y,t)\,T(z,t) \tag{6.25}$$

where $T(x,t)$ is the solution found for position x at time t assuming Y and Z to be infinite, $T(y,t)$ the solution for position y at time t assuming X and Z to be infinite, and $T(z,t)$ the solution for position z at time t assuming X and Y to be infinite.

The case for a short cylinder is illustrated in the following example.



(a)



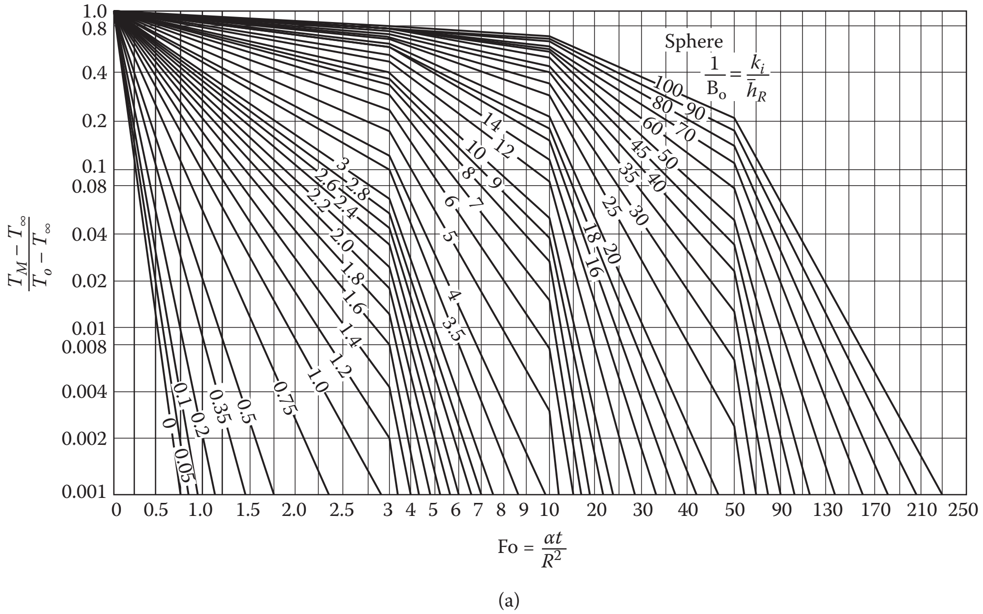
(b)

FIGURE 6.13 (a) Variation of the center temperature of a cylinder with dimensionless time. (b) Variation of temperature in a cylinder as a function of position.

Example 6.6

Small cylinders of a plastic are to be heated by air at 65°C (149°F) from a uniform temperature of 20°C (68°F) to a midpoint temperature of 60°C (140°F). The cylinder diameter and length are, respectively, 6.0 mm (0.236 in.) and 25 mm (0.984 in.), and the average convective heat-transfer coefficient between the air and the cylinder is estimated to be 50 W/m^{2}K (8.8 Btu/h·ft^2·°F). The properties of the plastic are density 1186 kg/m^3 (74 lb$_m$/ft^3), thermal conductivity 0.194 W/m·K (0.112 Btu/h·ft·°F), and specific heat 1520 J/kgK (= 0.365 Btu/lb$_m$°F).

Find the heating time necessary to bring the midpoint temperature to 60°C.



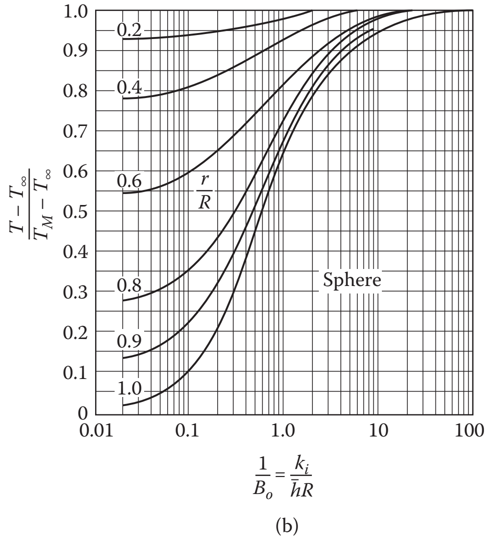


FIGURE 6.14 (a) Variation of the center temperature of a sphere with dimensionless time. (b) Variation of temperature in a sphere as a function of position.

Solution

The small cylinder can be modeled as an infinitely long cylinder of radius 3.0 mm, intersected by plane surfaces of 12.5 mm half-thickness perpendicular to the cylinder axis. (See Figure 6.15.)

The thermal diffusivity is

$$\alpha = \frac{0.194}{1{,}186(1{,}520)} = 1.076 \times 10^{-7}\,\frac{\text{m}^2}{\text{sec}}\left(= 4.15 \times 10^{-3}\,\frac{\text{ft}^2}{\text{hr}}\right)$$

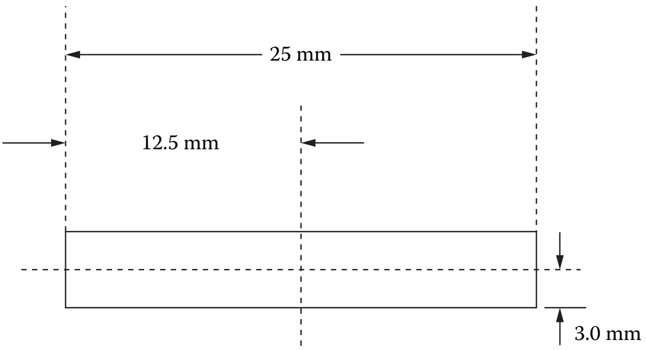

FIGURE 6.15 Cylindrical acrylic pellet analyzed in Example 6.6.

The Fourier number for the cylinder is

$$Fo = \frac{(1.076\times10^{-7})t}{(3.0\times10^{-3})^2} = \frac{(4.15\times10^{-3})t}{(0.118/12)^2(3600)}$$
$$= 1.196\times10^{-2}t$$

where t is in seconds.

The Fourier number for the plane is

$$Fo = \frac{1.076\times10^{-7}t}{(12.5\times10^{-3})^2} = \frac{4.15\times10^{-3}t}{(0.492/12)^2(3600)}$$
$$= 6.89\times10^{-4}t$$

where t is in seconds.

The reciprocal Biot number for the cylinder is

$$\frac{1}{Bo} = \frac{0.194}{50(3.0\times10^{-3})} = \frac{0.112}{8.8(0.118/12)} = 1.29$$

and for the plane it is

$$\frac{1}{Bo} = \frac{0.194}{50(12.5\times10^{-3})} = \frac{0.112}{8.8(0.492/12)} = 0.310$$

The dimensionless temperature change for the center of the cylinder is

$$\frac{T_m - T_\infty}{T_o - T_\infty} = \frac{60-65}{20-65} = \frac{140-149}{68-149} = 0.111$$

This quantity is the product of the solutions for the cylinder and the plane for the same time t^*:

$$\left(\frac{T_m - T_\infty}{T_o - T_\infty}\right)_{pellet,t=t^*} = \left(\frac{T_m - T_\infty}{T_o - T_\infty}\right)_{cylinder,t=t^*} x \left(\frac{T_m - T_\infty}{T_o - T_\infty}\right)_{plane,t=t^*}$$

This is a trial-and-error solution, but an initial upper bound can be found by neglecting the relatively minor effect of the plane ends. Therefore, from Figure 6.13a, for

$$\frac{T_m - T_\infty}{T_o - T_\infty} = 0.111 \quad \text{at} \quad \frac{1}{Bo} = 1.29$$

Fo is found to be about 1.8 and *t* is found from

$$t = \frac{1.8}{1.196 \times 10^{-2}} = 151 \text{ s}$$

For a second estimate, try t = 120 s, with *Fo* = 1.44 for the cylinder and *Fo* = 0.083 for the plane from Figure 6.12a. For the cylinder,

$$\left(\frac{T_m - T_\infty}{T_o - T_\infty}\right)_{cylinder} = 0.17$$

and for the plane,

$$\left(\frac{T_m - T_\infty}{T_o - T_\infty}\right)_{plane} = 0.92$$

giving an estimate for

$$\left(\frac{T_m - T_\infty}{T_o - T_\infty}\right)_{pellet} = 0.156$$

A third estimate of t = 135 s gives *Fo* = 1.61 for the cylinder, *Fo* = 0.093 for the plane,

$$\left(\frac{T_m - T_\infty}{T_o - T_\infty}\right)_{cylinder} = 0.14, \quad \left(\frac{T_m - T_\infty}{T_o - T_\infty}\right)_{plane} = 0.88, \quad \text{and} \quad \left(\frac{T_m - T_\infty}{T_o - T_\infty}\right)_{pellet} = 0.12$$

This is as close as the charts can be read, and probably as close as the normal uncertainties and approximations in such problems justify, so the required heating time is 135 s.

The temperature on the outside surface of the pellet at the lengthwise center can be found from Figure 6.13b. Reading at

$$\frac{r}{R} = 1.0 \quad \text{and} \quad \frac{1}{Bo} = 1.29$$

gives

$$\left(\frac{T - T_\infty}{T_0 - T_\infty}\right) = 0.73$$

where T is the temperature at the surface. Then,

$$T = 65 + 0.73\ (60 - 65) = 61.4°C$$

6.2.7 Numerical Methods

The previous sections have dealt with a number of important conduction problems, but all had specific geometric limitations and usually idealized assumptions. Numerical methods (which, for all practical purposes, require the use of a computer) can handle a much broader range of problems, including any geometry that can be described in terms of surfaces and intersects, variable physical properties (including temperature and spatial variation), and surface heat-transfer mechanisms, including convection and radiation, internal heat generation, and transient behavior.

The methods used are too specialized and detailed to describe here, but Patankar's book [10] is a good starting point. Commercial software codes are widely available.

6.3 SINGLE-PHASE CONVECTION HEAT TRANSFER

6.3.1 Mechanisms of Convection

Most industrial heat-transfer problems involve the transfer of heat between a solid surface and a flowing fluid. This process is termed *convective heat transfer*, where convection may be defined as the transport of heat from one point to another in a flowing fluid as a result of macroscopic motions of the fluid, the heat being carried as internal energy.

In laminar flow, the heat transfer occurs by conduction from the wall to the adjacent fluid molecules and then from molecule to molecule in the flowing fluid. The fluid immediately at the wall is normally at zero velocity relative to the wall and at the wall temperature. The temperature profile in the flowing fluid is determined by the thermal properties of the fluid (mainly the thermal conductivity) and its velocity profile.

In turbulent flow, the heat is first transferred by conduction through a very thin layer of relatively uneddied flow immediately adjacent to the wall. Further from the wall, small eddies develop in the flow, becoming larger at greater distances from the wall. The effect of the eddies is to rapidly disperse the heat from near the wall to the bulk of the fluid. Hence, the major resistance to heat transfer in turbulent flow is in the laminar region near the wall; the greater the Reynolds number, the thinner this region is, and the greater the rate of heat transfer.

Many flows in practice are neither clearly laminar nor turbulent, but may be termed as "transitional," "developing," or "disturbed." The best known example is the transition region in a tube or pipe, described in greater detail below.

Another distinction among flows is whether the flow is forced by an external means such as a pump (termed *forced convection*) or whether the flow arises as a result of a density difference developed in the fluid circuit as a result of the heat transfer (termed *natural convection* or *thermosiphon action*). Some cases include both mechanisms.

In any case, the fluid temperature at the wall is different from that at the centerline of the flow. When the fluid is being heated, the wall temperature is higher than the centerline temperature, and vice versa for cooling the fluid. The "bulk" or "mixing cup" temperature of the fluid, T, is the temperature that would be measured if the total flow through a cross section were collected over a given period and perfectly mixed. The bulk temperature is intermediate between the wall temperature and the centerline temperature (but usually close to the latter) and is the temperature that

is calculated from a heat balance. The difference between the wall, bulk, and centerline temperatures must be considered when dealing with a temperature-sensitive fluid.

These heat-transfer mechanisms have been modeled both analytically and numerically for many flow geometries. Most numerical methods require a computer to obtain an analytical answer, and because of the simplifications and assumptions required to obtain a solution, they are usually more accurate than the empirical methods discussed in this chapter. Good introductions to these methods are provided by Hewitt [1], Patankar [10], and Shah and London [11].

6.3.2 Film Coefficient of Heat Transfer

For the majority of convective heat-transfer cases, the heat flux ($\dot{q}/A$) between the surface and the fluid is nearly proportional to the temperature difference between the bulk fluid and the wall ($T - T_w$). A constant of proportionality h or α is termed the *film coefficient* of heat transfer and is defined by

$$\dot{q}/A = h\left|(T - T_w)\right| \quad (6.26)$$

where the bars denote that the absolute value of temperature difference is to be used. The area A used in the equation is usually (but not necessarily; see Section 6.3.3) the surface area across which the heat actually flows; this area should always be carefully defined to avoid confusion. For example, for heat transfer to a fluid inside a plain cylindrical tube, the heat-transfer area is $A_i = \pi d_i L$, where d_i is the inside diameter, L is the tube length over which heat transfer occurs, and h_i is defined as the film heat-transfer coefficient based on (or referenced to) the inside heat-transfer surface of the tube.

The value of h is found from correlations specific to the flow geometry (e.g., inside a tube or across a bank of tubes) and also depends upon the fluid velocity and physical properties. These correlations come primarily from experimental data and are usually expressed as functions of dimensionless numbers to generalize them. The form of the correlation may arise from theory or mechanistic models. In a very few instances, dimensional equations may be the only forms available; they must be used with data given in the stated dimensions and are usually of very limited generality.

Certain heat-transfer processes, notably nucleate boiling, do not follow the proportionality described above. Nevertheless, the concept of a film heat-transfer coefficient is so convenient for practical computation that it is often used in these cases. Special care is required to ensure that the heat flux, the temperature difference, and the coefficient are consistent.

Because the film coefficient correlations are based on experimental data, the calculated coefficients are not more accurate than those data. Further, the conditions in the experiments are often different from those in practical applications. The result is that the best correlations (e.g., the Petukhov-Popov correlation for turbulent flow [17] in long plain round tubes) have an uncertainty of about ±10%, and correlations for more complex cases are significantly less accurate. The consequences of these uncertainties must be considered when applying the calculated results to the design of equipment or interpretation of equipment performance.

6.3.3 Dimensionless Numbers

Heat-transfer-coefficient correlations are usually presented in terms of dimensionless numbers, which are groups of variables that have no net dimensions when evaluated in any consistent system of units. The most important dimensionless numbers for heat transfer are defined next.

6.3.3.1 Reynolds Number, Re

The Reynolds number is defined as

$$\text{Re} = \frac{D\rho V}{\mu} = \frac{DG}{\mu} = \frac{DV}{\nu} \tag{6.27}$$

where D is a characteristic length of the system, ρ is the density of the flowing fluid, V is a characteristic velocity of the fluid, and μ is the fluid absolute viscosity. G (= ρV) is the mass velocity (more correctly, mass flux) of the fluid, and $\nu = (\mu/\rho)$ is the kinematic viscosity. The exact definitions of D and V depend upon the geometry of the system and must be carefully defined in each case.

For most calculations, the physical properties of the fluid are evaluated at the average bulk temperature of the fluid between the inlet and outlet (except for the wall viscosity μ_w in the Sieder-Tate correction factor below).

The Reynolds number is a measure of the rate of momentum transport in a flowing fluid to the rate of viscous dissipation of momentum to the bounding solid surface. More simply, it is a measure of the intensity of turbulence in the fluid. At low Reynolds numbers, the flow is laminar and typically goes through a transition region before becoming fully turbulent at higher Re. The values of Re characterizing these flow regimes are different for each flow geometry. For a fully developed flow in a plain round tube, the flow is laminar for Re < 2100–2300 and turbulent for Re > 7,000–10,000.

Example 6.7

Calculate the Reynolds number for water at 40°C (104°F) flowing at 2 m/s (6.56 ft/s) inside a plain round tube with 25.4 mm outside diameter by 21.2 mm inside diameter (1 in., 14 BWG tube, inside diameter 0.834 in.).

Solution

At 40°C, water has a density of 992 kg/m^3 (61.9 lb$_m$/ft^3) and a viscosity of 653 × 10^{-6} Ns/m^2 (0.653 cp or 1.58 lb$_m$/ft·h). From Equation (6.27),

$$\text{Re} = \frac{(21.2\times 10^{-3}\ \text{m})(992\ \text{kg/m}^3)(2\ \text{m/s})}{(653\times 10^{-6}\ \text{Ns/m}^2)((\text{kg m/s}^2)/\text{N})} = 64,400$$

or

$$\text{Re} = \frac{(0.834\ \text{in.})(61.9\ \text{b}_\text{m}/\text{ft}^3)(6.56\ \text{ft/s})(3600\ \text{s/hr})}{(12\ \text{in./ft})(1.58\ \text{lb}_\text{m}/\text{ft hr})} = 64,400$$

This value is in the turbulent flow regime.

6.3.3.2 Nusselt Number, Nu

The Nusselt number is defined as

$$\text{Nu} = \frac{hD}{k} \tag{6.28}$$

where h is the film-transfer coefficient, k is the thermal conductivity of the fluid, and D is a characteristic length of the system. The Nusselt number nondimensionalizes the film coefficient in terms of the thermal conductivity and a measure of the distance the heat must penetrate the fluid.

6.3.3.3 Stanton Number, St

An alternative way to represent the heat-transfer coefficient is by the Stanton number, defined as

$$St = \frac{h}{V\rho c_p} \tag{6.29}$$

where c_p is the specific heat of the fluid at constant pressure. The Stanton number is the ratio of the heat-transfer rate to the heat transported in the stream.

6.3.3.4 Colburn *j*-Factor for Heat Transfer, j_H

The Colburn *j*-factor is another representation of the heat-transfer coefficient and arises from a boundary layer theory model. It is defined as

$$j_H = St\ \mathrm{Pr}^{2/3}\left(\frac{\mu_w}{\mu}\right)^{0.14} \tag{6.30}$$

where St is the Stanton number defined in Section 6.3.3.3, Pr is the Prandtl number defined in Section 6.3.3.5, and $(\mu_w/\mu)^{0.14}$ is the Sieder-Tate term described in Section 6.3.3.9.

6.3.3.5 Prandtl Number, Pr

The Prandtl number is defined as

$$\mathrm{Pr} = \frac{c_p\mu}{k} \tag{6.31}$$

where c_p is the specific heat at constant pressure, μ is the absolute viscosity, and k is the thermal conductivity of the fluid. The Prandtl number is the ratio of the momentum diffusivity (μ/ρ) to the thermal diffusivity ($k/\rho c_p$) of the fluid.

6.3.3.6 Graetz Number, Gz

The Graetz number is defined as

$$Gz = \frac{D}{L}\cdot\frac{V\rho c_p D}{k} \tag{6.32}$$

where L is the distance from the start of heating (for heat transfer at a given point) or length of heat-transfer surface (for total amount of heat transferred). The Graetz number is primarily of interest for laminar flow heat transfer with a developing temperature profile.

6.3.3.7 Peclet Number, Pe

The Peclet number is defined as

$$Pe = \frac{V\rho c_p D}{k} \tag{6.33}$$

$$= \mathrm{Re}\,\mathrm{Pr} \tag{6.34}$$

The Peclet number reflects the ratio of heat transferred by convection to that transferred by conduction and is most commonly found in applications in laminar flow or with liquid metals.

6.3.3.8 Grashof Number, Gr

The Grashof number is defined as

$$Gr = \frac{g\beta\Delta TL^3}{\nu^2} = \frac{g\beta\rho^2\Delta TL^3}{\mu^2} \tag{6.35}$$

where g is the gravitational acceleration (9.81 m/s^2 or 32.2 ft/s^2 for most applications), β is the thermal expansion coefficient for the fluid, and ΔT is the temperature difference between the bulk fluid and the heat-transfer surface. L is a characteristic dimension that is defined for each geometry. The Grashof number appears in natural convection heat-transfer correlations. The Rayleigh number (Ra) is the product of the Grashof and Prandtl numbers:

$$Ra = \frac{g\beta\rho^2\Delta TL^3c_p}{\mu k} \tag{6.36}$$

6.3.3.9 The Sieder-Tate Term

In heat transfer, the fluid at the wall has the same temperature as the wall, different from the bulk temperature. While all fluid properties are to some degree functions of temperature, the viscosity is most strongly affected. If the viscosity at the wall is lower than the bulk value, the boundary layer is thinner than for the isothermal case, and the heat-transfer coefficient is higher than that predicted for the constant property case. Correspondingly, the coefficient is reduced if the viscosity at the wall is higher than the bulk value. The effect is usually small (5 to 10%) but can be much larger with viscous fluids or large temperature differences.

Sieder and Tate [12] suggested a simple but broadly applicable correction factor, $(\mu/\mu_w)^{0.14}$, where μ is the viscosity at the bulk average temperature and μ_w is the viscosity at the corresponding wall temperature. The correction factor should be limited to the range from 0.5 to 2.0. The viscosity of liquids generally decreases with increasing temperature, while gases show the opposite behavior.

6.3.4 Single-Phase Heat-Transfer Correlations for Common Geometries in Forced Convection

A comprehensive collection of single-phase correlations is given by Kakac et al. [13]. A selection of the most important cases is treated in this section.

6.3.4.1. Inside Round Tubes

6.3.4.1.1 Laminar Flow, $\mathrm{Re} = \dfrac{D_i\rho V_i}{\mu} < 2100$

Prediction of the heat-transfer coefficient for this problem is complicated by the fact that the local coefficient is very high at the start of heat transfer and decreases as the conduction into or out of the fluid builds up an adverse temperature gradient. A number of analytical and numerical solutions for this and other constant cross-sectional geometries are given by Shah and London [11], but most

of them assume constant physical properties and hence fail to show the effect of natural convection induced by the density change due to heating or cooling. One well-known analytical solution is the so-called Graetz-Nusselt problem (parabolic velocity profile) for fully developed laminar flow in a plain round tube (described by Shah and London [11] and Sieder and Tate [12]). The exact solution is unwieldy and is usually represented by the Hausen Equation (15):

$$\frac{\bar{h}_i D_i}{k} = \left[3.65 + \frac{0.0668\,\mathrm{Re}\,\mathrm{Pr}(D_i / L)}{1 + 0.04[\mathrm{Re}\,\mathrm{Pr}(D_i / L)]^{2/3}}\right]\left(\frac{\mu}{\mu_w}\right)^{0.14} \tag{6.37}$$

where $\bar{h}_i$ is the average heat-transfer coefficient over the heat-transfer length of the tube L. The Sieder-Tate term has been added. This equation does not include natural convection effects. The Palen-Taborek equation [16] does consider natural convection:

$$\frac{\bar{h}_i D_i}{k} = 2.5 + 4.55(\mathrm{Re}^\circ)^{0.37}(d_i / L)^{0.37}\,\mathrm{Pr}^{0.17}\left(\frac{\mu}{\mu_w}\right)^{0.14} \tag{6.38}$$

where

$$\mathrm{Re}^\circ = \mathrm{Re} + 0.8\mathrm{Gr}^{0.5}\exp(-0.42 / \mathrm{Gr}^2) \tag{6.39}$$

The temperature difference ΔT used in the Grashof number is the average temperature difference between the bulk fluid and the wall over the heat-transfer length. This equation applies only to horizontal tubes.

For vertical tubes, the natural convection effect depends upon both the flow direction and whether the fluid is being heated or cooled. This problem is examined in the work of Jakob [14] and in Section 2.5.10 of the *Heat Exchanger Design Handbook* [1].

6.3.4.1.2 Turbulent Flow, $\mathrm{Re} = \frac{D_i \rho V_i}{\mu} > 7000$

The Sieder-Tate equation [12],

$$\frac{h_i D_i}{k} = 0.023\,\mathrm{Re}^{0.8}\,\mathrm{Pr}^{1/3}\left(\frac{\mu}{\mu_W}\right)^{0.14} \tag{6.40}$$

is convenient and reliable for Reynolds numbers above about 7000. The Petukhov-Popov equation [17] is generally regarded as the best available for this case:

$$\frac{h_i D_i}{k} = \frac{(f_F / 2)\,\mathrm{Re}\,\mathrm{Pr}}{1.07 + 12.7(f_F / 2)^{1/2}(\mathrm{Pr}^{2/3} - 1)}\left(\frac{\mu}{\mu_W}\right)^{0.14} \tag{6.41}$$

where

$$f_F = (3.64\log_{10}\mathrm{Re} - 3.28)^{-2} \tag{6.42}$$

(The Sieder-Tate term has been added, and f_F is the Fanning friction factor for smooth tubes in turbulent flow.)

The local heat-transfer coefficient near the tube entrance is somewhat higher than these values because of the disturbed flow conditions. The above values are reached after about 40 diameters into the tube.

Example 6.8

Calculate the heat-transfer coefficient and heat flux for water at the conditions given in Example 6.7. The tube wall temperature is 60°C (140°F).

Solution

At 40°C (104°F), water has a specific heat of 4.183 kJ/kg·K (1.00 Btu/lb_m) and a thermal conductivity of 0.631 W/m·K (0.365 Btu/h·ft·°F). At 60°C (140°F), water has a viscosity of 467 × 10^{-6} N·s/m^2 or 0.467 cP (1.13 lb_m/ft·h). Other properties are given in Example 6.7.

The Reynolds number in Example 6.7 was found to be 64,400, so the flow is turbulent, and the use of Equations (6.40)–(6.42) is required.

Solution by the Sieder-Tate equation:

The Prandtl number at 40°C is

$$\Pr = \frac{(4.183 \text{ kJ/kg K})(635\times10^{-6} \text{ Ns/m}^2)(1 \text{ kg m/s}^2 \text{ N})(1000 \text{ Ws/kJ})}{(0.631 \text{ W/mK})} = 4.21$$

The Sieder-Tate term is

$$\left(\frac{\mu}{\mu_w}\right)^{0.14} = \left(\frac{653\times10^{-6}}{467\times10^{-6}}\right)^{0.14} = \left(\frac{1.58}{1.13}\right)^{0.14} = 1.048$$

From Equation (6.40), the Nusselt number is

$$\text{Nu} = \frac{h_i D_i}{k} = 0.023(64{,}400)^{0.8}(4.21)^{1/3}(1.048) = 274$$

and the film heat-transfer coefficient (based on inside of tube surface area) is

$$h_i = 274\left(\frac{0.631 \text{ W/mK}}{21.2\times10^{-3}\text{m}}\right) = 8{,}150 \text{ W/m}^2\text{K (or } 8{,}150 \text{ W/m}^2\text{C), or } 1{,}430 \text{ Btu/hr ft}^2\ {}^\circ\text{F}$$

The corresponding heat flux is

$$q/A_i = h_i(T_W - T_b) = (8{,}150 \text{ W/m}^2\text{C})(60-40)\text{C} = 163{,}000 \text{ W/m}^2\text{, or } 51{,}500 \text{ Btu/hr ft}^2$$

Solution by the Petukhov-Popov equation:

Using the values for Re, Pr, and $(\mu/\mu_\infty)^{0.14}$ developed above, Equation (6.42) gives

$$f_F = [3.64 \log_{10} 64{,}400 - 3.28]^{-2} = 0.00494$$

and Equation (6.41) gives

$$Nu = \frac{h_i D_i}{k} = \frac{(0.00494/2)(64,400)(4.21)}{1.07 + 12.7\left(\frac{0.00494}{2}\right)^{1/2}[(4.21)^{2/3} - 1]}(1.048) = 337$$

Then

$$h_i = 337\left(\frac{0.631\,\text{W/mK}}{21.2 \times 10^{-3}\,\text{m}}\right) = 10{,}020\ \text{W/m}^2\text{K (or 10,020 W/m}^2\text{K), or 1,760 Btu/hr ft}^2\,°\text{F}$$

The coefficients are based on the inside-tube heat-transfer surface. The corresponding fluxes are

$$q/A_i = (10{,}020\ \text{W/m}^2\text{C})(60 - 40)\text{C} = 200{,}400\ \text{W/m}^2\text{, or 63,400 Btu/hr ft}^2$$

The agreement between the two correlations in this case is within about 20%, which is an example of the possible differences in two different but accepted correlations.

6.3.4.1.3 Transition Flow, 2100 < Re < 7000

Prediction of the heat-transfer coefficient in the transition flow regime is uncertain due to the strong effects of entrance conditions and instability of the flow pattern. Gnielinski [18] modified the Petukhov-Popov equation to accommodate the transition region and extend it into the turbulent flow range:

$$\frac{h_i D_i}{k} = \frac{(f_F/2)(\text{Re} - 1000)\text{Pr}}{1 + 12.7(f_F/2)^{1/2}(\text{Pr}^{2/3} - 1)}\left[1 + \frac{D_i}{L}\right]^{2/3}\left(\frac{\mu}{\mu_w}\right)^{0.14} \quad (6.43)$$

Again, f_F is given by Equation (6.42). The Sieder-Tate term has been added to the equation.

6.3.4.2 Internally Enhanced Tubes

Many techniques—straight, spiraled, and circular fins; twisted tape and wire inserts; and various corrugations—improve the heat-transfer coefficient or increase the heat-transfer area inside tubes. There is always an increased pressure drop as well as increased cost associated with these enhancements. There may also be a change in the fouling characteristics, which may be either a positive or negative factor, depending upon the circumstances. These tubes are ordinarily considered in cases where the inside-tube heat-transfer coefficient is substantially lower than the outside coefficient, since the use of enhanced tubes can only be justified if increased cost and possible operational complications are offset by a savings in the overall size and cost of the heat exchanger. Webb [7] provides an excellent overview of enhanced heat transfer for a wide variety of geometries and operational conditions.

6.3.4.3 Inside Annular Channels

An annular channel is the space between two concentric cylindrical tubes, shown in Figure 6.16. This geometry is used in double-pipe heat exchangers, as described later. The primary interest is on heat transfer on the outside surface of the inner tube. In evaluating the Reynolds, Nusselt, and

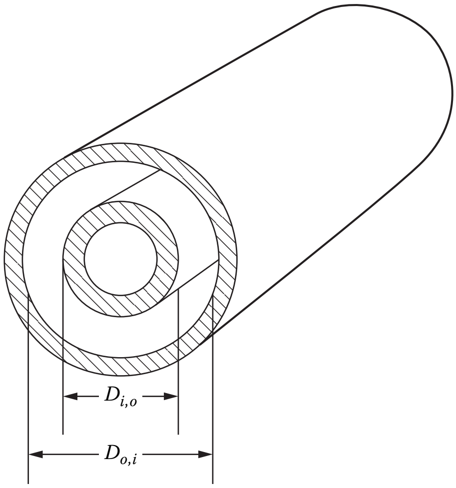

FIGURE 6.16 Annulus channel formed between two concentric round cylinders. $D_{o,i}$ is the inside diameter of the outer cylinder, and $D_{i,o}$ is the outside diameter of the inner cylinder.

Peclet numbers, the characteristic length for an annulus is the diametral clearance between the two cylinders, $(D_{o,i} - D_{i,o})$, where $D_{o,i}$ is the inside diameter of the outer cylinder and $D_{i,o}$ is the outside diameter of the inner cylinder.

6.3.4.3.1 Laminar Flow, Re ≤ 2300

Heat transfer to a laminar flow in an annulus is complicated by the fact that both the velocity and thermal profiles are simultaneously developing near the entrance and, often, over the length of the heated channel. Natural convection may also be a factor. It is usually conservative (i.e., predicted heat-transfer coefficients are lower than those experienced) to use equations for the fully developed flow.

For the usual case of heat transfer on the inner surface of the annulus, Martin [19] recommends, for fully developed flow, the following:

$$\text{Nu} = \frac{\bar{h}(D_{o,i} - D_{i,o})}{k} = 3.66 + 1.2\left(\frac{D_{i,o}}{D_{o,i}}\right)^{-0.8} \tag{6.44}$$

Equations for other cases are given in the *Heat Exchanger Design Handbook* [1].

6.3.4.3.2 Turbulent flow, Re ≥ 7000

Petukhov and Roizen [20] recommend, for heat transfer at the inner surface of the annulus,

$$\frac{\text{Nu}_{\text{annulus}}}{\text{Nu}_{\text{tube}}} = 0.86\left(\frac{D_{i,o}}{D_{o,i}}\right)^{-0.16} \tag{6.45}$$

where Nu_{tube} is calculated from Equations (6.41) and (6.42).

6.3.4.3.3 Transition Flow, 2300 < Re < 7000

Calculations in transition flow are very uncertain, and design in this range should be avoided if possible. The *Heat Exchanger Design Handbook* [1] gives an extended procedure involving linear interpolation with Reynolds number between 2,300 and 10,000, giving generally conservative results.

6.3.4.4 Flow across a Circular Cylinder

Heat transfer in flow across a circular cylinder occurs in many situations over a wide range of conditions. The dominant flow mechanisms change gradually from creeping laminar at very low Re to a fully developed turbulent boundary layer on the forward surface of the cylinder with a strongly eddied wake region at high Re. A combination of flow modeling and extensive experimental data have suggested the following correlations (modified from Eckert and Drake [21]):

For $1 \leq \text{Re} \leq 1000$:

$$Nu = (0.43 + 0.50\,\text{Re}^{0.5})\,\text{Pr}^{0.38}\left(\frac{\mu}{\mu_w}\right)^{0.25} \tag{6.46}$$

For $1000 \leq \text{Re} \leq 2 \times 10^5$:

$$Nu = 0.25\,\text{Re}^{0.6}\,\text{Pr}^{0.38}\left(\frac{\mu}{\mu_w}\right)^{0.25} \tag{6.47}$$

In these equations, the cylinder diameter D_o is used in Nu and Re, and the undisturbed approach velocity is used in Re.

Example 6.9

Calculate the rate of heat loss by convection from the outer surface of an uninsulated 4-in. Schedule. 40 pipe (D_o = 4.500 in. = 0.114 m) exposed to wind blowing at 8.0 m/s (26.3 ft/s) perpendicular to the pipe. The air is at −23°C (−9.4°F), and the pipe surface is at 27°C (80.6°F).

Solution

Air properties at −23°C and 1 atm abs are

Density, ρ = 1.41 kg/m^3 (0.088 lb$_m$/ft^3)
Viscosity, μ = 1.49 × 10^{-5} kg/m·s (0.0360 lb$_m$/ft·h)
Thermal conductivity, k = 0.0223 W/m·K (0.0127 Btu/h·ft·°F)
Specific heat, c_p = 1.00 × 10^3 Ws/kgK (0.24 Btu/lb$_m$°F)

The air viscosity at the surface of the pipe (at 27°C) is μ_w = 1.98 × 10^{-5} kg/m·s (0.0478 lb$_m$/ft·h).

$$\text{Re} = \frac{D_o \rho V}{\mu} = \frac{(0.114\text{ m})(1.41\text{ kg/m}^3)(8.0\text{ m/s})}{(1.49 \times 10^{-5}\text{ kg/ms})} = 86{,}300$$

$$\text{Pr} = \frac{c_p \mu}{k} = \frac{(1.00 \times 10^3\text{ Ws/kg K})(1.49 \times 10^{-5}\text{ kg/ms})}{0.0223\text{ W/m K}} = 0.668$$

From Equation (6.47),

$$\frac{hD_o}{k} = 0.25(86{,}300)^{0.6}(0.668)^{0.38}\left(\frac{1.49 \times 10^{-5}}{1.98 \times 10^{-5}}\right)^{0.25} = 183$$

$$h = 183\frac{(0.0223\ \text{W/m}\cdot\text{K}))}{0.114\ \text{m}} = 35.6\ \text{W/m}^2\text{K}\ (= 6.27\ \text{Btu/h}\cdot\text{ft}^2\ {}^\circ\text{F})$$

The heat flux is

$$Q/A = h(T_{pipe} - T_{air})$$

$$= (35.6\ \text{W/m}^2\text{K})[(27°\text{C}) - (-23°\text{C})]$$

$$= 1780\ \text{W/m}^2 = 564\ \text{Btu/h·ft}^2$$

and the heat loss per meter of pipe is

$$Q/h = \left(1780\frac{\text{W}}{\text{m}^2}\right)(\pi)(0.114\ \text{m})$$

$$= 637\ \text{W/m}\ (= 663\ \text{Btu/hr per foot of length})$$

6.3.4.5 Flow across Tube Banks

Banks of tubes are used in shell-and-tube heat exchangers and in air-cooled heat exchangers because they provide a high heat-transfer surface per unit volume of heat exchanger in a mechanically strong, easily manufactured, and reasonably maintainable configuration. Plain tubes are commonly used when the heat-transfer coefficients on each side of the surface are comparable, and circumferentially finned tubes are often used when one coefficient is substantially lower. Low fins (1.5 to 3 mm high) are often used in shell-and-tube exchangers, and high fins (10 to 25 mm high) in air-cooled exchangers.

6.3.4.5.1 Banks of Plain Tubes

The Reynolds number used for characterizing flow is

$$\text{Re} = \frac{D_o \rho V_{\max}}{\mu} \tag{6.48}$$

where D_o is the outside diameter of the tube, $V_{\max}$ the maximum velocity attained during flow across the bank (i.e., through the passages where adjacent tubes approach most closely), and ρ and μ are, respectively, the density and viscosity of the fluid at its average bulk temperature in the bank. There is no sharp transition in flow behavior as the Reynolds number increases from the laminar flow region (Re < 100) to the fully turbulent region (Re > 6000). There is, however, a strong dependence on the geometry of the tube bank.

For shell-and-tube exchangers, four different basic geometries of tube layout are used, defined by the angle between the approach-flow direction and the axis connecting the centers of adjacent tubes (Figure 6.17). The 30° and 45° orientations are generally preferred on the basis of heat transfer vs. pressure-drop performance. The 30° configuration provides more heat-transfer area per unit volume than the 45° arrangement and is usually chosen if mechanical cleaning of the outside heat-transfer surface is not required. The 45° layout provides clear lanes through the tube field for cleaning.

The other important geometrical parameter is the pitch ratio, defined as the distance between the centers of adjacent tubes, P_t, divided by the tube outside diameter, D_o. The smaller the pitch

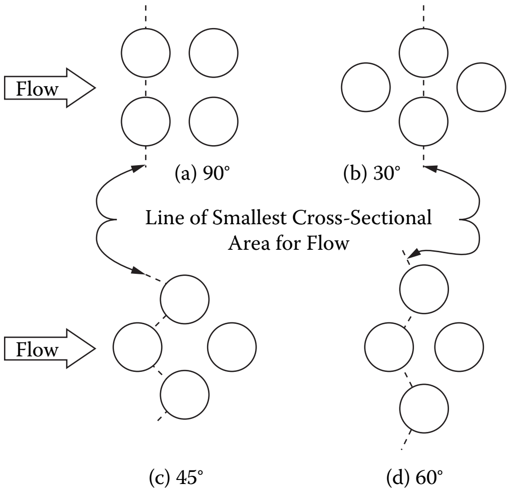

FIGURE 6.17 Typical tube layouts used in shell-and-tube heat exchangers.

ratio, the greater the surface area per unit volume; practical construction considerations set the minimum pitch ratio to about 1.25. As the pitch ratio is increased, the pressure drop for a given flow rate decreases much faster than the heat-transfer coefficient, but requires a relativity modest increase in heat-exchanger size. For handling liquids, the pitch ratio is usually chosen between 1.25 and 1.5; for gases and in vacuum service (including condensing and vaporizing), pitch ratios of 2 or even greater can be considered.

Generalized transfer and pressure-drop correlations for several commonly used ideal (no bypass or leakage flows) tube banks are shown in Figures 6.18, 6.19a, and 6.19b over the usual Reynolds number range. Figure 6.20 gives more specialized and accurate curves over a narrower but critical range.

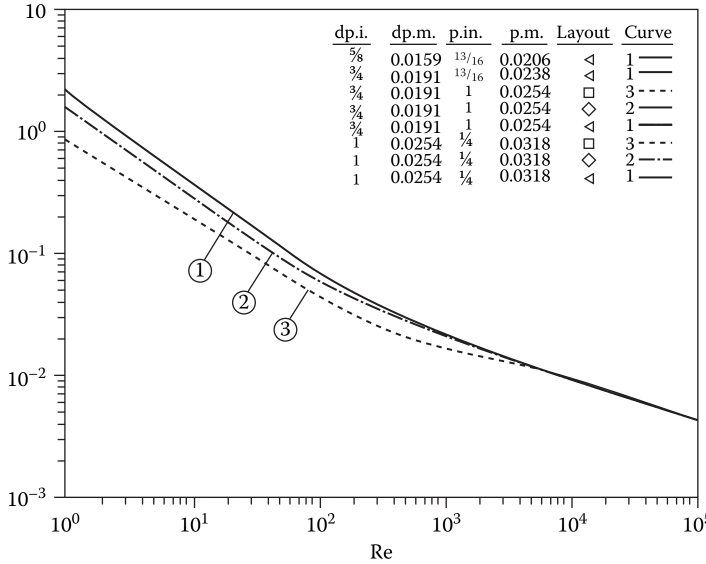

FIGURE 6.18 Correlation of Colburn *j*-factors for ideal tube banks.

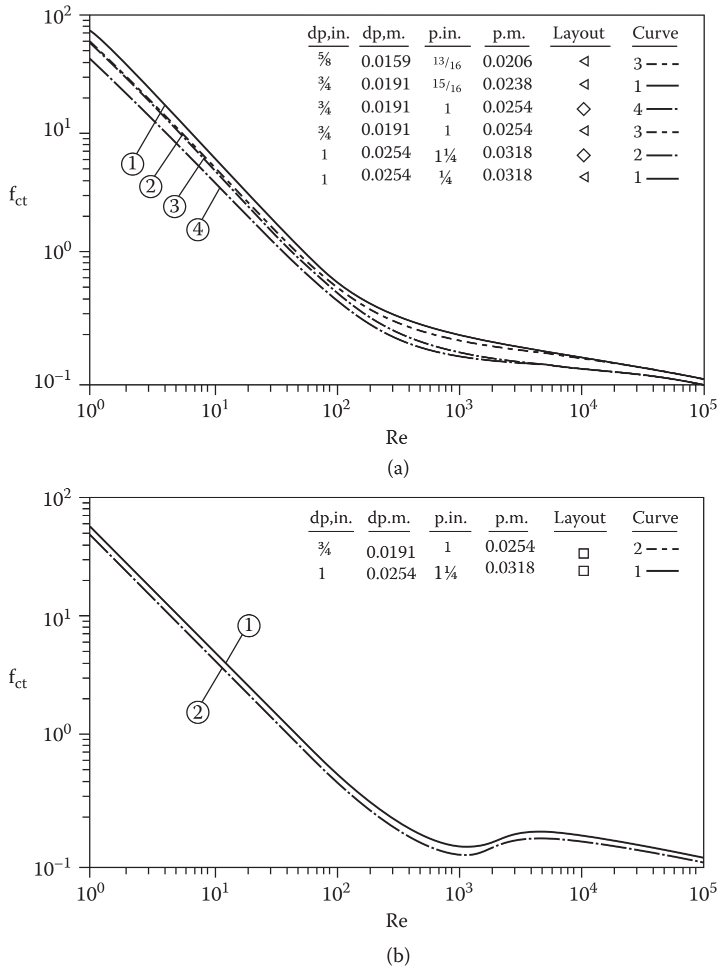

FIGURE 6.19 (a) Correlation of friction factors for ideal tube banks, 30° and 45° layouts. (b) Correlation of friction factors for ideal tube banks, 90° layouts.

This heat-transfer correlation is in terms of the Colburn *j*-factor, defined as

$$j = \left(\frac{h}{c_p \rho V_{\max}}\right) \mathrm{Pr}^{2/3} \left(\frac{\mu_w}{\mu}\right)^{0.14} \tag{6.49}$$

where $V_{\max}$ is the highest velocity reached by the fluid in passing through the tube bank, i.e., through the smallest cross-sectional area for flow as shown in Figure 6.17. Note that for the 45° and 60° configurations, this velocity is reached between tubes in adjacent rows for pitch ratios in the usual range of interest ($P_t/D_o < 1.71$ for 45° layout). This equation is valid for tube banks with 10 or more rows of tubes in depth. For shallower tube banks, there is some reduction in the average coefficient. Zukauskas et al. [24] present an extended discussion of this phenomenon and a generalized (but less accurate) correlation for a wide range of tube-bank geometry.

The pressure-drop correlation is given in Figures 6.18, 6.19a, 6.19b, and 6.20 in terms of the modified Chilton-Genereaux friction factor f_{ct} as a function of Reynolds number, where

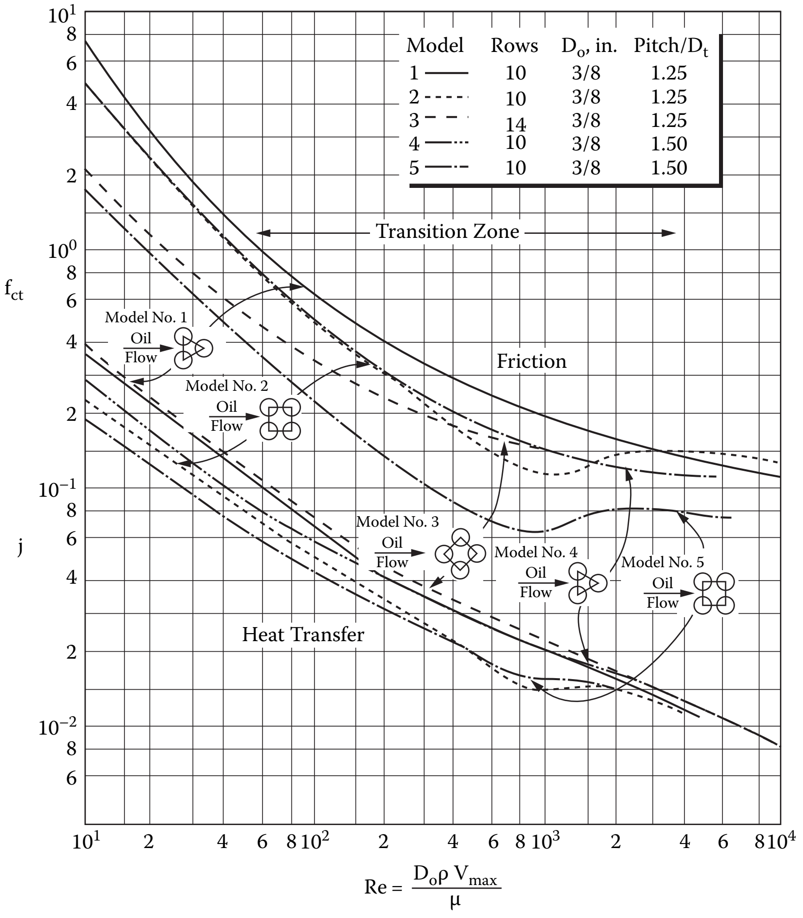

FIGURE 6.20 Summary of Delaware ideal tube-bank friction factor and Colburn *j*-factor data.

$$f_{ct} = \frac{2\Delta p g_c}{4\rho V_{max}^2 N}\left(\frac{\mu}{\mu_w}\right)^{0.14} \tag{6.50}$$

In this equation, N is the number of major restrictions in the tube bank (i.e., the number of times the flow reaches its maximum velocity in flowing through the tube bank). In the 30° and 90° arrangements, N is equal to the number of tube rows crossed in the bank; for the 45° and 60° layouts, N is one less than the number of rows crossed. The term Δp is the frictional pressure drop across the tube bank.

Example 6.10

Calculate the heat-transfer coefficient and frictional pressure loss for the following case: Water at an average temperature of 20°C (68°F) is flowing at the rate of 50 kg/s (110 lb_m/s) across a tube bank composed of 274 tubes, each 25.4 mm (1.00 in.) in diameter and 1 m long in a 30° layout with a 1.25 pitch ratio, as shown in Figure 6.21.

There are 7 rows with 20 tubes per row and 6 rows with 19 tubes per row. The heat-transfer and pressure-drop characteristics are represented by curve 1 in Figures 6.18 and 6.19a and by model 1 in Figure 6.20. The tube surface temperature is 60°C (140°F).

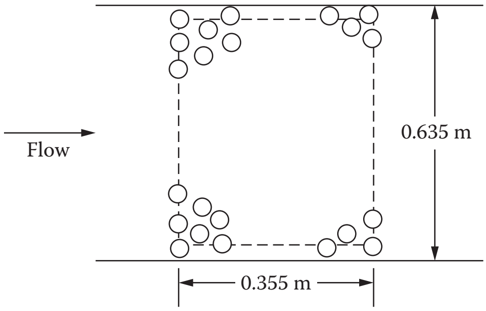

FIGURE 6.21 Flow across the 30°, 1.25 pitch ratio tube bank in Example 6.10.

Solution

Water properties at 20°C are

Density, $\rho = 1.001 \times 10^3$ kg/m^3 (= 62.5 lb$_m$/ft^3)
Viscosity, $\mu = 1.007 \times 10^{-3}$ kg/ms (= 2.44 lb$_m$/ft hr)
Thermal conductivity, $k = 0.597$ W/m K (= 0.345 Btu/hr ft °F)
Specific heat, $c_p = 4.183 \times 10^3$ Ws/kg K (= 0.999 Btu/lb$_m$ °F)
Water viscosity at 60°C, $\mu_w = 4.71 \times 10^{-4}$ kg/ms (= 1.70 lb$_m$/ft hr)

Free-flow area: Because there are different numbers of tubes in adjacent rows, there are two different free-flow areas and, hence, different calculated heat-transfer coefficients and pressure losses per row. For the rows with 20 tubes, the free-flow area will be smaller and the velocity, heat-transfer coefficient, and pressure drop per row will be higher than those for rows with 19 tubes. We can obtain a reasonable estimate by using an average velocity. For a row with 20 tubes, the minimum free-flow area is

$$S_{\mathrm{min},20} = [0.635 \text{ m} - 20(25.4 \times 10^{-3} \text{ m})](1 \text{ m}) = 0.127 \text{ m}^2 \ (= 1.367 \text{ ft}^2)$$

and the corresponding velocity is

$$V_{\mathrm{max,\,20}} = \frac{(50 \text{ kg/s})}{(1001 \text{ kg/m}^3)(0.127 \text{ m}^2)} = 0.393 \text{ m/s} = 1.29 \text{ ft/s}$$

The corresponding values for a 19-tube row are $S_{\mathrm{min,\,19}} = 0.152$ m^2 (1.64 ft^2) and $V_{\mathrm{max,\,19}} = 0.329$ m/s (1.08 ft/s). The average maximum velocity is 0.361 m/s. (Large clearances between the outermost tubes and the side walls result in significant and ineffective bypass flows and should be avoided in good design.)

Continuing with this average velocity,

$$\mathrm{Re} = \frac{(2.54 \times 10^{-2} \text{ m})(1.001 \times 10^3 \text{ kg/m}^3)(0.329 \text{ m/s})}{(1.007 \times 10^{-3} \text{ kg/ms})} = 8310$$

From Figure 6.20, using curve 1, $f_{\mathrm{ct}} = 0.12$ and $j = 0.0090$. The pressure drop for $N = 13$ major restrictions (13 rows of a 30° layout) is from Equation (6.49):

$$\Delta p = \frac{4(0.12)(1.001\times 10^3 \text{ kg/m}^3)(0.361 \text{ m/s})^2(13)}{2(1)}\left(\frac{4.71\times 10^{-4}}{1.007\times 10^{-3}}\right)^{0.14}$$

$$= 366\frac{\text{kg}}{\text{m}\cdot\text{s}^2} = 366 \text{ N/m}^2 = 366 \text{ Pa} = 5.3\times 10^{-2} \text{ lb}_\text{f}/\text{in.}^2$$

The heat-transfer coefficient is obtained from Equation (6.48), where

$$\text{Pr} = \frac{(4.183\times 10^3 \text{ Ws/kg K})(1.007\times 10^{-3} \text{ kg/ms})}{(0.597 \text{ W/m K})} = 7.06$$

and

$$h = \frac{0.0090(4.183\times 10^3 \text{ Ws/kg K})(1.001\times 10^3 \text{ kg/m}^3)(0.361 \text{ m/s})}{(7.06)^{2/3}\left(\frac{4.71\times 10^{-4}}{1.007\times 10^{-3}}\right)^{0.14}}$$

$$= 4.11\times 10^3 \text{ W/m}^2\text{K} (= 724 \text{ Btu/h}\cdot\text{ft}^2\cdot{}^\circ\text{F})$$

6.3.4.5.2 Banks of Low-Finned Tubes

The limited experimental results of Williams and Katz [25] and Briggs et al. [26] can be used to modify the results for plain tubes to apply to cross flow in banks of low-finned tubes commonly used in shell-and-tube heat exchangers.

The plain-tube *j*-factor curves can be used for the corresponding low-finned tubes for Reynolds numbers above 1000. At lower Re, the retardation of the flow between the fins reduces the *j*-factor. It is necessary to calculate V_{max}, taking into account the flow area between the fins. The root diameter of the tube (i.e., the tube diameter at the base of the fins) is used in the Reynolds number. The coefficient thus calculated is based on the entire external tube area including fins, but a fin efficiency (calculated by the method of Section 6.2.4.3) must be applied to the fin area.

For calculating pressure drop, the friction factors given in Figures 6.19a, 6.19b, and 6.20 should be multiplied by a factor of 1.5.

6.3.4.5.3 Banks of High-Finned Tubes

The experimentally based correlation of Briggs and Young [27] is recommended for this case:

$$\frac{h_o D_r}{R} = 0.134\,\text{Re}^{0.68}\,\text{Pr}^{1/3}\left(\frac{H}{s}\right)^{-0.2}\left(\frac{Y}{s}\right)^{-0.12} \tag{6.51}$$

The heat-transfer coefficient h_o is referenced to the entire outside tube surface, including fins, and the fin efficiency is found from Section 6.2.4.3. D_r is the root diameter of the tube (to the base of the fins), H is the fin height, Y is the fin thickness, and s is the face-to-face spacing between the fins. The Reynolds number Re is defined as

$$\text{Re} = \frac{D_r \rho V_{max}}{\mu} \tag{6.52}$$

where V_{max} is calculated at the minimum flow area between tubes, including the flow area between the fins.

Pressure drop is calculated from the correlation of Robinson and Briggs [28]:

$$\Delta p = \frac{f_r N \rho V_{max}^2}{g_c} \tag{6.53}$$

where N is the number of rows of tubes, and f_r is the friction factor found from the following equation:

$$f_r = 18.93\,\mathrm{Re}^{-0.316}\left(\frac{P_t}{D_r}\right)^{-0.927}\left(\frac{P_t}{P_1}\right)^{0.52} \tag{6.54}$$

where Re is defined by Equation (6.52), P_t is the distance between centers of adjacent tubes, and P_1 is the distance between centers of adjacent tubes in successive rows, measured along the diagonal. For the usual equilateral triangular tube layout, $(P_t/P_1) = 1$.

In-line banks of high-finned tubes are not usually used in air-cooled heat-transfer equipment because the preferential flow path between the fin tips of adjacent tubes allows flow bypassing and reduces the apparent heat-transfer coefficient. This effect tends to disappear in the deeper tube banks used in convection sections of fired heaters.

6.3.4.6 Heat Transfer in Packed and Fluidized Beds

Packed beds, often composed of catalyst pellets, are used widely in the chemical industries. Fluid flows through the bed and exchanges heat with the bed material. Heat-transfer processes within the bed and between the bed and the container walls are also of concern. Gnielinski ([29], summarized in [1]) presents a comprehensive listing of available data and gives the following equations valid over a Reynolds number range from 100 to 2×10^4 and void fractions $0.26 < \psi < 1$:

$$\mathrm{Nu}_{packed\ bed} = \frac{(h_{packed\ bed})D_{sphere}}{k_{fluid}} = f_\psi \mathrm{Nu}_{single\ sphere} \tag{6.55}$$

where

$$\mathrm{Nu}_{single\ sphere} = 2 + \sqrt{\mathrm{Nu}_{lam}^2 + \mathrm{Nu}_{turb}^2} \tag{6.56}$$

$$\mathrm{Nu}_{lam} = 0.664\sqrt{\mathrm{Re}_\Psi}\,\sqrt[3]{\mathrm{Pr}} \tag{6.57}$$

$$\mathrm{Nu}_{turb} = \frac{0.037\,\mathrm{Re}_\psi^{0.8}\,\mathrm{Pr}}{1 + 2.443\,\mathrm{Re}_\psi^{-0.1}(\mathrm{Pr}^{2/3} - 1)} \tag{6.58}$$

$$\mathrm{Re}_\psi = \frac{D_{sphere}\rho V_{free}}{\mu} \tag{6.59}$$

$$f_\psi = 1 + 1.5(1 - \psi) \tag{6.60}$$

$$\psi = \frac{V_{total} - V_s}{V_{total}} \tag{6.61}$$

In these equations, D_{sphere} is the diameter of the spheres; V_{free} is the fluid velocity in the cross section of the empty vessel; ρ and μ are, respectively, the density and absolute (dynamic) viscosity of the fluid; and V_{total} and V_s are, respectively, the volume of the empty vessel and the total volume of the spheres respectively.

The corresponding pressure drop can be estimated by the Ergun Equation [27]:

$$\frac{\Delta p}{L}\frac{D_p}{\rho V_s^2}\left(\frac{\varepsilon^3}{1-\varepsilon}\right) = 150\frac{1-\varepsilon}{\left(\dfrac{D_p \rho V_s}{\mu}\right)} + 1.75 \tag{6.62}$$

where L is the height of the bed and ε is the porosity.

Fluidized beds are widely used in chemical processing, but the heat-transfer and fluid-flow characteristics are too complex to be adequately treated here. Martin (in [1], Section 2.8.4) gives an excellent overview.

6.3.5 Single-Phase Heat Transfer in Natural Convection

In natural convection heat transfer, fluid motion is induced by the density difference between the fluid in contact with the solid heat-transfer surface and the bulk fluid. The density difference is related to the temperature difference between wall and bulk by

$$\Delta\rho = \rho_{wall} - \rho_{bulk} = \beta\bar{\rho}(T_{bulk} - T_{wall}) \tag{6.63}$$

where β is the thermal expansion coefficient of the fluid at constant pressure, defined by

$$\beta = -\frac{1}{r}\left(\frac{\partial \rho}{\partial T}\right)_p \tag{6.64}$$

and $\bar{\rho}$ is the mean density,

$$\bar{\rho} = \frac{1}{2}(\rho_{wall} + \rho_{bulk}) \tag{6.65}$$

For small density differences, β can be assumed constant. The value of β can be found from a table of density vs. temperature (at constant pressure) over the temperature range of interest.

The resulting induced flow may be laminar (usually at small temperature differences and/or viscous fluids) or turbulent, or often in a transition or mixed laminar and turbulent regime. Correlations may be based on analytical or experimental studies, and numerical methods are now available. A major limitation to analytical solutions is that constant viscosity is generally assumed, whereas the variation of viscosity with temperature is likely to have a major effect upon the velocity gradient and the dominant flow regime near the heat-transfer surface.

Other factors that need to be considered in any natural convection calculation include the geometry of the container (if any), flows generated from (or limited by) other surfaces in the vicinity, the interaction with forced flows, and possible radiative heat-transfer interactions. Because natural

convection heat-transfer coefficients are generally low, radiation effects should always be considered in any analysis. It should be noted that local convective heat-transfer coefficients often vary with position and can be quite different from the mean value over a specified surface. Typical correlations of mean values for several common geometries are given below; more extensive treatments are given in the *Heat Exchanger Design Handbook* [1], Sections 2.5.7–2.5.10, and in Hewitt et al. [30] and Incropera and DeWitt [31]. Physical properties used in these correlations are to be evaluated at the "film temperature," taken to be the average between the solid surface and bulk fluid temperatures.

6.3.5.1 Natural Convection from a Vertical-Plane Surface

For a vertical-plane heat-transfer surface of height L, the Grashof number is defined as

$$\mathrm{Gr}_L = \frac{gL^3\rho^2\beta\left|(T_{surf} - T_{fluid})\right|}{\mu^2} \tag{6.66}$$

A local value for any distance x from the leading edge ($0 < x \leq L$) is defined by replacing L by x in this equation. The corresponding Rayleigh number is found by multiplying Gr by the Prandtl number,

$$\mathrm{Ra}_{L \text{ or } x} = \mathrm{Gr}_{L \text{ or } x}\,\mathrm{Pr} \tag{6.67}$$

For Ra < 10^9, the flow is laminar, and the heat-transfer coefficient varies with distance. For Ra > 10^9, the flow is turbulent, and the heat-transfer coefficient is independent of position. The corresponding equations are from the *Heat Exchanger Design Handbook* [1], Section 2.5.7, by Churchill and Chu [32]. These are presented as follows.

1. Laminar, constant temperature surface:
   The local heat-transfer coefficient at x is

$$\mathrm{Nu}_x = \frac{h_x x}{k} = 0.68 + 0.503\mathrm{Ra}_x^{1/4} f_1(\mathrm{Pr}) \tag{6.68}$$

where

$$f_1(\mathrm{Pr}) = \left[1 + \left(\frac{0.492}{\mathrm{Pr}}\right)^{9/16}\right]^{-4/9} \tag{6.69}$$

The average coefficient from $x = 0$ to $x = x$ ($x \leq L$) is

$$\overline{\mathrm{Nu}_x} = \frac{\overline{h_x} x}{k} = 0.68 + 0.67\mathrm{Ra}_x^{1/4} f_1(\mathrm{Pr}) \tag{6.70}$$

2. Laminar, constant heat-flux surface:
   The local coefficient at x is

$$\mathrm{Nu}_x = \frac{h_x x}{k} = 0.68 + 0.563R_x^{1/4} f_2(\mathrm{Pr}) \tag{6.71}$$

where

$$f_2(\mathrm{Pr}) = \left[1 + \left(\frac{0.437}{\mathrm{Pr}}\right)^{9/16}\right]^{-4/9} \tag{6.72}$$

The average coefficient from $x = 0$ to $x = x$ ($x \le L$) is

$$\overline{\mathrm{Nu}_x} = 0.67\mathrm{Ra}_x^{1/4} f_2(\mathrm{Pr}) \tag{6.73}$$

where ΔT in Ra_x is based on the wall temperature at $x/2$.

3. Turbulent flow, $\mathrm{Ra}_x > 10^9$:
   The heat-transfer coefficient for a turbulent boundary layer is

$$\overline{\mathrm{Nu}_x} = \frac{\bar{h}_x x}{k} = 0.15\mathrm{Ra}_x^{1/3} f_3(\mathrm{Pr}) \tag{6.74}$$

where

$$f_3(\mathrm{Pr}) = \left[1 + \left(\frac{0.492}{\mathrm{Pr}}\right)\right]^{-16/27}$$

4. Combined laminar and turbulent flow:
   These equations can be combined to give an average coefficient over a vertical length L:

$$\overline{\mathrm{Nu}_L} = 0.68 + 0.67\mathrm{Ra}_L^{1/4}[f_1(\mathrm{Pr})][1 + 1.6\times10^{-8}\mathrm{Ra}_L[f_1(\mathrm{Pr})]^4]^{1/12} \tag{6.75}$$

6.3.5.2 Natural Convection from Horizontal Plates

Heat transfer in this case depends upon the dimensions of the surface and which surface (upper or lower) is heated or cooled. Hewitt et al. [30] recommend the following equations:

1. Upper surface of heated plate or lower surface of cooled plate:

$$\overline{\mathrm{Nu}_L} = \frac{\bar{h}L}{k} = 0.54\mathrm{Ra}_L^{1/4} \quad \text{for } (10^4 \le \mathrm{Ra}_L \le 10^7) \tag{6.76}$$

$$\overline{\mathrm{Nu}_L} = \frac{\bar{h}L}{k} = 0.15\mathrm{Ra}_L^{1/3} \quad \text{for } (10^7 \le \mathrm{Ra}_L \le 10^{11}) \tag{6.77}$$

2. Lower surface of heated plate or upper surface of cooled plate:

$$\overline{\mathrm{Nu}_L} = 0.27\mathrm{Ra}_L^{1/4} \quad \text{for } (10^5 \le \mathrm{Ra}_L \le 10^{10}) \tag{6.78}$$

The characteristic length L used in the Rayleigh and Grashof numbers is defined as

$$L = \frac{A}{P} \tag{6.79}$$

where A is the plate surface area and P is the perimeter.

6.3.5.3 Natural Convection from a Horizontal Cylinder

For a long horizontal cylinder (i.e., negligible end effects), Churchill and Chu [32] recommend

$$\overline{\text{Nu}}_D = \frac{\bar{h}D}{k} = \left\{ 0.60 + \frac{0.387\text{Ra}_D^{1/6}}{\left[1 + \left(\frac{0.559}{\text{Pr}}\right)^{9/16}\right]^{8/27}} \right\}^2 \quad \text{for } (\text{Ra}_D \le 10^{12}) \tag{6.80}$$

The cylinder diameter D is the characteristic length in the Nusselt and Rayleigh numbers, and $\bar{h}$ is the mean heat-transfer coefficient over the entire surface of the cylinder.

6.3.5.4 Natural Convection between Two Horizontal Parallel Plates

For two horizontal parallel plates whose dimensions are large compared with the spacing L between them, and where the bottom plate is hotter than the top plate, Globe and Dropkin [33] recommend

$$\overline{\text{Nu}}_L = \frac{\bar{h}L}{k} = 0.069\text{Ra}_L^{1/3}\text{Pr}^{0.074} \quad \text{for } (3 \times 10^5 < \text{Ra}_L < 7 \times 10^9) \tag{6.81}$$

6.3.5.5 Other Geometries

Correlations for a variety of other geometries are provided in the *Heat Exchanger Design Handbook* [1] and by Gnielinski [29] and DeWitt and Incropera [31].

6.4 CONDENSATION AND VAPORIZATION HEAT TRANSFER

6.4.1 Mechanisms of Condensation

A vapor or vapor/gas mixture will condense to a liquid on any surface that is even slightly below the saturation temperature (or dew point) of the vapor at the existing pressure. This is true even if the vapor is highly superheated or multicomponent. In the latter case, the dew point decreases as condensation proceeds.

There are four mechanisms of condensation: dropwise, filmwise, direct contact, and homogenous. In dropwise condensation, the vapor initially condenses as multitudes of tiny droplets on preferred sites on the surface. The droplets grow rapidly by conduction through the droplet until gravity or vapor shear overcomes surface tension and the droplets run off the surface. As long as the surface remains nonwetting, the cycle is repeated. Dropwise condensation gives heat-transfer coefficients as high as 60,000 W/m^{2}K (10,000 Btu/h·ft^2·°F) for steam. Most surfaces are initially nonwetting, at least for steam, because of residual shop oil or other surface contamination, but become wetting after a short time, typically a few hours. Once the surface is rendered wetting, filmwise condensation dominates, with substantially reduced coefficients. Attempts to maintain a nonwetting surface by introducing promoters such as metallic stearates or by coating the surface with a thin film of Teflon

have proven operationally impractical. However, care must be taken when starting up new equipment with condensing steam as a heating medium because the initial high heat-transfer rate can lead to high surface temperatures and excessive fouling rates on the other stream.

When the condensing surface is completely wetted, the condensate film flows under the influence of gravity and vapor shear, and its heat-transfer characteristics can be reasonably predicted from hydrodynamic principles. This is the usual design mode for condensation and is developed in detail in the next section.

Direct-contact condensation occurs when a subcooled liquid is sprayed into the vapor or allowed to flow down a structural surface in a vapor space. Condensation occurs directly on the surface of the coolant. Heat-transfer rates for this equipment (such as barometric condensers) are strongly dependent upon the sprayer characteristics and/or the particular structured surface, and must be obtained from the vendor.

If a body of vapor can be sufficiently subcooled without contact with a surface (by radiation, for example), theory predicts that a liquid phase can form spontaneously. This process is termed *homogenous condensation*, and fog formation is often cited as an example. However, the subcooling required is so great that it is unlikely to occur in any process situation. Fog formation *does* occur in process condensers, but the probable mechanism is condensation on tiny droplets carried over from a previous processing step (a distillation column, for example, where bubble collapse produces large numbers of submicroscopic droplets).

The present discussion is limited to filmwise condensation on a few common geometries. There are several comprehensive and specialized references that can be consulted: the *Heat Exchanger Design Handbook* [1] covers an especially wide range of theory and application, while Hewitt et al. [30] and Incropera and DeWitt [31] present good summaries. Collier and Thome [34] cover convective condensation processes.

6.4.2 Design Equations for Filmwise Condensation

For condensation of a pure vapor, the basic assumptions are that (a) the latent heat of condensation is released at the interface between the vapor and the liquid condensate film and (b) the interface temperature is equal to the saturation temperature of the vapor at the existing pressure. The heat-transfer rate through the condensate film depends upon the thickness and heat-transfer mechanisms of the film, which in turn depend upon the geometry of the condensing surface and the flow regime of the condensate (laminar or turbulent, gravity driven or vapor-shear driven). The presentation and discussion of the correlations is organized in the following sections according to the basic geometry.

6.4.2.1 Condensation on Vertical-Plane and Tubular Surfaces

6.4.2.1.1 Gravity Driven

In the absence of a strong vapor flow, the condensate film on a vertical surface drains under the influence of gravity only. At low flow rates, the flow is laminar, and a theoretical analysis by Nusselt [35] is applicable. The local value of the coefficient at a distance x from the start of condensation is

$$h_x = \left[\frac{k_\ell^3 \rho_\ell (\rho_\ell - \rho_v) \lambda g}{4 \mu_\ell (T_{sat} - T_w) x} \right]^{1/4} \tag{6.82}$$

where k_ℓ, ρ_ℓ, and μ_ℓ are the thermal conductivity, density, and viscosity of the condensate, respectively; ρ_v is the vapor density; λ is the latent heat of condensation; g is the gravitational acceleration (usually 9.81 m/s^2 or 32.2 ft/s^2); and T_{sat} and T_w are the vapor saturation temperature and wall temperature, respectively.

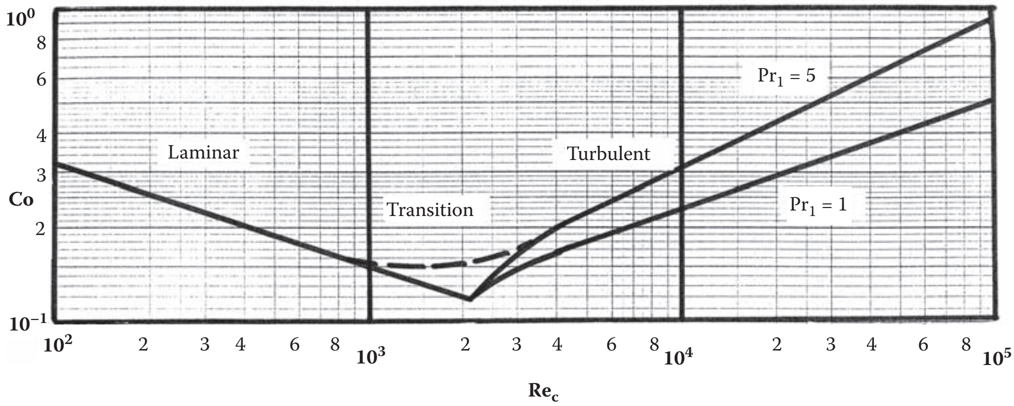

FIGURE 6.22 Condensation number versus Reynolds number for gravity-driven condensation on a vertical surface.

The average coefficient for a condensing surface of length L is obtained by integrating Equation (6.82), assuming an isothermal surface, to obtain

$$h_c = 0.943\left[\frac{k_\ell^3 \rho_\ell(\rho_\ell - \rho_v)\lambda g}{\mu_\ell(T_{sat} - T_w)L}\right]^{1/4} \tag{6.83}$$

It is usually sufficiently accurate to use an average wall temperature and to evaluate the condensate properties at the arithmetic mean film temperature, $1/2(T_{sat} + T_w)$.

These equations are strictly valid only for a plane vertical surface. However, they can be used for inside or outside vertical tubes with small error because the condensate film is thin compared with the diameter of a typical tube. Because of rippling and other nonidealities, the predicted coefficients are about 10–20% below experimental values.

A condensate Reynolds number can be defined as

$$\mathrm{Re}_c = \frac{4\Gamma}{\mu_\ell} \tag{6.84}$$

where Γ is the condensate mass flow rate m_c per unit length of drainage perimeter. For a plane wall, the drainage perimeter is the width of the plane; for a tube, it is the circumference, πD_o or πD_i. At Re_c above about 1000, the condensate becomes turbulent. The transition region shows substantially higher but not very predictable coefficients, compared with the Nusselt solution. The fully turbulent film was analyzed by Colburn [36]. These results are shown in Figure 6.22 in generalized form of the condensation number, Co, defined as

$$Co = h_c\left[\frac{\mu_\ell^2}{k_\ell^3 \rho_\ell(\rho_\ell - \rho_v)g}\right]^{1/3} \tag{6.85}$$

as a function of Re_c.

6.4.2.1.2 Vapor-Shear Driven

If vapor velocities are high enough, the vapor shear on the condensate interface initiates turbulence in the condensate film and causes it to flow off the surface more rapidly. These effects increase the

heat-transfer rate, most strongly when gravity and vapor flow are collinear but even when the forces are opposed. Boyko and Kruzhilin [37] developed an equation for fully developed vapor-shear controlled condensation and validated it experimentally for flow in horizontal tubes. However, it is also applicable to vertical flows:

$$\frac{h_c D_i}{k_\ell} = 0.024\left(\frac{D_i G_T}{\mu_\ell}\right)^{0.8} (\mathrm{Pr}_\ell)^{0.43}\left[\frac{\sqrt{(\rho/\rho_m)_i} + \sqrt{(\rho/\rho_m)_o}}{2}\right] \tag{6.86a}$$

where

$$(\rho/\rho_m)_i = 1 + \left(\frac{\rho_\ell - \rho_v}{\rho_v}\right)x_i \tag{6.86b}$$

and

$$(\rho/\rho_m)_o = 1 + \left(\frac{\rho_\ell - \rho_v}{\rho_v}\right)x_o \tag{6.86c}$$

The term h_c is the effective mean heat-transfer coefficient for condensing a stream from an inlet quality (mass fraction vapor) x_i to an outlet quality x_o. For the usual case of totally condensing a saturated vapor stream ($x_i = 1$; $x_o = 0$), the bracketed term in Equation (6.86a) becomes

$$\left[\frac{1 + \sqrt{\rho_\ell/\rho_v}}{2}\right] \tag{6.86d}$$

G_T is the mass velocity (mass flux) of the entering fluid, defined as the mass flow rate in kg/s (lb_m/h) divided by the cross-sectional area of the tube or the flow channel. The subscript ℓ refers to the physical properties of the condensate and v to the vapor. Equation (6.86a) may be used to calculate the local condensing heat-transfer coefficient at any quality x by replacing the bracketed term by

$$\left[\sqrt{1 + \left(\frac{\rho_\ell - \rho_v}{\rho_v}\right)x}\right] \tag{6.86e}$$

6.4.2.1.3 Selection of a Condensing Correlation

Four possibilities for a condensing film on a vertical surface exist: laminar, transition, turbulent gravity driven, and turbulent vapor-shear driven. How does one select the correct one? Consideration of the problem reveals that the flow situation that most likely exists in a given case is also the one that gives the highest coefficient. Therefore, the recommended procedure is to find the coefficients given, respectively, by Equation (6.82), Figure 6.22, and Equation (6.86a, b, c, d, e), and choose the highest one. Caution, however, should be taken because all of the correlations have uncertainties of at least 10–20%.

Example 6.11

Saturated propane vapor at 55°C (131°F) and 1900 kPa abs (275 $lb_f/in.^2$ abs) is flowing downward at a rate of 25 kg/h (55.1 lb_m/h) through a vertical 1-in. 14 BWG tube (inside diameter of 0.834

in. = 21.2 mm). The inside surface temperature of the tube is 40°C (104°F). How long a tube is required to completely condense the propane vapor?

Solution

Latent heat of condensation of propane at 55°C (131°F): 271 kJ/kg (116.5 Btu/lb_m)
Density of propane vapor at 5°C and 1900 kPa abs: 44.0 kg/m^3 (2.75 lb_m/ft^3)
Physical properties of liquid propane at a film temperature of 47.5°C (117.5°F):
Density: 453 kg/m^3; (28.3 lb_m/ft^3)
Viscosity: 75.6×10^{-6} Pa·s = 75.6×10^{-6} N·s/m²; (0.183 lb_m/ft·h)
Thermal conductivity: 82.3×10^{-3} W/m·K; (0.0476 Btu/h·ft·°F)
Specific heat: 3.07 kJ/(kgK); (= 0.733 Btu/lb_m°F)
Prandtl number:

$$\Pr_\ell = \frac{(3.07\text{ kJ/kg K})(75.6\times10^{-6}\text{ N s/m}^2)}{(82.3\times10^{-3}\text{ W/m K})}\left(\frac{1\text{ W}}{1\text{ J/s}}\right)\left(\frac{10^3\text{ J}}{1\text{ kJ}}\right)\left(\frac{1\text{ kg m/s}^2}{1\text{ N}}\right) = 2.82$$

The mass velocity, G_T, is

$$G_T = \left(25\frac{\text{kg}}{\text{hr}}\right)\Big/\left[\frac{\pi(21.2\times10^{-3}\text{ m})^2}{4}\right]\left(3600\frac{\text{s}}{\text{hr}}\right) = 19.7\text{ kg/m}^2\text{s}\left(=1.45\times10^4\frac{\text{lb}_\text{m}}{\text{ft}^2\text{hr}}\right)$$

$$\Gamma = \frac{(25\text{ kg/hr})}{(3600\text{ s/hr})\pi(21.2\times10^{-3}\text{ m})} = 0.104\text{ kg/ms } (= 252\text{ lb}_\text{m}\text{/ft hr})$$

$$\text{Re}_c = \frac{4(0.104\text{ kg/ms})}{75.6\times10^{-6}\text{Pa s}}\left(\frac{1\text{ Pa s}}{1\text{ kg m s}}\right) = 5{,}500$$

indicating that condensate film is turbulent.

From Figure 6.22, read Co = 0.15. From Equation (6.85),

$$h_c = 0.15\left\{\frac{(82.3\times10^{-3}\text{ W/m K})^3(453\text{ kg/m}^3)[(453-44)\text{kg/m}^3](9.81\text{ m/s}^2)}{(75.6\times10^{-6}\text{ Ns/m}^2)^2}\right\}^{1/3}$$

$$= 4450\text{ W/m}^2\text{ K } (= 784\text{ Btu/h ft}^2)$$

Check the Boyko-Kruzhilin equation: Since the condensation path is from saturated vapor in (x_i = 1.0) to saturated liquid out (x_o = 0), use Equation (6.86d) for the bracketed term in Equation (6.86a):

$$\frac{h_c D_i}{k_\ell} = 0.024\left[\frac{(21.2\times10^{-3}\text{ m})(19.7\text{ kg/m}^2\text{s})}{(75.6\times10^{-6}\text{ N s/m}^2)}\left(\frac{1\text{ N s}^2}{\text{kg m}}\right)\right]^{0.8}(2.82)^{0.43}\left[\frac{1+\sqrt{453/44}}{2}\right] = 77.8$$

$$h_c = 77.8\left[\frac{82.3\times10^{-3}\text{ W/m K}}{21.2\times10^{-3}\text{ m}}\right] = 302\text{ W/m}^2\text{K } (= 53.2\text{ Btu/h·ft}^2\text{·°F})$$

In this case, the condensation process that gives the highest coefficient is gravity-driven, turbulent film, and the proper coefficient to use is h_c = 4,450 W/m²K.

The total heat duty to be removed should include the relatively small contribution of subcooling the condensate from the saturation temperature to the mean film temperature of about 47.5°C:

$$q = (25\text{ kg/hr})\left[(271\text{ kJ/kg}) + \left(3.07\frac{\text{kJ}}{\text{kg K}}\right)(7.5\text{ K})\right]$$

$$= 7.35 \times 10^3\text{ kJ/h} = 2.04\text{ kW } (= 6.97 \times 10^3\text{ Btu/h})$$

The tube inside surface area required is

$$A_i = \frac{\dot{q}}{h_c \Delta T} = \frac{2.04 \times 10^3\text{ W}}{(4,450\text{ W/m}^2\text{ K})(15\text{ K})} = 0.0306\,\text{m}^2 (= 0.328\,\text{ft}^2)$$

and the length L required is

$$L = \frac{0.0306\,\text{m}^2}{\pi(21.2 \times 10^{-3}\text{ m})} = 0.459\,\text{m} (= 1.51\,\text{ft})$$

6.4.2.2 Condensation inside a Horizontal Tube

6.4.2.2.1 Gravity Driven

At low flow rates, a vapor may be condensed inside a horizontal or nearly horizontal tube under the condition that the condensate film drains down the inside surface of the tube by gravity and in laminar flow into the liquid pool at the bottom of the tube and then out the tube outlet. Kern [38] proposed a simple modification of the Nusselt equation for condensation outside horizontal tubes (see next section) that can be used for this case:

$$h_c = 0.761\left[\frac{k_\ell^3 \rho_\ell (\rho_\ell - \rho_v) g L}{m_c \mu_\ell}\right]^{1/3} \tag{6.87}$$

where m_c is the mass flow rate of the condensate formed in the tube.

6.4.2.2.2 Vapor-Shear Driven

At sufficiently high vapor flow rates, vapor shear causes the condensate film to become turbulent and drain from the tube more rapidly. The Boyko-Kruzhilin equation (6.86a, b, c, d, e) was validated by condensing steam data.

6.4.2.2.3 Selection of a Correlation

Similar to the case for vertical tubes, the correlation (either Equation (6.87) or Equation (6.86a, b, c, d, e)) giving the higher coefficient for a given case most likely represents the actual controlling flow situation. There is a transition region between the two correlations, where the actual coefficient may be 20–30% higher than the prediction of either correlation. In designing for condensing inside "horizontal" tubes, it is important to ensure that the tube is actually slightly inclined downward toward the exit; 1/4 to 1/2 in. per foot of length is usually sufficient for good drainage.

6.4.2.3 Condensation outside Horizontal Tubes and Tube Banks

6.4.2.3.1 Single Horizontal Tubes with Gravity-Driven, Laminar Flow

Nusselt's solution for this case [35] is

$$h_c = 0.725\left[\frac{k_\ell^3\rho_\ell(\rho_\ell - \rho_v)\lambda g}{\mu_\ell(T_{sat} - T_w)D}\right]^{1/4} \tag{6.88}$$

which may be put in the equivalent forms

$$h_c = 0.952\left[\frac{k_\ell^3\rho_\ell(\rho_\ell - \rho_v)gL}{m_c\mu_\ell}\right]^{1/3} \tag{6.89}$$

where m_c is the mass flow rate of the condensate, and

$$h_c = 1.51\left[\frac{k_\ell^3\rho_\ell(\rho_\ell - \rho_v)g}{\mu_\ell^2}\right]^{1/3}\mathrm{Re}_c^{-1/3} \tag{6.90a}$$

where

$$\mathrm{Re}_c = \frac{4m_c}{\mu_\ell L} \tag{6.90b}$$

and L is the length of the tube.

6.4.2.3.2 Multiple Horizontal Tubes in a Vertical Row

Nusselt [35] also analyzed this problem, assuming that the condensate drained from an upper tube at bottom dead center as a continuous sheet, falling on the next lower tube and flowing down and around that tube in undisturbed laminar flow. Under these highly idealized conditions, the average coefficient for a row of tubes N tubes high is

$$h_{c,N} = h_{c,1}\,N^{-1/4} \tag{6.91}$$

Because of the flow disturbances implicit in the actual drainage of the condensate, this equation is too conservative, and an alternative procedure is described in Section 6.4.2.3.4 below.

6.4.2.3.3 Effect of High Cross-Flow Vapor Velocity

A high vapor velocity, in cross flow on a cylinder, causes rippling and turbulence in the condensate and results in an increase (compared with Equation (6.89)) in the heat-transfer coefficient beginning at vapor Reynolds numbers (based on maximum vapor velocity flowing around the tube and the tube diameter) above 20,000, rising to as much as a 10-fold increase at Reynolds numbers about 100,000 [39]. Such high velocities are usually unacceptable because of high pressure drop, vibration, and erosion.

6.4.2.3.4 Estimation of Heat Transfer for Flow across a Tube Bundle

Because of the opposing effects (which are individually poorly understood) of the phenomena described in the previous two sections, any calculation of condensing heat-transfer coefficient on

a bundle of horizontal tubes (as in a shell-and-tube heat exchanger) is uncertain. An acceptable procedure for most purposes is to ignore both the row-number effect and the vapor-shear enhancement and use the single-horizontal-tube equations (6.88), (6.89), (6.90a), and (6.90b) for the entire tube bundle.

6.4.3 Special Cases in Condensation

6.4.3.1. Enhanced Surfaces in Condensation

Enhanced surfaces can often significantly increase the effective heat-transfer coefficient in condensation, especially if the condensing heat-transfer coefficient is the limiting factor in the overall heat-transfer-coefficient equation. Such enhancements include low fins on horizontal tubes, which increase the heat-transfer area, and fluting on vertical tubes and plane surfaces, which thins the condensate film over part of the surface by surface-tension effects. However, these improvements are limited by condensate retention between the fins and flooding of the drainage paths [7, 34].

6.4.3.2 Condensation in the Presence of a Noncondensable Gas

Condensing vapors often contain a gas that is noncondensable and effectively insoluble in the condensate, such as a small concentration of air in steam. The condensation process may be little affected by the presence of noncondensables at the start of condensation. As the condensation proceeds, the concentration of the noncondensable increases, the dew point decreases (decreasing the temperature difference for heat transfer), and the mass-transfer resistance to the vapor diffusing to the condensing surface increases and may eventually control the rate of condensation. This process was first seriously studied by Colburn and Hougen [40] and more recently by Mueller [41]. A fundamentally sound design procedure requires commercially available computer-based design methods, but a reasonable estimate can be made using the method described next.

6.4.3.3 Condensation of a Multicomponent Vapor

Condensation of a multicomponent vapor, often including noncondensable gases, is a common design problem in the process industries and in energy-producing cycles and air-conditioning and refrigeration systems using mixed working fluids or refrigerants. As the less-volatile components preferentially condense, the dew point continuously falls, and the rate of condensation is controlled by the diffusion and counterdiffusion of the various components to and away from the condensing surface. It is usually assumed that the remaining vapor and the condensate are in thermodynamic equilibrium at every point in the process, but this is only approximately true, even if care is taken to keep the total vapor and condensate streams in intimate contact throughout the condenser. If the condensate is allowed to fall out of contact with the remaining vapor, the condenser acts as a poor fractionator, and the condensing capability is sharply reduced.

The basic fluid dynamics and heat- and mass-transfer processes for multicomponent condensation are poorly understood, and the computation is difficult; available design methods are both heuristic and feasible only for computer solution. The basic model was developed by Silver [42] and put in more general form by Bell and Ghaly [43]. Computer-based design methods that have been validated against experimental data are commercially available.

6.4.3.4 Condensation of Superheated Vapor

A superheated vapor may be condensed directly from the vapor state by contact with a surface that is below the saturation temperature or the dew point of the vapor. The heat-transfer coefficient is predicted by the equations in this section if the saturation temperature (*not* the superheat temperature) is used as the effective temperature for heat transfer, i.e., a desuperheater/condenser may be

designed as if all of the heat load (including the sensible heat for desuperheating the vapor to the saturation temperature) were transferred at the same rate as for the saturated vapor as long as the condenser surface temperature and the coolant temperature are below the saturation temperature.

A further consequence is that the superheated vapor will fail to directly condense *only* if the surface temperature is above the saturation temperature, and this will only occur if the local heat flux is *higher* than would be obtained if the vapor were condensing on the surface. Note that this implies, first, that a desuperheater is not necessary to desuperheat a vapor if the only concern is that the heat-transfer rate of a superheated vapor is too low, and second, that care must be taken with superheated vapors such that the local heat-transfer rate and surface temperature are not too high for the coolant stream, causing excessive fouling or film boiling (see next section on vaporization).

6.4.4 Mechanisms of Vaporization

Vaporization processes may be divided into "pool boiling," in which the hot surface is immersed in a pool of liquid and the vapor bubbles may flow freely away from the hot surface, driven by the difference in phase densities, and "convective vaporization," where the liquid and vapor flow together along or away from the hot surface, driven either by natural convection of the two-phase mixture (termed *thermosiphon action*) or by an externally forced convection (e.g., by a circulating pump).

Pool boiling may be further divided into several processes, dependent primarily upon the temperature difference between the hot surface temperature and the saturation temperature (boiling temperature) of the liquid. Typical behavior for a light hydrocarbon at its saturation temperature boiling off of a typical metal tube surface is shown in Figure 6.23, in which the heat flux to the liquid is plotted against the temperature difference between the hot surface, T_w, and the saturation temperature, T_{sat}.

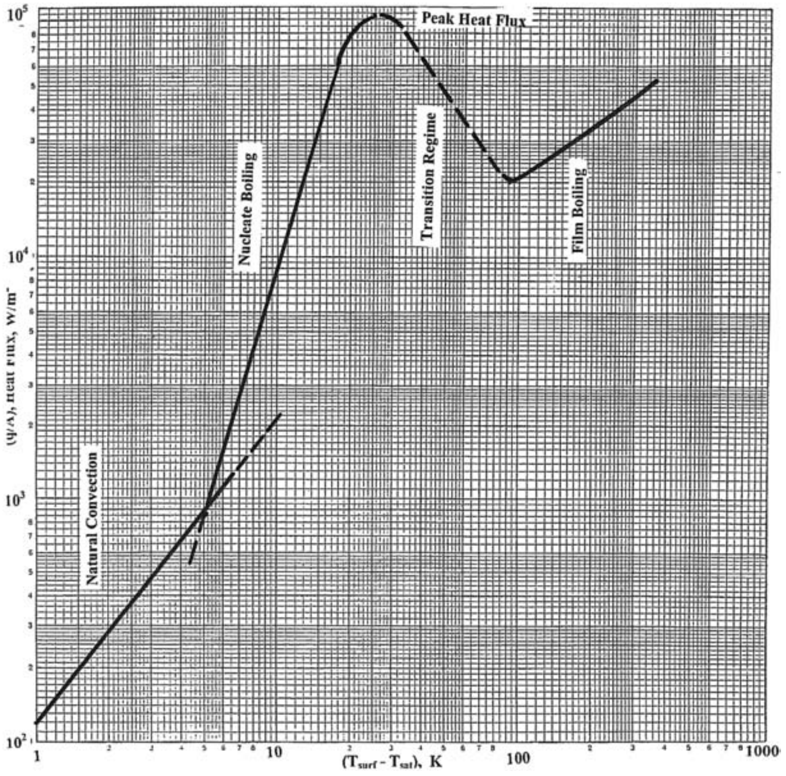

FIGURE 6.23 Pool boiling curve for a light hydrocarbon at atmospheric pressure.

At temperature differences below about 3–5°K (5–9°F), the heat transfer is by natural convection to the liquid; the slightly superheated liquid rises quiescently to the free-liquid surface and vaporizes with no obvious evidence of boiling action. At temperature differences above about 5°K (9°F), vapor bubbles begin to form at specific nucleation sites on the surface, grow, detach, and rise to the free surface, while the process repeats itself regularly. Nucleation sites are usually microscopic pits, scratches, grain boundaries, or other surface irregularities where gas or vapor is trapped to initiate the bubble growth. The smoother the surface, the greater is the superheat required to initiate nucleation and nucleate boiling. Surfaces such as glass may be so devoid of nucleation sites that the liquid may be highly superheated before a random piece of dust sets off a sudden nucleation, desuperheating, and burst of vapor generation. Rough surfaces may nucleate at very small superheats.

Once stable nucleate boiling is established, the heat flux and vapor generation rate are strong functions of the temperature difference. As the surface temperature increases, more nucleation sites are activated, and the bubble generation rate increases at already active sites. Each surface has its own characteristics, and those can change with time as a result of corrosion, fouling, mechanical damage, or even how the equipment was shut down. Consequently, any estimate of nucleate boiling heat-transfer coefficients is approximate.

However, there is an upper limit on the heat flux that can be sustained in nucleate boiling. As the heat flux, and therefore the vapor generation, rises, it is increasingly difficult for sufficient liquid to reach the surface to maintain the vapor generation. At the peak nucleate boiling heat flux, the liquid reaching the surface is equal to the vapor generation rate. This condition, termed the "peak" or "critical" heat flux, can be estimated using equations given in the next section.

If the peak heat flux is exceeded even momentarily and/or locally, a portion of the surface dries out and usually further heats up, and becomes essentially useless for heat transfer. The dry-out process will usually spread over more surface and result in a pronounced decrease in the heat-transfer rate. This is termed the *transition boiling regime*, and extended operation in this regime may result in rapidly increasing fouling and loss of heat-transfer capability, until the next cleaning. Once the transition boiling regime has been entered, only a sharp reduction in the surface temperature, or even complete shutdown, can restore the nucleate boiling regime. If the heat source is hot enough, the surface temperature rises until the surface is covered by a continuous film of vapor and the heat-transfer rate reaches a minimum. This condition is termed the *Leidenfrost point* and marks the beginning of the "film boiling regime."

In film boiling, all heat is transferred by conduction/convection through the vapor and by radiation from the hot surface to the liquid interface. Further increases in surface temperature result in a slow increase in the heat transfer. However, heat transfer in film boiling is poor and may result in severe fouling and even thermal decomposition of the boiling fluid. If the heat source is a constant-flux device, such as an electrical resistance heater, the surface temperature may rise to the melting point and the equipment may be permanently damaged. Film boiling should be avoided. When starting up boiling equipment, it is important to introduce the cold liquid first to prevent initial overheating of the surface into the film boiling regime.

In convective vaporization, the same boiling regimes are encountered, but modified by the net motion of the two-phase fluid past the surface. At low velocities or high heat fluxes, the convection effect is small, and nucleate boiling dominates. At higher velocities, the heat-transfer rate is dominated by the two-phase mixture sweeping across the surface. It is still important to avoid transition and film boiling, but the onset of these phenomena is complicated by many factors. (See [1, 34].)

6.4.5 Boiling Heat-Transfer Correlations

6.4.5.1 Nucleate Boiling

Prediction of nucleate-boiling heat transfer is complicated by the strong dependence of bubble nucleation on boiling surface characteristics that are hard to quantify or even identify and measure.

Of the many correlations in the literature, none give consistently accurate predictions. As good as any, and simpler than most, is the Mostinski [44] equation, which is dimensional and must be used with the units specified:

$$h = 0.1011 p_{cr}^{0.69} (q/A)^{0.7} [1.8 p_R^{0.17} + 4 p_R^{1.2} + 10 p_R^{10}] \tag{6.92a}$$

where h is the nucleate-boiling heat-transfer coefficient in W/m^{2}K, p_{cr} is the critical pressure of the boiling fluid in bar abs, (q/A) is the boiling heat flux in W/m^2, and p_R is the reduced pressure, the pressure of the boiling process divided by the critical pressure of the boiling liquid (p_R is dimensionless).

In U.S. customary units, the Mostinski equation is

$$h = 0.00658 p_{cr}^{0.69} (q/A)^{0.7} [1.8 p_R^{0.17} + 4 p_R^{1.2} + 10 p_R^{10}] \tag{6.92b}$$

Here, h is in Btu/h·ft^2·°F, p_{cr} is in lb$_f$/in.^{2} abs, and (q/A) is in Btu/h·ft^2. In both of these equations,

$$(q/A) = h(T_{surf} - T_{sat}) \tag{6.93}$$

6.4.5.2 Critical Heat Flux in Pool Boiling

The critical heat flux in pool boiling can be predicted reasonably closely by an equation developed by Zuber et al. [45] and Lienhard and Dhir [46], as reported by Hewitt et al. [30].

$$(q/A)_{crit} = 0.149 i_{fg} \rho_v^{1/2} [\sigma g (\rho_\ell - \rho_v)]^{1/4} \tag{6.94}$$

where i_{fg} is the latent heat of vaporization; ρ_ℓ and ρ_v are the densities of the liquid and vapor phases, respectively; σ is the surface tension; and g is the gravitational acceleration. In using U.S. customary units, it is necessary to include $g_c = 4.17 \times 10^8$ lb$_m$ft/lb$_f$ h^2 in the bracketed term to get the correct dimensions. Equation (6.94) is valid within about ±15% for most pool boiling geometries (flat plate, cylinder, etc.), but a more complete and accurate table of correction factors is given by Collier and Thome [34].

6.4.5.3 Natural and Forced Convection Vaporization

The present best correlation for convective vaporization upwards in a vertical tube (the usual case) is by Steiner and Taborek (47), also described in detail by Collier and Thome [34]. It combines the nucleate-boiling and convective contributions in a continuous function that satisfies the asymptotic conditions at both pool boiling and full convective flow-dominated extremes. The complete method is too extensive to include here, but the following equations are valid for most boiling cases of interest.

The heat-transfer coefficient for the combined nucleate-boiling and convective vaporization processes, h_{TP}, is related to the nucleate-boiling coefficient h_{NB}, and the convective coefficient, h_c, by

$$h_{TP} = [(h_{NB})^3 + (h_c)^3]^{1/3} = \frac{(q/A)}{T_{surf} - T_{sat}} \tag{6.95a}$$

Either the nucleate-boiling correlation given by Equations (6.92a) and (6.92b) or the extended methods given in the literature [34, 47] can be used for h_{NB}. The two-phase convective coefficient h_c is related to the single-phase liquid coefficient $h_{\ell 0}$ by

$$h_c = h_{\ell 0} F_{TP} \tag{6.95b}$$

where $h_{\ell o}$ is calculated from Equations (6.41) and (6.42), treating the entire mass flow rate as liquid. The two-phase flow correction factor F_{TP} is given by

$$F_{TP} = [(1-x)^{1.5} + 1.9x^{0.6}(\rho_\ell / \rho_v)^{0.35}]^{1.1} \tag{6.95c}$$

Example 6.12

A two-phase mixture of steam and water is flowing upward in a 1-in. OD (25.4 mm) 14 BWG tube (ID = 0.834 in. [21.2 mm]) at 185°C (366°F) and 11.225 bar abs (165 psig). The total mass flow rate is 0.284 kg/s (0.626 lb_m/s). The local quality (mass fraction vapor) is 0.05, and the local heat flux is 250 kW/m^2 (79,250 Btu/h·ft^2). Calculate the local heat-transfer coefficient and the local inside tube wall temperature.

Solution

The thermophysical properties required are

Liquid density, ρ_ℓ: 881.67 kg/m^3 (54.99 lb_m/ft^3)
Vapor density, ρ_v: 5.745 kg/m^3 (0.3634 lb_m/ft^3)
Liquid viscosity, μ_ℓ: 145.2 × 10^{-6} kg/m·s (0.351 lb_m/ft·h)
Liquid thermal conductivity, k_ℓ: 671.1 × 10^{-3} (0.388 Btu/h·ft·°F)
Liquid Prandtl number, Pr_ℓ: 0.957
Critical pressure, p_{crit}: 220.55 bar abs (3206 lb_f/in.^{2} abs)
Reduced pressure, p_R: 11.225 bar/220.55 bar = 0.0509

First, evaluate h_{TP} from Equation (6.95a), utilizing Equation (6.92a) to calculate h_{NB}, and using Equations (6.41), (6.42), (6.95c), and (6.95b) to calculate h_o, F_{TP}, and h_c, respectively.

Calculation of h_{NB}:

$$h_{NB} = 0.1011(220.55)^{0.69}(250{,}000)^{0.7} \times [1.8(0.0509)^{0.17} + 4(0.0509)^{1.2} + 10(0.0509)^{10}]$$
$$= 30{,}100\ \text{W/m}^2\ \text{K} \ (= 5300\ \text{Btu/hr ft}^2\,°\text{F})$$

(Note: This is a dimensional equation, so the units are not "calculable" in the usual sense.)

Calculation of h_o:

$$\text{Re} = \frac{D_i \rho_\ell v_{\ell 0}}{\mu_\ell}$$

$$v_{\ell o} = \frac{0.284\ \text{kg/s}}{\left(881.67 \dfrac{\text{kg}}{\text{m}^3}\right)\dfrac{\pi}{4}(21.2 \times 10^{-3}\ \text{m})^2} = 0.913\ \text{m/s} \ (= 2.99\ \text{ft/s})$$

$$\text{Re} = \frac{(21.2 \times 10^{-3}\ \text{m})(881.67\ \text{kg/m}^3)(0.913\ \text{m/s})}{(145.2 \times 10^{-6}\ \text{kg/m s})} = 118{,}000$$

$$f_F = (3.64\log_{10}118,000 - 3.28)^{-2} = 0.00434$$

$$\frac{h_{\ell 0}D_i}{k_\ell} = \frac{\left(\dfrac{0.00434}{2}\right)(118,000)(0.957)}{1.07 + 12.7\left(\dfrac{0.00434}{2}\right)^{1/2}[(0.957)^{2/3} - 1]} = 233$$

$$h_{\ell o} = 233\frac{(671.1\times 10^{-3})}{(21.2\times 10^{-3})} = 7,390\frac{\text{W}}{\text{m}^2\ \text{K}}\left(= 1300\frac{\text{Btu}}{\text{hr ft}^2\text{°F}}\right)$$

Calculation of F_{TP}:

$$F_{TP} = \left[(1-0.05)^{1.5} + 1.9(0.05)^{0.6}\left(\frac{881.67}{5.745}\right)^{0.35}\right]^{1.1} = 3.05$$

$$h_c = 7,390(3.05) = 22,500\frac{\text{W}}{\text{m}^2\ \text{K}}\left(= 3960\frac{\text{Btu}}{\text{hr ft}^2\text{°F}}\right)$$

Calculation of h_{TP}:

$$h_{TP} = [(30,100)^3 + (22,500)^3]^{1/3}$$

$$h_{TP} = 33,800\ \text{W/m}^2\ \text{K}\ (= 5950\ \text{Btu/hr ft}^2\ \text{°F})$$

Calculation of $T = T_{wall} - T_{sat}$:

$$\Delta T = \frac{q/A}{h_{TP}} = \frac{250,000\ \text{W/m}^2}{33,800\ \text{W/m}^2\ \text{K}}$$

$$\Delta T = 7.40\text{°C}\ (= 13.3\text{°F})$$

6.4.6 Special Cases in Vaporization

6.4.6.1 Boiling outside Tube Bundles

Kettle reboilers generate vapor for process purposes by boiling the liquid outside a bundle of horizontal tubes. This process was historically considered to be an example of pool boiling, with the coefficient calculated by a typical nucleate boiling correlation and a maximum heat flux either fixed by experience [48] or by some modification of Equation (6.94) reflecting the size of the tube bundle [49, 50].

Recent studies have demonstrated that the boiling process is actually a convective one, with the vapor generated on the lower tubes creating a rising and growing two-phase flow across the upper tubes. The vapor and liquid separate at the top of the bundle and the clear liquid flows downward around the sides of the bundle to complete the circuit. Computer-based design methods employ this model, and the existing database is discussed by Collier and Thome [34].

6.4.6.2 Enhanced Surfaces in Boiling

A variety of enhancements to the boiling process are commercially available. Low-finned tubes are commonly used with many organic liquids (which tend to give low boiling coefficients) to increase the heat-transfer area available. Other surfaces are designed to increase the availability of nucleation sites or increase the circulation rate of the boiling liquid past the heat-transfer surface by natural convection. These surfaces are particularly effective in initiating and improving the boiling performance at very low temperature differences. However, they generally do little or nothing to increase the critical heat flux. Manufacturers' data and recommended design practices are necessary to fully utilize the advantages of these special surfaces.

6.4.6.3 Subcooled Boiling

Boiling also will occur with a liquid that is below its saturation temperature if the hot surface temperature is sufficiently above the nucleation temperature for the surface. The bubbles thus formed collapse quickly when they move from the surface into the bulk subcooled liquid, resulting in high heat-transfer rates. Moderate subcooling at the entrance to a vaporizer can be assumed to be heated by heat transfer at the same rates as for the saturated boiling process, if the saturation temperature of the fluid at the existing pressure is used in the temperature difference.

6.5 HEAT EXCHANGERS

6.5.1 Introduction

Heat exchangers vary in heat-transfer surface area from less than 1 m^2 (10 ft^2) to over 10,000 m^2 (100,000 ft^2), in service temperatures from near absolute zero to over 1400°C (2500°F), and in pressures from near full vacuum to over 600 bar (atmospheres). The smaller ones used for routine duties like jacket water and lube oil cooling can often be ordered quickly from standardized designs or assembled from off-the-shelf components. The larger exchangers and those used for process stream heating, cooling, or phase change are usually custom-designed, implying among other things specialized design and fabrication personnel and facilities, and longer delivery times. Those intended for extreme conditions are always custom designs.

This section describes the major types of heat exchangers used in the process industries, their major construction features and options, and their most common applications. Next is a subsection devoted to the basic equations of heat-exchanger design, including the concept of an overall heat-transfer coefficient, the basic design equation (used mainly in computer-based design methods), and the mean temperature difference formulation (used primarily with hand-based design methods). The next subsection describes the basic logic of heat-exchanger design methods, whether by hand or by computer. The last subsection introduces fouling mechanisms and techniques for amelioration.

The *Heat Exchanger Design Handbook* [1] is the most comprehensive reference, but Shah and Sekulic [51] and Kakac and Liu [52] are more handy and cover most areas. Hewitt et al. [30] includes much information on heat exchangers. Qualitative factors in design and application are discussed by Bell [53]. Other, more specialized references are given with the descriptions of the various types.

Most heat exchangers for the process industries are designed by computer programs. There are commercially available design programs for most common heat-exchanger types. Many manufacturers employ their own programs. Many have proprietary programs for their equipment, which vary in accuracy and reliability. All design programs are to some degree heuristic in that they incorporate correlations that have not been tested over the full range of possible process variables. All make assumptions (such as the uniformity of flow distribution among a multitude of parallel tubes, for example) that are not exactly achievable and may be seriously compromised in some situations. The input data are always to some degree uncertain, especially

when multicomponent systems are involved. Operational parameters vary under normal conditions and may change significantly with long-term process changes or during startup, shut down, or emergency operations. It is highly recommended that every heat-exchanger design be reviewed by someone knowledgeable in both the equipment and the process application before being accepted.

6.5.2 Types of Heat Exchangers and Their Selection

6.5.2.1 Criteria for Heat-Exchanger Selection

Different heat-exchanger types may be feasible for any given service. The criteria for selecting the best exchanger for a given application are listed below in the usual order of importance:

1. The heat exchanger must perform the required thermal changes on the process streams within the allowed pressure drops.
2. The heat exchanger must withstand service conditions. There are mechanical stresses imposed by the exchanger's weight and those externally imposed by piping stresses, wind and seismic loading, and mechanical handling during initial installation, normal operation, and turnaround. The temperature differences within the exchanger create thermal stresses, which are dealt with by various design features. The heat exchanger must withstand corrosive attack, primarily handled by selection of the materials of construction. Erosion and vibration are controlled by limiting velocities, especially in certain critical areas near the nozzles and wherever the flow changes directions in the heat exchanger. The heat exchanger must also be designed either to minimize the buildup of fouling or to withstand the mechanical effects of fouling as it develops.
3. The heat exchanger must allow mechanical and chemical cleaning of any portions of heat-transfer surface or other vital components that become fouled, and it must allow replacement of the tubes, gaskets, and other short-lived components during the normal lifetime of the exchanger. Maintenance should require minimum downtime, handling difficulties, and labor cost.
4. The heat exchanger must provide operational flexibility, permitting operation over the probable range of conditions without instability, excessive fouling, vibration problems, or freeze-up that might damage the exchanger itself. Changes in process conditions (e.g., change in feed-stream composition, turndown) and in environmental conditions (e.g., daily and seasonal changes in atmospheric temperature) must be considered.
5. Cost is always an important factor. Cost considerations include first cost and installation as well as the cost of lost production. The latter cost (while the heat exchanger is out of service or overloaded) often is a critical criterion in determining the acceptability of a heat exchanger.
6. Other criteria include maximum weight, length, or diameter limitations as well as the use of standard tube sizes or other replaceable components that are carried in inventory.
7. The experience (good or bad) of operating and maintenance personnel with existing heat exchangers should be considered.

6.5.2.2 Double-Pipe Heat Exchangers

A typical double-pipe heat exchanger is illustrated in Figure 6.24. It consists of an inner pipe or tube within a larger diameter outer pipe, with one fluid flowing through the inner pipe and another flowing through the annular space between the inner and outer pipes. The inner pipe may have external or internal longitudinal fins (or both, or other internal enhancement) to change the heat-transfer area ratio. (See Section 6.5.3 for the rationale for the use of finning.) Multiple units may be connected in series to provide the required heat-transfer area. Parallel exchangers may be

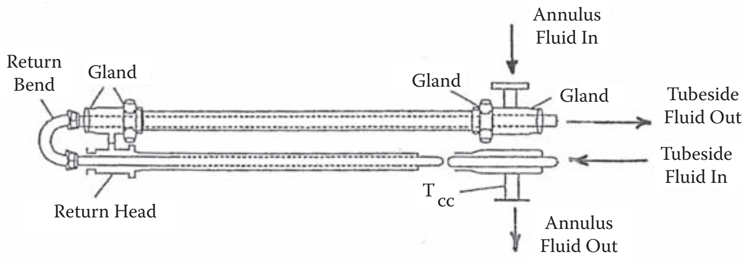

FIGURE 6.24 Basic double-pipe heat exchanger, with arrows showing countercurrent flow.

provided to meet pressure-drop limits. Pure countercurrent, pure cocurrent, and various series- or parallel-flow arrangements may be used.

Double-pipe exchangers are comparatively bulky, heavy, and expensive per unit heat-transfer area and hence are usually limited to units of less than 50 m^2 (500 ft^2), though there is no absolute limit. The advantages of the double-pipe exchanger lie in the flexibility of application and piping arrangement. They can be quickly assembled by plant maintenance crews and are usually cleanable on either side. Uniform and stable flow distribution in each channel of a double-pipe heat exchanger is assured by providing a pump for each parallel section; this can be of particular importance in cooling viscous liquids.

6.5.2.3 Shell-and-Tube Heat Exchangers

Shell-and-tube heat exchangers are the workhorses of the process industries and other applications. The basic configuration, flow across/along a bank of cylindrical tubes, is mechanically strong, provides high heat-transfer surface per unit volume, and allows the use of a variety of special design features to meet many unusual and extreme conditions of chemical processing. The cost per unit area is relatively low, especially in low-carbon steel. The major disadvantage is that they are inflexible once they are constructed, and an exchanger that does not perform satisfactorily in service is usually difficult to modify. Sometimes, performance can be upgraded by replacing the tubes with externally or internally enhanced tubes (e.g., low-finned tubes, twisted wire or tape inserts, etc.).

Most shell-and-tube exchangers are built to the standards of the Tubular Exchanger Manufacturers Association—TEMA Standards [54]—which cover nomenclature, manufacturing standards, recommended good practices, and much else, but do not include thermal design methods. These exchangers generally must conform to the ASME Boiler and Pressure Vessel Code [55] or comparable standards in other countries. Most refinery and chemical process exchangers also satisfy API Standard 660 [56], and power plant exchangers are covered under the various standards of the Heat Exchange Institute [57]. Singh and Soler [58] present mechanical design procedures, and Yokell [59] gives a comprehensive survey of exchanger nomenclature, components, manufacturing techniques, inspection procedures, and maintenance.

The TEMA standards identify three classes of exchanger construction: Class R covers exchangers for the generally severe requirements of the refinery and related processing industries. Class C meets the moderate requirements of commercial and general process applications. Class B meets the special requirements of chemical process service, mainly addressed to the use of special alloys for corrosion resistance. There is relatively little difference between the requirements, and most process-plant exchangers are built to Class R standards.

Figure 6.25 is a schematic diagram of a typical shell-and-tube heat exchanger. The tubes are the basic component of the shell-and-tube exchanger, providing the heat-transfer surface between one fluid flowing inside the tubes and another fluid flowing across the outside of the tubes. The tubes are generally drawn or extruded seamless metal, or welded. Low-carbon or alloy steel, stainless steel, copper, Admiralty, cupronickel, Inconel, aluminum, or titanium tubes are common; other materials may be specified for special applications.

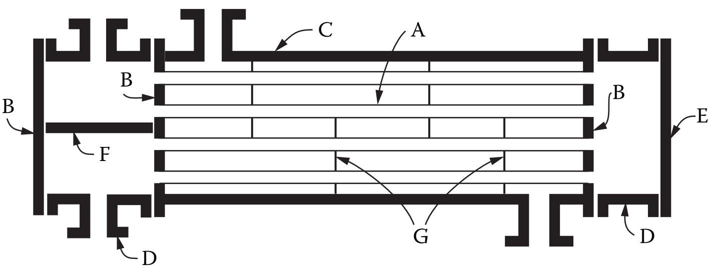

FIGURE 6.25 Diagram of a typical fixed tubesheet heat exchanger, TEMA AEL, with two tube-side passes. (A: tubes, B: tubesheets, C: shell, D: tube-side channels and nozzles, E: channel covers, F: pass dividers, G: baffles)

The tubes may be either bare or with low fins on the outside. Low-fin tubes are used when the fluid on the outside of the tubes (the "shell-side" fluid) has a substantially lower heat-transfer coefficient than the fluid on the inside of the tubes (the "tube-side" fluid). A low-fin surface provides 2 1/2 to 5 times as much heat-transfer area on the outside as the corresponding bare tube, and this area ratio helps to offset the lower heat-transfer coefficient. If low-fin tubes are used, it is necessary to calculate the efficiency by the methods given in Section 6.2.4 of this chapter. Other tube enhancements are available; the thermal/hydraulic characteristics of these devices generally need to be provided by the manufacturer.

The tubes are inserted into drilled holes in the tube sheets ("B" in Figure 6.25) and held in place either by roller expansion into two circumferential grooves cut into each tubesheet hole, or by welding to the tubesheet, or both. A properly expanded tube-to-tubesheet joint is very strong, but may eventually leak; in this case, a seal weld may also be used.

The shell ("C" in Figure 6.25) confines and guides the shell-side fluid through the exchanger. TEMA gives a standard nomenclature to designate the shell configuration and the associated tube-side channels and nozzles, shown here as Figure 6.26. The basic configuration of a shell-and-tube exchanger can be quickly conveyed by three letters chosen from Figure 6.26: The first letter, chosen from the first column, identifies the front head (tube-side inlet); the second letter, from the second column, identifies the shell type (especially the shell-side nozzle positions); the third letter identifies the rear head type. Thus, the exchanger in Figure 6.25 is AEL.

The E shell is the most common configuration; the shell-side fluid enters at one end of the shell and exits at the other. The nozzles may be on opposite sides of the shell (as shown) or on the same side, as piping convenience may dictate. The shell may be horizontal or vertical—especially for condensing (flow downward) or vaporizing (flow upward).

The F shell has a longitudinal baffle on the shell side, which allows for two shell-side passes and countercurrent flow if there are also two tube-side passes. (The advantages and disadvantages of multipass flow are discussed below.) However, it is important to the thermal performance that there be no physical leakage around the side edges of the longitudinal baffle. This can be achieved by welding the longitudinal baffle to the front tubesheet and the shell; in small-diameter shells, this is achieved by cutting the shell in half longitudinally and welding it with the longitudinal baffle between the two halves. Various baffle-sealing devices are also used. Heat transfer also occurs across the baffle by conduction, reducing the efficiency of the exchanger. The effect can be minimized by using a "sandwich" baffle with a layer of insulation. Rozenmann and Taborek [60] discuss the thermal effects of longitudinal baffle leakage. The F shell is almost exclusively used for single-phase flow in the shell.

G and H shells are used primarily for vaporizing the shell-side fluid, especially as horizontal thermosiphon reboilers. Partial longitudinal baffles force the entering liquid to flow across the entire length of the tubes and minimize the possibility of dry-out or stagnant vapor pockets. Leakage

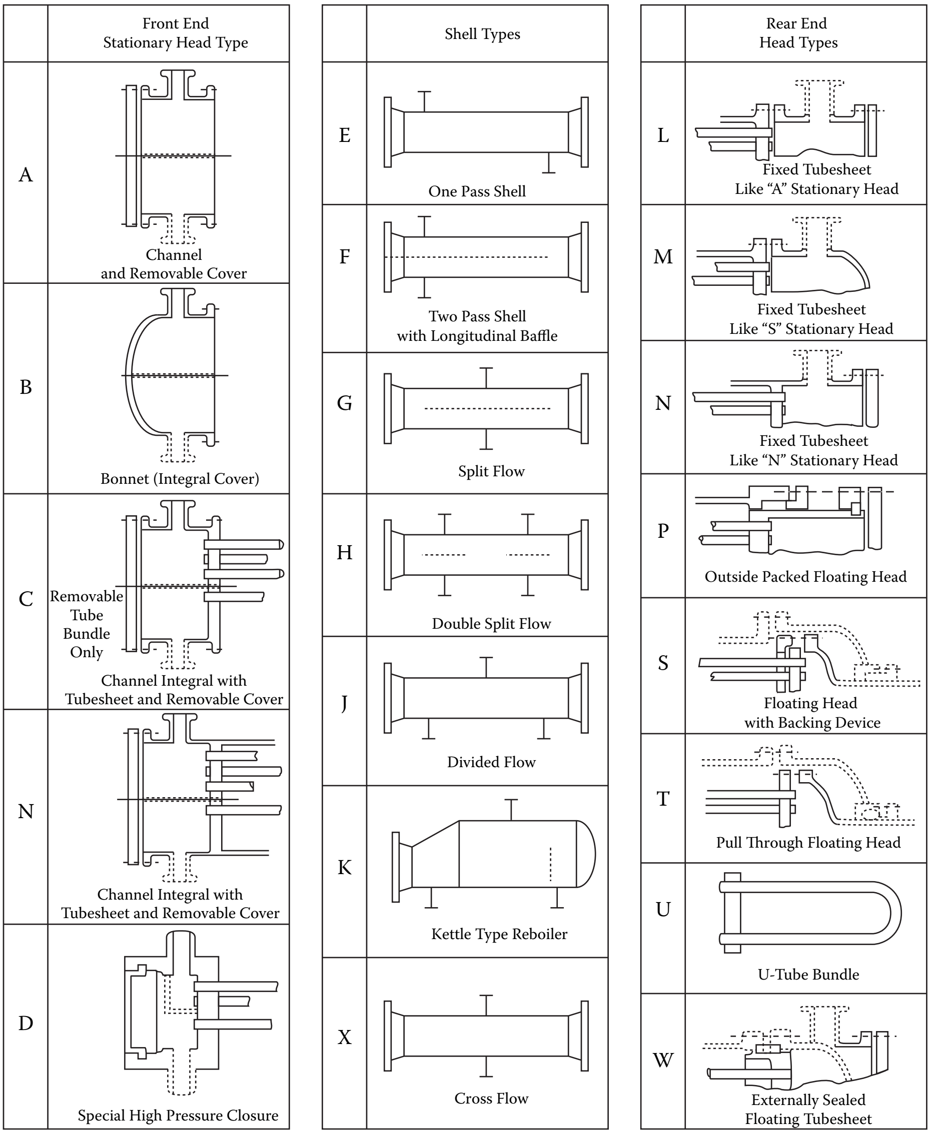

FIGURE 6.26 TEMA shell-and-tube heat exchanger nomenclature. (Reprinted with permission from *Standards of Tubular Exchanger Manufacturers Association*, 9th ed., Tarrytown, NY (2007).)

across the longitudinal baffles is less serious in this case than for the F shell; the baffles should fit closely in the shell and be secured against vibration, but need not be welded to the shell.

The J shell is mainly used for condensation of low-pressure vapor because it splits the flow, reducing velocities and resulting in lower pressure drops. It is also sometimes used for single-phase flow. The J shell can also be used with the two nozzles on top, and two J shells can be mounted nozzle to nozzle in series for long-condensing-range vapors.

The K shell is used for boiling on the shell side ("kettle reboiler") with steam or hot fluid inside a bundle of U-tubes; less commonly, a floating head may be used with straight tubes. The large-diameter shell allows for disengagement of most of the entrained liquid from the vapor; further drying of the vapor can be achieved with mesh demister pads or centrifugal vane separators at the outlet shell-side nozzle. The liquid level is ordinarily maintained at the top of the tube bundle by a weir (as shown in the drawing) or an external liquid-level control device.

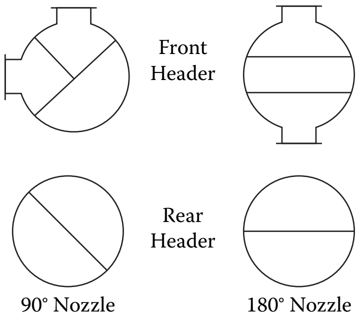

FIGURE 6.27 Possible nozzle and pass-partition plate configuration for four tube-side passes.

The X (or cross flow) shell gives the lowest pressure drop of all the configurations and hence is commonly used as a vacuum condenser. It is essential to secure good vapor distribution across the length of the shell. This can be accomplished in three ways: (a) multiple inlet nozzles from a separate manifold, (b) omitting several rows of tubes and cutting down the support baffles at the top of the tube field, or (c) attaching a large elongated nozzle ("bathtub nozzle") to the top of the shell.

The front-end (stationary head) types are identified by the first letter in the TEMA shorthand nomenclature. The A type is a flanged channel that bolts to the shell flange on one side and has a flanged removable cover on the other. In Figure 6.26, the dashed lines through the center and lower nozzle denote the position of the pass divider (or pass-partition plate) F in Figure 6.25, if two tube passes are used. Arrangements for more tube-side passes are shown in Figure 6.27. The removable cover allows tube inspection, cleaning, or replacement without disturbing the piping to the exchanger. Type B front-end header is the bonnet type, which is often less expensive than the A type but does not allow tube inspection without disconnecting the tube-side plumbing.

Types C and N front headers provide increasingly monolithic construction with fewer gaskets and hence less opportunity for leakage, but also less flexibility of maintenance and greater concern for thermal stress relief. The N type is especially used for nuclear power and hazardous fluid applications.

The D head uses a special closure similar to the breech of an artillery piece, with application to high-pressure feed-water heaters in power plants and some high-pressure chemical processes.

The rear head design is driven by the need to accommodate or relieve the thermal stresses between shell-and-tube bundles due to their different temperatures. If the temperature differences are not too great, a fixed tubesheet rear head, TEMA types L and M (essentially identical to types A and B front heads), can be used. For low shell-side pressures, thermal stress relief can be provided by expansion rolls or bellows in the shell. Tube-side expansion joints can be employed with a floating-head design inside a shell bonnet to provide a single tube-side pass.

If the thermal stresses are too great to be accommodated by a fixed tubesheet design, a U-tube configuration (TEMA U) can often be used. This design eliminates the second tubesheet, and each tube is free to expand or contract independently of the shell or other tubes, and the bundle usually can be easily removed for cleaning or repair. However, countercurrent flow is possible only with an F shell, which usually means that the tube bundle cannot be removed. The U-bend area must be stabilized against vibration, either by rod arrays supporting the tubes or by moving the shell nozzle forward of the U-bend and inserting a full circle tube support at the start of the U-bends. Only the outermost tubes in a U bundle can be individually replaced. It is customary to plug any leaking tubes until the thermal performance is significantly compromised and then remove and replace the entire bundle.

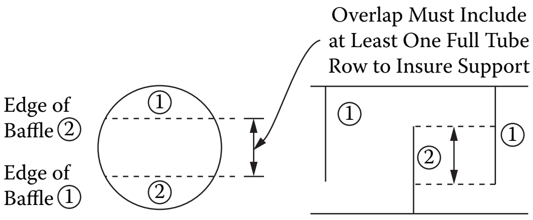
The outside packed and externally sealed floating-head designs, TEMA P and W, rely upon packing between the shell flange and the floating tubesheet to seal the shell-side fluid against leakage to the atmosphere and are largely limited to water or inert gases as the shell-side fluid.

They do allow single-tube pass design if fitted with a rear head tube-side nozzle and flexible piping. Individual tube replacement is possible.

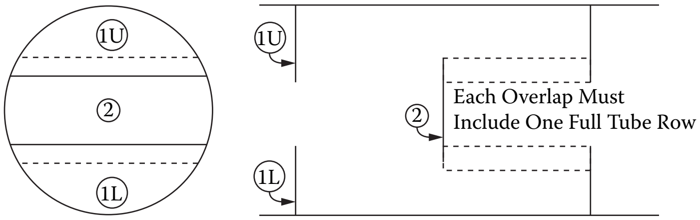
The floating head with backing device (also termed "split-ring floating head") and pull-through floating-head designs, TEMA S and T, provide more positive sealing of the shell-side fluid, with the T design used for the most critical cases. While Figure 6.26 indicates (by the dashed lines) that a rear-head packed tube-side nozzle (and hence single tube-side pass) is possible, this increases the possibility of shell-side fluid leakage and is rarely used.

All of the floating-head designs require elimination of some of the peripheral tubes (compared with the same diameter fixed tubesheet design) in order to accommodate the tubesheet flange or skirt. Omission of these tubes also creates bypass flow paths around the tube bundle, reducing the flow rate and heat-transfer coefficient across the tubes and reducing the effective temperature difference for heat transfer. These bypass lanes can be partially blocked and the thermal effectiveness largely restored by inserting sealing strips—metal strips that are about as wide as the clearance between the shell and the tube bundle and run the length of the exchanger through slots cut into the baffles. The strips are installed symmetrically on both sides of the tube bundle and both sides of the central plane—one pair about every six tube rows in the direction of flow is suggested. Tie rods and spacers located in the bypass lanes also help block the flow but are not as effective as sealing strips.

The essential purpose of the shell-side baffles (item G in Figure 6.25) is to support the tubes against sagging and vibration. A secondary role is to guide the shell-side flow across and through the tube bundle to achieve maximum thermal effectiveness for the allowable pressure drop. The most common configuration is the single segmental baffle, shown in Figure 6.28a. The baffle cut and spacing are design variables chosen (within the limits set by the TEMA standards) to best meet these requirements. Typically, the baffle cut is 15–25% of the shell inside diameter for liquids and 40–45% for gases. Spacing and cut will usually be selected so that the baffle window free-flow area is about 50–100% of the tube bundle free cross-flow area. A tube vibration analysis is used in all questionable cases to verify that damaging levels of vibration will not occur. TEMA also specifies the diametral clearances between tube and baffle hole and between baffle and shell inside diameter; these clearances are necessary for bundle assembly and removal and for tube replacement.



(a) Single Segmental Baffle.



(b) Double Segmental Baffle.

FIGURE 6.28 (a) Single-segmental baffle configuration. (b) Double-segmental baffle configuration.

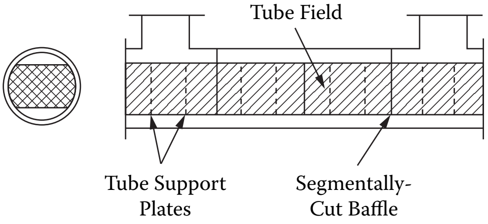


FIGURE 6.29 Diagram of a shell-and-tube heat exchanger with no tubes in the window (NTIW).

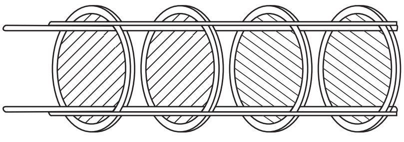

FIGURE 6.30 Schematic of the RODbaffle™ configuration for shell-and-tube heat exchangers.

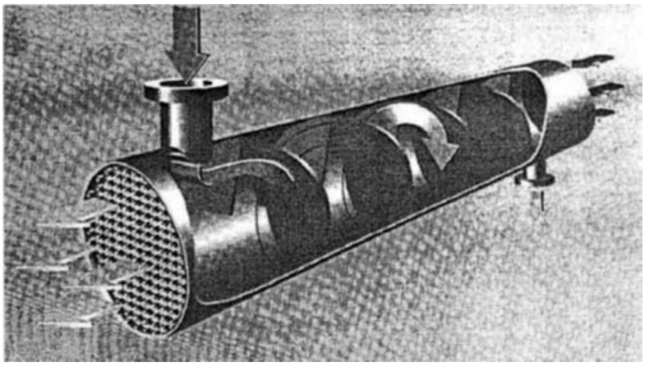

FIGURE 6.31 Schematic of shell-side flow in a helically baffled heat exchanger. (Courtesy, Lummus Technology Heat Transfer, Bloomfield, NJ, USA, with permission.)

Alternative tube support methods include double-segmental baffles (shown in Figure 6.28b), strip baffles, "no tubes in the window" (NTIW) construction (Figure 6.29), RODbaffles™ (Figure 6.30), helical baffles (Figure 6.31), and self-supporting tubes (Figure 6.32). Strip baffles are an extension of the double-segmental baffle concept, further dividing the central baffle into two or more strips with gaps between, and adding a third (or more) strips to the two wing baffles. It is essential that all of the segments/strips overlap their neighbors by at least one full row of tubes to maintain bundle integrity.

The "no tubes in the window" (NTIW) design (Figure 6.29) eliminates all of the tubes that pass through the window areas. These tubes have the longest unsupported span between baffles and are thus the most prone to vibrate. To further secure the remaining tubes, intermediate support plates can be inserted between the baffles. These plates further reduce the unsupported length, but have little effect upon pressure drop or heat transfer.

The RODbaffle design (Figure 6.30) replaces the plate baffles with an array of parallel rods welded to a full circle rod or plate that fits inside the shell. The rods in each grid have a diameter equal to the nominal clearance between the tubes and are spaced so that two rows of tubes fit between two adjacent rods. Four grids form a set, and any number of sets can be used in an exchanger, depending upon length. The second grid in the set is similar to the first, but has the rods offset by one tube diameter. The third and fourth grids are like the first and second, respectively, but rotated 90°. The individual grids are spaced from 100 mm (4 in.) to 300 mm (12 in.) apart, as

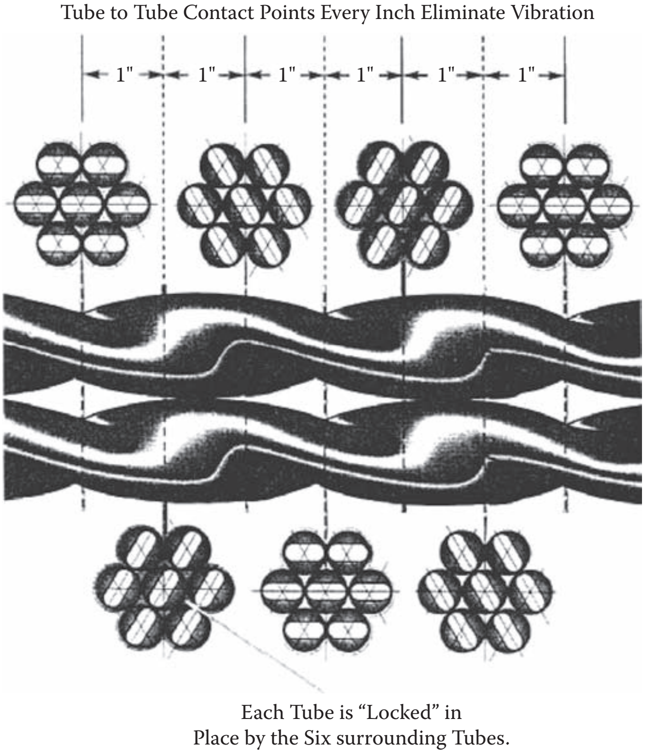

FIGURE 6.32 Diagram of two Twisted Tubes®, showing how tubes are mutually self-supporting. (Courtesy of Koch Heat Transfer Company LP.)

required, to provide support and rigidity, and each tube is supported on all four sides in each set. The sets are held together by welded tie rods. Tube vibration is effectively eliminated, and the nearly longitudinal flow gives significantly reduced pressure drop and a somewhat reduced heat-transfer coefficient than the corresponding conventionally baffled exchanger. Annular distributors (see below) are often specified for RODbaffle exchangers to minimize pressure drop and ensure good distribution.

Helically baffled heat exchangers, illustrated in Figure 6.31, are a recent development. The spiral path through the shell side eliminates or reduces eddy regions and bypass flows, resulting in improved heat transfer for a given pressure drop [61].

Twisted Tube™ construction (Figure 6.32) eliminates the need for baffles altogether, since the tubes can be oriented ("tuned") to contact surrounding tubes periodically along the exchanger. The shell-side flow is longitudinal, and special correlations have been developed for both heat transfer and pressure drop on both sides of the surface. Laminar flow inside the tube is enhanced by the secondary flow induced by the twisted flow path.

Impingement plates are another shell-side construction feature that may be required to prevent tube vibration or erosion. The impingement plate is placed under the shell-side inlet nozzle and should be larger than the nozzle opening, with an escape area off the edges of the plate that is twice the flow area of the nozzle. The impingement plate is attached to the shell or the tie rods. TEMA standards specify the conditions under which an impingement plate is required.

An alternative to the impingement plate is the annular distributor (Figure 6.33), which, through the use of a partial double shell, absorbs the impact of the inlet fluid jet and distributes the fluid more uniformly into the tube bundle. An annular distributor is designed to require a low-pressure

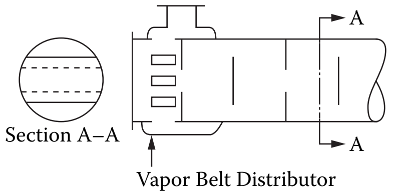

FIGURE 6.33 Annular distributor for a shell-and-tube heat exchanger, with double-segmental baffles.

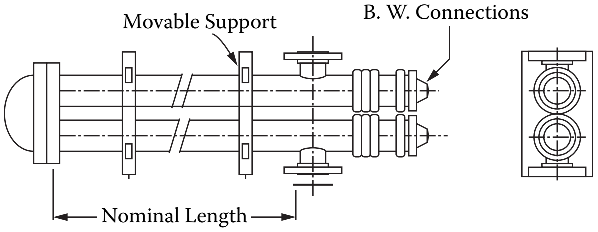

FIGURE 6.34 Schematic of a hairpin heat exchanger. (Reprinted by permission of Koch Heat Transfer LP.)

loss, and is often specified for use with RODbaffle exchangers. It also allows flexibility in the placement of the first baffle. Annular collectors can also be used for the exit flow.

6.5.2.4 Multitube ("Hairpin") Heat Exchangers

The multitube heat exchanger, also termed a "hairpin" heat exchanger, in reference to its prime construction feature, is shown schematically in Figure 6.34. It is intermediate between the double-pipe and the shell-and-tube types, consisting of a bundle of U-tubes arranged in two parallel shells connected by an end fitting accommodating the U-bend. This provides true countercurrent flow. Tube support is required as in shell-and-tube exchangers; the U-bends are active heat-transfer surfaces and must be stabilized against vibration. Sizes range up to 2500 m^2 (25,000 ft^2).

6.5.2.5 Gasketed-Plate Heat Exchanger and Related Partially Welded Variants

Figure 6.35 is a schematic of the basic gasketed-plate heat exchanger, consisting of a pack of embossed thin plates gasketed around the outer edges and the inlet and outlet fluid ports to seal against fluid leakage to the atmosphere and the other fluid. A pair of plates with the gasketing shown as heavy lines is shown in Figure 6.36. The plates are pressed from a wide variety of metals; however, low-carbon steel is not used because it is usually not cost competitive with an equivalent shell-and-tube exchanger. Plastic plates (usually fiber reinforced or graphite loaded for enhanced thermal conductivity) are available for especially corrosive applications. The plates are available in sizes up to about 4 m (14 ft) by 1.2 m (4 ft) wide, and a single large rack can hold up to 500 plates.

The plates can be supplied with some ports closed off to allow for various series- or parallel-flow arrangements for each stream to optimize the pressure-drop utilization and match the temperature profiles of the streams. Plates with special port designs and increased spacing are available for condensing or partial-vaporization services. The plates are embossed with a chevron or staggered rectangular pattern, providing numerous contact areas between adjacent plates to protect against collapse on the low-pressure side. The resulting tortuous flow pattern causes turbulent flow, even at low Reynolds numbers, resulting in high heat-transfer coefficients and pressure gradients.

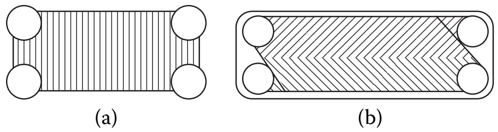

FIGURE 6.36 Two types of plates for the gasketed-plate heat exchanger: (a) parallel-corrugated plate; (b) cross-corrugated plate ("herringbone" or "chevron" pattern).

The gaskets are made from a variety of elastomers; they are confined in grooves around the plate edges and ports, and must be firmly and uniformly compressed to provide an effective seal. These gasket sets can generally be reused, allowing plate exchangers to be regularly disassembled for cleaning or sterilization. The gasket material and construction limit the temperature range and pressures of the application. Small plates can be used up to about 20–25 bar (300–375 psig) at temperatures below about 100°C (210°F), whereas large plates are limited to about 8 bar (120 psig). Maximum temperatures are about 150°C (300°F) with reusable gaskets. Jacketed asbestos gaskets can be used to about 250°C (480°F), but cannot be reused. Limits vary among manufacturers and with the specific designs. Designs with pairs of plates welded together have been manufactured. These designs allow higher pressure operation on the welded channel side, but sacrifice some of the flexibility of disassembly and reassembly. A diffusion-bonded Monobloc™ construction is also available for very high pressure operation, but it cannot be disassembled.

Major manufacturers have design and rating programs that reflect the pressure-drop and heat-transfer characteristics of their specific plates, which can vary widely and are generally proprietary. API [62] provides standards for gasketed-plate exchangers. Where higher alloy construction is required, gasketed-plate exchangers generally have a lower capital cost and are more compact than shell-and-tube exchangers of comparable thermal capacity. Fouling is generally less severe (though fluids containing larger solid particles or fibrous materials tend to plug the fine channels) due to the high turbulence and shear stress developed, and most designs can be disassembled easily for cleaning. Reassembly without leaks can be more difficult unless maintenance crews are specially

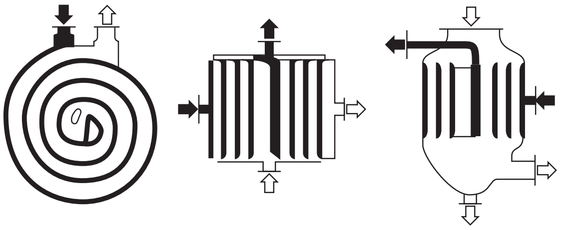

FIGURE 6.37 Schematic diagrams of spiral-plate heat exchangers: (a, b) basic construction for two fluids in counterflow, (c) configured for condensation or reboiler service.

trained and equipped. The low temperature and pressure limits are the chief restriction upon the use of gasketed-plate exchangers.

The spiral-plate heat exchanger (Figure 6.37) is closely related to the gasketed plate. One type is constructed by winding two long plates together in a spiral to form open channels for each fluid and then welding the open edges of adjacent plates on each side to form two continuous channels, each open on one edge on opposite sides. The open edges are then closed off by covers on either side of the spiral structure, held in place by peripheral clamps. The plates are spaced by welded stubs or embossed nubs on the plates. Gaskets are used to seal the plate edges against the covers and the atmosphere. Another type has one channel left open for cross flow in that channel and can be used in column internal and external reflux condensers and reboilers.

Spiral-plate exchangers provide high surface densities. The induced secondary flow results in enhanced heat-transfer coefficients, especially for viscous fluids, and reduced sedimentation-type fouling. Spiral-plate exchangers can be easily opened for cleaning by high-velocity water jets.

6.5.2.6 Plate-Fin (Matrix) Heat Exchangers

Plate-fin, or matrix, heat exchangers offer a high volumetric density of heat-transfer surface, on the order of 1000 m^2/m^3 (based on the entire surface in contact with any fluid) and hence are of interest in cryogenic processes requiring extreme insulation and in gas-to-gas applications. The essential construction features are shown in Figure 6.38. The prime heat-transfer surface is the aluminum fin, consisting of thin sheets that have been folded to form arrays of longitudinal fins and brazed to parting sheets separating the fluid channels. Side bars close the channels against the surroundings. The fins, parting sheets, and side bars are stacked in the desired pattern, omitting the side bars where fluid inlets and exits are desired, and the entire assembly is then furnace- or salt-bath brazed. Finally the inlet and exit manifolds are welded to the assembly.

The diagram shows three streams in one exchanger, and units handling up to 12 or 14 different streams have been constructed. Different numbers of parallel channels and different fin geometries can be used for the several fluids. Only nonfouling fluids can be used in plate-fin exchangers due to the fine channels and the inability to disassemble for cleaning. A major concern is achieving uniform flow distribution among the several parallel channels for each fluid, requiring careful design of the distributor section for each channel.

Each manufacturer has specialized design procedures for their equipment. The manufacturers have formed ALPEMA, the Brazed Aluminium Plate-Fin Manufacturers' Association, which has issued *The ALPEMA Standards* [63] for the design, construction, operation, and maintenance of this equipment.

6.5.2.7 Air-Cooled Heat Exchangers

Air-cooled heat exchangers use air as the cooling medium to dissipate low-temperature waste heat, and the two basic configurations are shown in Figure 6.39. Design is dictated by the poor thermal

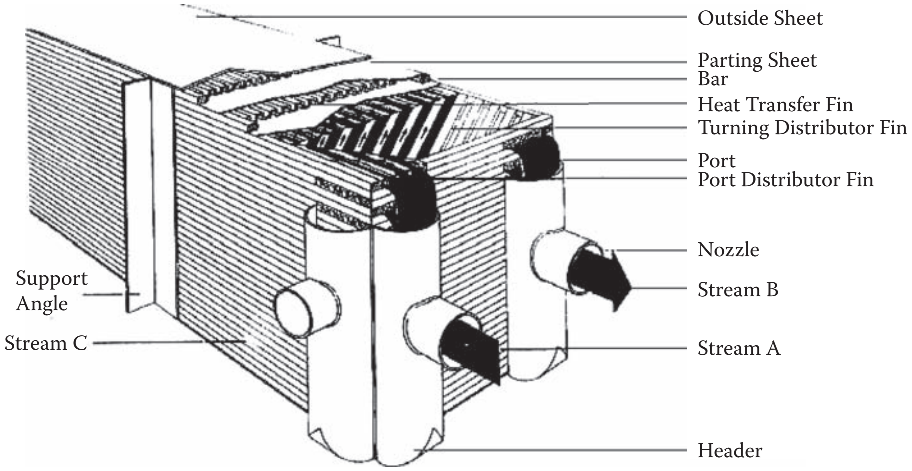

FIGURE 6.38 Cutaway view of a brazed aluminum plate fin (or matrix) heat exchanger configured for three streams. (Courtesy Chart Energy and Chemicals, Inc., La Crosse, WI, a wholly owned subsidiary of Chart Industries, Cleveland, OH.)

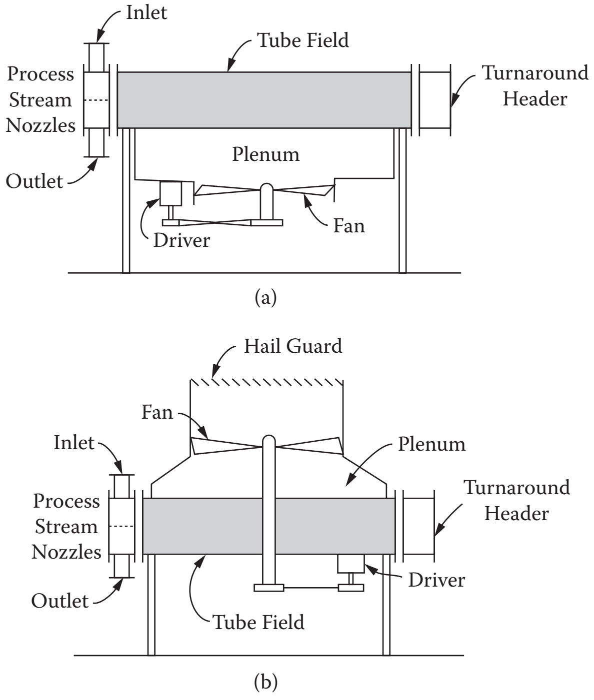

FIGURE 6.39 Schematic diagrams of air-cooled heat exchangers: (a) forced draft, (b) induced draft.

properties of air. The low density of atmospheric air and its low specific heat require the moving of large volumes of air, requiring large single-stage axial flow fans. These fans can only achieve low pressure rises; a typical design pressure drop for the air side is 3/4 in. of water (0.027 psi, or 0.19 kPa). Consequently, the air is limited to low velocities—a face velocity of about 10 ft/s (3 m/s) for a six-row tube bank is typical. The low velocity and low thermal conductivity result in low heat-transfer coefficients and require the use of high-finned tubes (Section 6.3.4.5.3).

The basic heat-transfer surface is a bank of 1 to 20 (but usually 3 to 12) rows of high-finned tubes. The fluids enter the tubes by box headers (pipe headers at higher pressures), with the tubes welded into one wall of the header; internal dividers are used in the headers to create multiple tube passes. The header cover may be bolted to the header, or the header may be welded, with threaded plugs opposite the tube ends to facilitate assembly and tube cleaning. The tubes are slanted downward toward the exit (about 1/4 in. per ft) to facilitate drainage. Occasionally, especially for turbine steam condensation, an A-frame configuration is employed, with the tubes slanted about 30° from the vertical and the fans mounted in forced draft at the base of the A, thereby reducing the plan area required.

Forced- and induced-draft arrangements are used in about equal numbers, depending upon the relative advantages in a particular situation. The forced-draft arrangement locates the fan and driver below the tube bundle, allowing greater rigidity and access for servicing the fan and driver, and creating turbulence in the air flow across the tube field. However, the air flow is somewhat maldistributed, with highest velocities immediately over the fan blade tips and significantly lower velocities in the corners and edges of the layout and over the fan hubs. The air exhaust velocity is essentially the face velocity, and is more subject to recirculation around, underneath, and back into the cooler, reducing the effective temperature difference for heat transfer. The induced-draft configuration produces a higher exhaust velocity (typically about 2 1/2 times the face velocity) and results in a more uniform velocity distribution across the tube field. However, the heat-transfer coefficient for the first two or three rows of tubes is reduced significantly while the turbulent flow is developing [64]. The plenum shroud protects the tubes from hail and from sudden rain storms.

Proper selection and positioning of the fans is crucial to successful operation. Standard practice calls for the fan area to be about 40% of the face area. The fan placement should provide the most uniform air flow through the tube bank possible. A scale drawing of the fan circle over the tube-field layout should be made, especially for air-cooled exchangers with multiple tube-side services, to ensure that all of the tube field is reasonably included in the flow field.

The fans may be driven by electric motors or by turbines. In either case, it is almost always necessary to use either a gear reducer or a belt drive to achieve the proper fan speed; maximum fan tip speed is about 1500 ft/min (7.7 m/s). Where feasible, two fans (or more) should be used with each bay of the exchanger. This allows one fan to be on constant speed, while the other is controlled to achieve the desired process outlet temperature for existing ambient conditions. Both variable and variable-pitch control systems are used. API [65] provides the standards for air-cooled heat exchangers in the process industries.

6.5.2.8 Mechanically Aided Heat Exchangers

Two kinds of heat exchangers require direct application of mechanical energy to the heat-transfer surface to achieve reasonable heat-transfer rates. The first is the stirred-tank reactor with a motor-driven paddle, propeller, or helical flight inside the reactor. A wide variety of heat-transfer surface configurations is available, including tube coils, welded plates, and helical tubing coils. External jackets are also available and may be used independently or in conjunction with the internal surface. Correlations for heat-transfer and power requirements are mostly proprietary to the manufacturer, but some general correlations are available in Volume 3 of the *Heat Exchanger Design Handbook* [1].

Scraped-surface exchangers, illustrated in Figure 6.40, are used for fractional crystallizers, dewaxing coolers, and heating and cooling of extremely viscous or solid-containing liquids. They are specialty items, manufactured by a relatively small number of firms, each of which has its own design methods and correlations. They are expensive and require constant attention and maintenance. The type shown in the figure applies a constant scraping force to the solid surface as fixed by the spring characteristics. Another type—the "hydrodynamic blade"—has the scraper blade

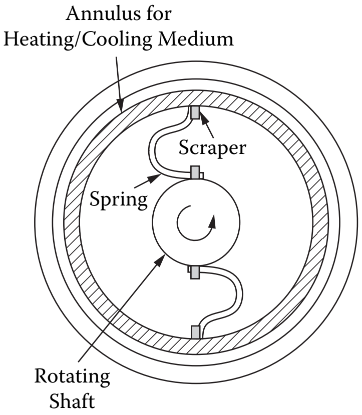

FIGURE 6.40 Cross-sectional view of a scraped-surface heat exchanger with spring-loaded blades.

mounted on a jointed arm, with the blade free to swing outward by centrifugal force as the shaft rotates; the force acting on the scraped surface is thus controlled by the rotational speed.

6.5.3 Principles of Heat-Exchanger Design

6.5.3.1 Heat Transfer between Two Fluids Separated by a Wall

Figure 6.41 shows a cross section of a typical heat-exchanger tube with a hot fluid inside at temperature T and a cold fluid outside at t. (The following argument applies to hot fluid outside and cold inside with appropriate change of sign. It applies whether the respective heat-transfer processes are single-phase convection, or condensation or vaporization, always noting that heat flows from the hot fluid to the cold.) The figure also shows fouling films on both surfaces, which is almost always the practical situation; fouling is discussed in more detail in Section 6.5.5.

Under the reasonable assumptions that the heat-transfer process is at near-steady state (i.e., conditions at any given point do not vary rapidly with time) and that the longitudinal heat-transfer rates along the tube are negligible compared with those radially through the tube wall, the heat-transfer rate, Q (watts or Btu/h), for a tube of length L (m or ft) is given by the following equations:

$$Q = h_i A_i (T - T_{fi}) \tag{6.96a}$$

$$Q = \frac{A_i (T_{fi} - t_{wi})}{R_{fi}} \tag{6.96b}$$

$$Q = \frac{(2\pi L) k_w (t_{wi} - t_{wo})}{\ln(r_o / r_i)} \tag{6.96c}$$

$$Q = \frac{A_o (t_{wo} - t_{fo})}{R_{fo}} \tag{6.96d}$$

$$Q = h_o A_o (t_{fo} - t) \tag{6.96e}$$

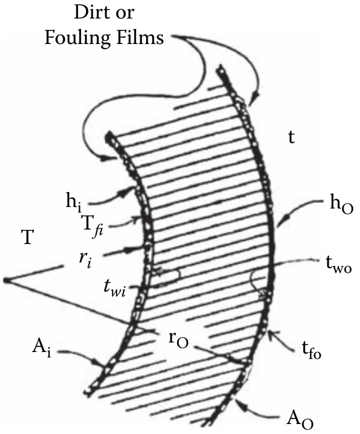

FIGURE 6.41 Cross section of fluid-to-fluid heat transfer through a tube wall.

In these equations, h_i and h_o are the inside and outside film heat-transfer coefficients, A_i and A_o are the inside and outside surface areas of the clean tube, R_{fi} and R_{fo} are the inside and outside surface fouling resistances, T_{fi} is the interface temperature between the fluid and the surface of the fouling deposit inside the tube, t_{fo} is the interface temperature between the fluid and fouling surface on the outside, t_{wi} and t_{wo} are the inside and outside tube wall temperatures, and k_w is the thermal conductivity of the tube material. Each of the terms in the denominator is a resistance to the heat flow, and their sum is the total resistance to heat transfer between the two fluids. These equations can be combined to eliminate the intermediate temperatures and find the heat-transfer rate using only the overall temperature difference ($T - t$):

$$Q = \frac{T - t}{\frac{1}{h_i A_i} + \frac{R_{fi}}{A_i} + \frac{\ln(r_o / r_i)}{2\pi L k_w} + \frac{R_{fo}}{A_o} + \frac{1}{h_o A_o}} \tag{6.97}$$

The overall heat-transfer coefficient U^* is based on any convenient reference area A^* and is defined by the equation

$$Q = U^* A^* (T - t) \tag{6.98}$$

Comparing the last two equations gives the overall heat-transfer coefficient in terms of individual resistances:

$$U^* = \frac{1}{\frac{A^*}{h_i A_i} + \frac{R_{fi} A^*}{A_i} + \frac{A^* \ln(r_o / r_i)}{2\pi L k_w} + \frac{R_{fo} A^*}{A_o} + \frac{A^*}{h_o A_o}} \tag{6.99}$$

Frequently, but not always, the total outside area of the tubes in a heat exchanger, A_o, is chosen as the reference area, and the resulting equation is

$$U = \frac{1}{\frac{A_o}{h_i A_i} + \frac{R_{fi} A_o}{A_i} + \frac{A_o \ln(r_o / r_i)}{2\pi L k_w} + R_{fo} + \frac{1}{h_o}} \tag{6.100}$$

Any other convenient, well-defined area, such as the inside heat-transfer area A_i, can be used as the reference area. For a typical low-finned tube, the effective outside area of the tube, A_{eff}, must include the fin efficiency, η_{fin}, from Figure 6.10.

$$A_{eff} = A_{prime} + \eta_{fin}A_{fin} \tag{6.101}$$

where A_{prime} is the outside surface area of the tube between the bases of the fins and A_{fin} is the total surface area of all the fins.

The relationship between area and overall heat-transfer coefficient is

$$U^*A^* = U_oA_o = U_iA_i = \ldots \tag{6.102}$$

Because the values of the heat-transfer coefficients are referenced to the area upon which they are based, care must be taken to always identify the reference area in any situation where there is any possibility of confusion or misunderstanding.

6.5.3.2 The Basic Design Integral

The above equations relate the heat-transfer rate to the local temperature difference ($T - t$) and the heat-transfer area A through the overall heat-transfer coefficient U. In almost all practical situations, one or both temperatures will vary along the length of the heat exchanger. The change in temperature of each stream is calculated from the enthalpy balance on that stream. To apply Equation (6.98) to the design of a heat exchanger in which the temperature difference is not constant, the equation needs to be written in differential form:

$$dA^* = \frac{dQ}{U^*(T-t)} \tag{6.103}$$

which can then be formally integrated over the entire heat duty of the heat exchanger, Q_T:

$$A^* = \int_0^{Q_T} \frac{dQ_T}{U^*(T-t)} \tag{6.104}$$

This is the basic design equation for heat exchangers having two fluids exchanging heat across a well-defined solid surface. The local fluid temperatures are calculated as a function of the entering temperatures and the amount of heat exchanged up to a given point in the heat exchanger. The individual film heat-transfer coefficients, and hence the overall coefficient, may also be functions of the amount exchanged, especially in condensing and vaporizing services, as discussed in Section 6.4.

Most large heat exchangers are designed using commercially available computer programs to evaluate Equation (6.104) numerically. However, if certain assumptions are made, the equation can be analytically solved to give a simple algebraic solution. This procedure is discussed in the next section.

6.5.3.3 The Mean Temperature Difference Concept

If certain assumptions are made, Equation (6.104) can be analytically integrated for a number of important heat-exchanger configurations and applications. The following set of assumptions is reasonably valid for many cases:

1. All elements of a given stream have the same thermal history. This implies good mixing of each stream at each cross section. Significant flow maldistribution or bypassing violates this assumption.
2. The heat exchanger is at steady state. This assumption is usually satisfied during normal operation.
3. Each stream has a constant specific heat. Isothermal phase transitions (corresponding to an effective specific heat of infinity) satisfy this requirement and, in fact, simplify the solution.
4. The overall heat-transfer coefficient is constant. This usually requires that the individual film coefficients, or at least the controlling one, be essentially constant.
5. The flow is either entirely cocurrent or countercurrent, as shown in Figures 6.42a, 6.42b, 6.43a, and 6.43b. This assumption is relaxed below for many multipass or cross-flow heat exchangers.
6. The heat exchanger is perfectly insulated, i.e., it does not exchange heat with any connections or surroundings.

Applying these assumptions and the appropriate heat balances to Equation (6.104) results in

$$A^* = \frac{Q_T}{U^*(LMTD)} \tag{6.105}$$

where A^* is the total reference heat-transfer area required in the heat exchanger, U^* is the overall heat-transfer coefficient based on A^*, and $LMTD$ is the logarithmic mean temperature difference for the exchanger, given by

$$LMTD = \frac{(T_i - t_i) - (T_o - t_o)}{\ln \dfrac{(T_i - t_o)}{(T_o - t_i)}} \quad \text{for cocurrent flow} \tag{6.106}$$

and

$$LMTD = \frac{(T_i - t_o) - (T_o - t_i)}{\ln \dfrac{(T_i - t_o)}{(T_o - t_i)}} \quad \text{for countercurrent flow} \tag{6.107}$$

Typical temperature profiles are shown for cocurrent flow in Figure 6.42b, where the outlet cold fluid temperature can never be greater than the outlet hot fluid temperature, and for countercurrent flow in Figure 6.43b, where the outlet cold fluid temperature can be greater than the outlet hot fluid temperature. It is readily shown that the countercurrent arrangement always transfers as much or more heat in a given heat exchanger than the cocurrent configuration for the same inlet temperatures and flow rates if the assumptions are satisfied. However, the surface temperature in the cocurrent arrangement is more nearly constant, which may be important if a heat-sensitive fluid or temperature-sensitive fouling is involved.

The mean temperature difference formulation may be extended to many heat-exchanger configurations that are neither purely countercurrent nor purely cocurrent. As noted in Section 6.5.2.3, most shell-and-tube exchangers have multiple tube passes, resulting in the tube-side fluid being in countercurrent flow to the shell-side in some passes and cocurrent in others. Typical temperature profiles for a 1-2 shell-and-tube exchanger are shown in Figures 6.44a and

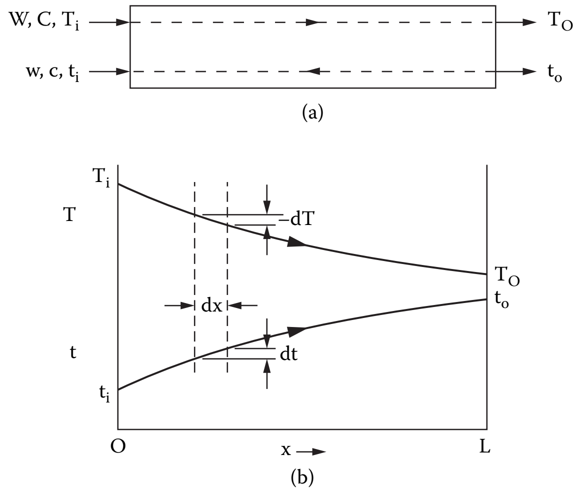

FIGURE 6.42 (a) Cocurrent flow pattern through a heat exchanger. (b) Typical temperature profiles through a cocurrent heat exchanger.

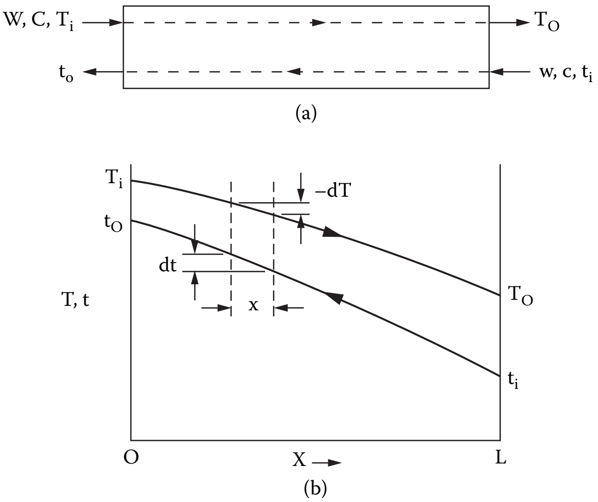

FIGURE 6.43 (a) Countercurrent flow pattern through a heat exchanger. (b) Typical temperature profiles through a countercurrent heat exchanger.

6.44b. Similarly, air-cooled exchangers as described in Section 6.5.2.7 have the air in cross flow to the tubes.

If certain additional assumptions are made, many of these cases can be handled by a modification of Equation (6.105):

$$A^* = \frac{Q_T}{U^*(MTD)} \tag{6.108a}$$

where

$$(MTD) = F(LMTD)_{counter\,current} \tag{6.108b}$$

and (*MTD*) is the effective mean temperature difference. The *MTD* is found by multiplying the logarithmic mean temperature difference *for countercurrent flow* (Equation (6.107)) by *F*, the configuration correction factor, which is discussed in detail below.

For this formulation to apply to shell-and-tube exchangers, it is assumed that each tube pass has the same number of tubes and that the tube-side coefficient in each pass is the same. The analysis also requires that there be sufficient baffles that the shell-side flow can be treated as longitudinal to the tubes, rather than as a series of cross-flow sections. Three or four baffles may be sufficient to meet this criterion if the shell-side temperature change is less than the minimum temperature difference between shell-side and tube-side fluids, and eight or more baffles are almost always sufficient for the assumption to be satisfied.

For air-cooled exchangers, it is assumed that each pass has the same number of tubes, that the coefficient is the same for all tubes, and that the passes are arranged countercurrent to the air flow.

The configuration correction factor *F* can be obtained by analytical or numerical integration of Equations (6.108a) and (6.108b) as a function of two dimensionless ratios, *P* and *R*, defined as

$$P = \frac{t_o - t_i}{T_i - t_i}; \quad R = \frac{T_i - T_o}{t_o - t_i} \tag{6.109}$$

The analytical solutions for *F* can be incorporated into computer design programs, and the numerical solutions can be represented over the practical range by curve fits. For hand use, however, graphical representation is more convenient and revealing. Extensive tables and graphs of *F* as a function of *P* and *R* for most configurations are given in the literature [1, 30, 51, 54, 56, 64, 65]. A few of the most common ones are included here as Figures 6.45 to 6.52.

Figures 6.44a and 6.44b show typical temperature profiles for a 1-2 shell-and-tube exchanger. If the outlet temperatures of the two streams are equal for this configuration, the value of *F* is usually close to 0.8. It is possible to design for the outlet temperature of the cold stream to exceed

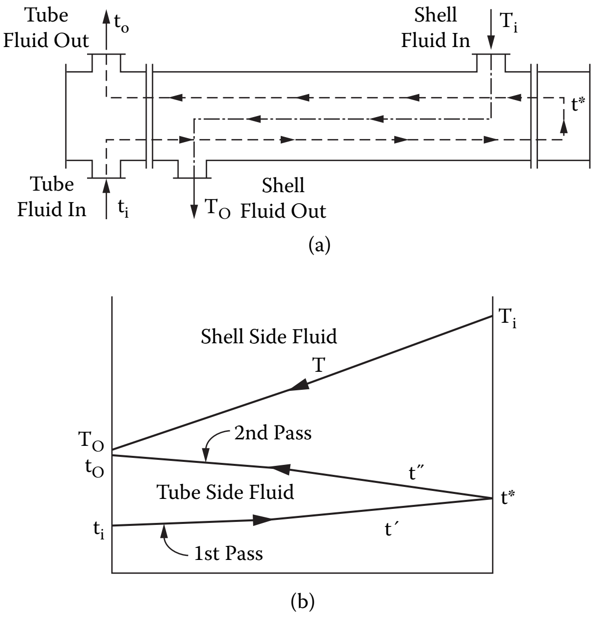

FIGURE 6.44 (a) Nominal flow pattern through a one-shell pass, two-tube pass (1-2) shell-and-tube heat exchanger. (b) Typical temperature profiles through a one-shell pass, two-tube pass (1-2) shell-and-tube heat exchanger.

the outlet of the hot stream. This is inefficient—part of the heat-transfer surface is transferring heat in the wrong direction—and this condition is seldom designed for. However, this condition may occur when starting up a clean exchanger, when flow rates are reduced, or for an oversurfaced heat exchanger. It also makes it difficult to obtain valid performance data on a clean heat exchanger. As a general rule, design of any exchanger with $F < 0.8$ or where F is read from the steep part of the curve should be considered carefully—it is probably inefficient, and even small departures from the ideal assumptions of the MTD method may render the exchanger thermodynamically incapable of achieving the design conditions.

When it is necessary to transfer heat between two fluids over wide overlapping temperature ranges with multiple tube pass exchangers, two or more exchangers may be connected in series, with the overall flows countercurrent, as shown in Figures 6.46 and 6.47. F increases rapidly as the number of exchangers in series increases, the only limit being the allowable pressure drops.

6.5.4 Logic of the Heat-Exchanger Design Process

Figure 6.53 diagrams the logical structure of the heat-exchanger design process, whether done by computer or by hand. If there is a validated computer design program available, the computer is faster and more precise, though not necessarily more accurate. But the human mind offers advantages, such as the ability to perceive problems and opportunities during the calculation, which may lead to solutions beyond the ken of the design logic built into the program. The combination of a good program and an experienced designer working interactively is best of all.

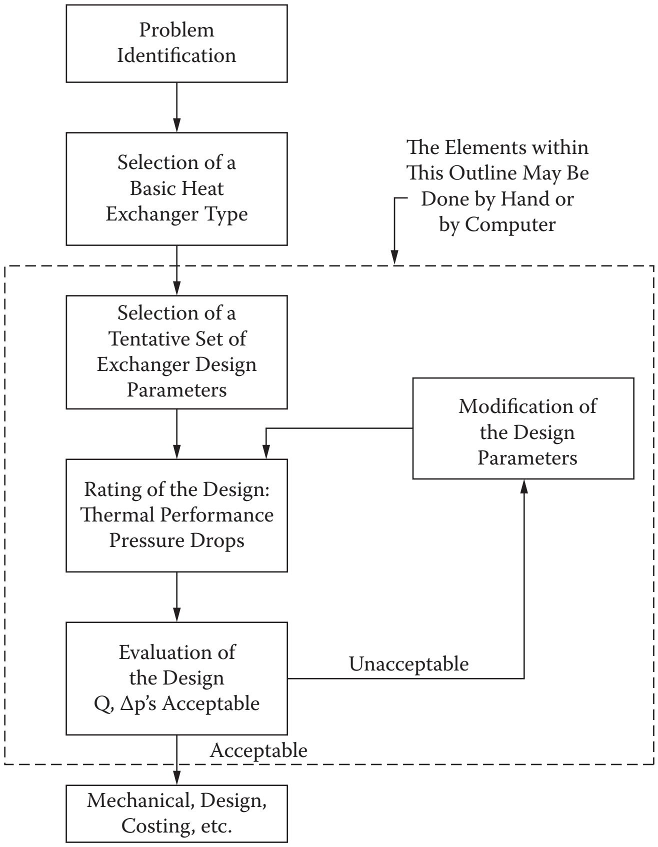

FIGURE 6.53 Logical structure of the process heat-exchanger design procedure.

The first step is to completely and unambiguously define the problem and provide the designer with all of the data required. This will include the flow rates, compositions, temperatures, and pressures of the streams. It is usually necessary to provide the thermodynamic and thermophysical properties over the range of temperatures and pressures to be encountered. Condensing and/or vaporizing curves, including equilibrium compositions, enthalpies, and phase mass fractions as functions of temperature for multicomponent mixtures, are essential. Design fouling resistances should be supplied as available from experience. Any requirements or limitations on diameter, length, weight, piping connections, supports, and construction features to facilitate maintenance must be given.

The next decision—selection of an exchanger type—is usually prefigured in arriving at the data provided above. However, it is well to consider alternative candidates for operational and maintenance advantages as well as for first cost. Criteria to be included are

1. Level of confidence in the design method
2. Level of confidence in the fabrication techniques
3. Level of confidence in plant operating and maintenance personnel
4. Operational flexibility, short and long term

The logic blocks in the outlined area carry out the thermal/hydraulic design of the exchanger. Whether by computer or hand, a starting configuration must be chosen, and there are certain minimum data that must be supplied even for a computer program, e.g., tube diameter, wall thickness, material, TEMA type, maximum shell length and diameter, etc. Most computer programs have a default process whereby most of the unspecified mechanical data are arbitrarily selected. With a computer program, the greatest concern is that the computations will converge to a feasible design from the initial data. For hand design, it is highly desirable to start with a design as close as possible to the final design to minimize computational time. An estimation procedure to provide a starting design for shell-and-tube exchangers is given in Section 3.1.4 of the *Heat Exchanger Design Handbook* [1].

The rating program, Figure 6.54, is the core of the design computations. It contains the subprograms for calculating the geometrical parameters (e.g., flow cross sections and heat-transfer area), the correlations for heat-transfer coefficients and temperature differences, and the correlations for pressure drops.

In the next step, the calculated thermal capability and the pressure drops for the candidate design are compared with the required values. The thermal capability must be satisfied (with any specified safety factor included), and the pressure drops should use as much of the allowable pressure drops as possible without exceeding the limits. Given, however, the uncertainties in the correlations and other design and operational factors, the allowable pressure drops should be chosen and interpreted to reflect this uncertainty. The computer is rigid in its decision regarding the acceptability of the design. The designer must apply the judgment whether a design with a somewhat

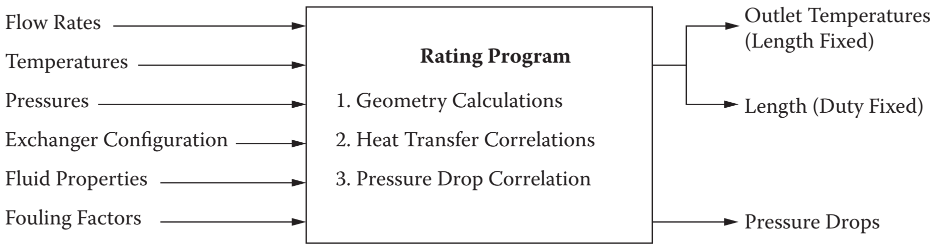

FIGURE 6.54 Rating program: core block of the heat-exchanger design process.

larger predicted pressure than the "allowable" but with superior qualifications in other respects should be accepted.

If any of the rating output is deemed "unacceptable" by the program, the "Design Modification" program takes over, following a very detailed sequence of evaluating what is acceptable and what needs to be changed in the design. The objective function is usually to minimize the surface area required within the pressure-drop limitations, since this usually leads to the minimum first cost. The changes made must satisfy applicable codes and standards, as well as accepting only feasible construction features and commercially available components, e.g., tubes. The number of logical paths through such a program is enormous, and it can never be completely checked out. Writing such a program requires the very highest knowledge and skill. Even so, illogical or suboptimal results may ensue, and the output must be carefully evaluated every time. The prudent designer will consider whether rerunning the program with a different set of input specifications (e.g., changing the TEMA type or the tube layout) may not produce a superior design.

6.5.5 Fouling

Fouling is any unwanted deposit on the heat-transfer surface of a heat exchanger or any deposit that interferes with the desired flow pattern in the heat exchanger. In the first case, fouling increases the resistance to heat transfer, resulting in reduced thermal capability or requiring higher temperature differences or increased velocities to maintain thermal performance. In the second case, pressure drop increases at the same throughput, and a higher fraction of the flow may be forced into bypass areas.

Fouling is the greatest unsolved problem in heat-exchanger design. The most comprehensive book on fouling is by Bott [66], and there are many individual papers, but there are few quantitative and generalizable principles. TEMA Standards [54] provides tables of suggested values of the fouling resistance for a wide variety of services, but the mechanisms are so complex and dependent upon the specifics of each stream, exchanger design, and operating conditions that predictions are very uncertain.

Fouling processes are time dependent, starting at or near zero in new or freshly cleaned exchangers, increasing in time, sometimes to an asymptotic limit and other times increasing without limit until the exchanger is shut down and cleaned. Fouling deposits are often due to a combination of mechanisms, which complicates both the choice of a fouling resistance and the recommended amelioration technique.

There are several fouling mechanisms:

1. Sedimentation: Deposition of silt or other suspended material in the fluid on the heat-transfer surface. These deposits are generally weak and can be reduced or eliminated by increasing the velocity. The fouling resistance often reaches a constant value as long as conditions are unchanged. In this case, additional surface can be provided through a fouling resistance, R_f, in the overall heat-transfer coefficient equation. Cleaning can usually be effected by the use of high-velocity water sprays, though mechanical scraping may be required for heavy deposits.
2. Corrosion of the surface: Rust on low-carbon steel or other deposits formed by chemical attack on the heat-transfer surface by the process fluid form quickly and are generally adherent. Transient behavior depends upon whether or not the deposit acts to protect the surface from further attack. Where available and cost effective, selection of a different metal or a higher alloy is the best preventive. Coating a base metal with a chemically resistant polymer has not been generally satisfactory and introduces a significant resistance to heat transfer. Extreme cases can be handled with all-polymer exchangers, but these have poor heat-transfer characteristics and low strength and temperature limits. Heavy corrosion layers can usually be removed by appropriate chemical treatment or by water jets or mechanical scraping, but this only exposes the cleaned surface to renewed attack.

3. Inverse solubility: Certain substances—notably calcium sulfate (gypsum)—occurring in water supplies are less soluble in hot water than in cold and will crystallize out upon a hot surface. Depending upon the strength of the deposit and the operational strategy (e.g., increasing the hot stream temperature to maintain heat flux), the deposit may reach an asymptote or continue growing (as in the constant heat-flux case). Fouling in cooling-water systems is usually complicated by other fouling mechanisms, notably sedimentation, corrosion, and biological fouling (discussed below). Process streams may show similar behavior to other stream components. Chemical controls to inhibit the deposition or weaken the deposit by destroying the crystalline structure are generally the best approach to controlling this type of fouling. Without such action, these deposits are often strong and usually require high-velocity water jets or mechanical scraping to remove.
4. Freezing: Freezing occurs when the surface temperature is below the freezing point of the fouling substance (which may be a minor constituent, neon in a helium liquefaction process, for example). Freezing can only be avoided by ensuring that the surface temperature is always and everywhere above the freezing temperature of any constituent. This is an example of the proper use of cocurrent flow. The deposit is usually easily removed by periodically raising the temperature and flushing out the melted residue.
5. Polymerization, charring, or chemical reaction: Many substances will form deposits of high-molecular-weight solids when heated too strongly (often exacerbated by the presence of oxygen). The deposits may range from hard and brittle to sticky, and frequent, vigorous mechanical cleaning is often the only choice to control fouling. Designing for lower surface temperatures (e.g., higher velocities, cocurrent flow) is sometimes possible, but selection of heat-exchanger type and configuration to simplify mechanical cleaning is also important.
6. Biological fouling: Water systems are subject to microbiological fouling (growth of algae and bacterial films) and macrobiological fouling (growth of barnacles, mussels, and other large organisms). Microbiological fouling is an organic film structure with a high water content on the heat-transfer surface. Biological fouling can be minimized by use of copper alloy tubing and can be controlled by chlorination and similar chemical treatments, both of which introduce operational and environmental problems. Microbiological fouling often occurs in conjunction with sedimentation, inverse solubility, and/or corrosion fouling, and a water-treatment specialist should be consulted in these cases. Macrobiological fouling occurs most commonly on the tubesheets and header surfaces, where the local velocities are low enough to allow the larvae to gain a foothold. Once established, the organisms can grow large enough to interfere with or entirely block fluid flow to the heat-transfer channels. These organisms are firmly attached and require vigorous mechanical action to knock them off.

The best source of design information on fouling is to find someone who has had to deal with a similar situation in the past and can give a historical perspective on what happened and how it was dealt with. The literature, especially the book by Bott [66], can be a source of case studies and contacts, and this information is fairly freely shared in the profession. The specialty water treatment chemical suppliers have large files of recorded experience in that area, and there is increasing use of chemicals in controlling fouling in process streams as well.

7.1 INTRODUCTION

Radiation heat transfer is important in furnaces, flames, high-temperature materials processing and manufacturing, solar energy utilization, cooling and insulation in space, and cryogenic systems. Typical furnaces include ethylene, vinyl chloride, styrene, and steam generation units. Thermal radiation is relevant to many industrial heating, cooling, and drying processes. Even at room temperature, heat transfer by radiation is often on the same order of magnitude as that by free convection. The main features of radiation that are distinct from conduction and convection are: energy can be transferred without an intervening medium; and energy transfer is not proportional to the temperature difference between surfaces, and is dependent upon the surface radiative properties, which are functions of wavelength and temperature.

Although radiation can travel in a vacuum, it originates from matter. All forms of matter emit radiation through the mechanisms of electronic transitions and lattice vibrations. In most solids and liquids, radiation emitted from the interior is strongly absorbed by adjoining molecules. Therefore, radiation from these materials can be treated as a surface phenomenon. Radiation in gases and some semitransparent solids and liquids, however, must be treated as a volumetric phenomenon.

Radiation travels at the speed of light, which is $c_0 = 2.9979 \times 10^8$ m/s in vacuum. Radiative transport is alternatively viewed as the propagation of a collection of particles, called photons, or

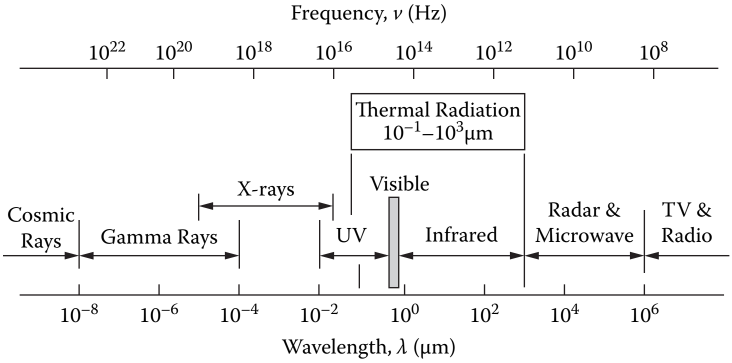

FIGURE 7.1 Thermal radiation: a region of the electromagnetic-wave spectrum.

as electromagnetic waves. In the *particle theory*, the energy of an individual photon is proportional to its frequency,

$$E_{\text{photon}} = h\nu \tag{7.1}$$

where $h = 6.6261 \times 10^{-34}$ J·s is Planck's constant, and ν is the frequency [Hz]. The momentum of each photon is $h\nu/c$. The particle theory is important in deriving the spectral distribution of thermal radiation and in the study of gas emission and absorption. The *wave theory* treats radiation as electromagnetic waves. One of the most important characteristics of a wave is its wavelength λ, which is related to its frequency and the speed of light by

$$\lambda\nu = c \tag{7.2}$$

The frequency is independent of the medium in which radiation propagates, but the speed of light and the wavelength are inversely proportional to the refractive index (n) of the medium. This is to say, $\lambda = \lambda_0 / n$ and $c = c_0 / n$. The refractive index of air is about 0.03% greater than 1 (the refractive index of vacuum), and therefore it is often approximated as 1.

Radiation at a single wavelength (or within a very narrow spectral band) is called monochromatic radiation (examples are lasers and high-temperature gas emission), whereas radiation in a broad wavelength region is called polychromatic or broadband radiation (such as that emitted from the sun). The visible spectrum covers the wavelength region from about 0.4 to 0.7 µm, a small region within the very broad electromagnetic spectrum shown in Figure 7.1. Thermal radiation, which is pertinent to heat transfer, refers to the spectral region from approximately 0.1 to 1000 µm, where the emission depends on temperature. It includes part of the ultraviolet region and the entire visible and infrared regions.

7.2 SURFACE EMISSION

7.2.1 Intensity, Emissive Power, and Irradiation

As illustrated in Figure 7.2, the *spectral intensity* of radiation emitted by an element surface dA in the direction (θ, ϕ) is defined as the rate of emitted energy (radiant power) dq per unit wavelength interval about λ, per unit solid angle about this direction, and per unit area of dA projected to the direction (θ, ϕ):

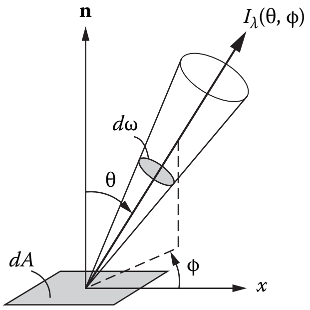

FIGURE 7.2 The definition of spectral intensity exitent from a surface.

$$I_\lambda(\lambda, \theta, \phi) = \frac{dq}{dA\cos\theta\, d\omega\, d\lambda} \tag{7.3}$$

where $d\omega = \sin\theta d\theta d\phi$, and the unit of I_λ is W/m²·sr·µm. The total intensity is the integral of the spectral intensity over all wavelengths.

The *emissive power E* is the total radiant power exitent from the surface (per unit area) toward the hemisphere due to thermal emission, which may be obtained by integrating dq in Equation (7.3) over the hemisphere and over all wavelengths. The spectral emissive power E_λ is the emissive power per unit wavelength interval about λ. If the emitted intensity is the same in all directions, the surface is called a diffuse emitter, for which $E = \pi I$ and $E_\lambda = \pi I_\lambda$.

The radiant power incident on a surface per unit area is called the *irradiation G*. Diffuse irradiation refers to the condition when the incident radiation is uniformly distributed in all directions, i.e., the incoming intensity is independent of the direction.

7.2.2 The Blackbody

The *blackbody* is an ideal surface that absorbs all incident radiation regardless of wavelength and direction. Furthermore, a blackbody is a diffuse emitter and, at any prescribed wavelength and temperature, no surface can emit more energy than a blackbody. The total emissive power of a blackbody depends only on its temperature and is given by the Stefan-Boltzmann law,

$$E_b = \pi I_b = \sigma T^4 \tag{7.4}$$

where $\sigma = 5.6704 \times 10^{-8}$ W/m²·K⁴ is the Stefan-Boltzmann constant, and T is the absolute temperature in kelvin [K]. In a medium of refractive index $n \neq 1$, the right-hand side (RHS) of Equation (7.4) needs to be multiplied by n^2. The spectral emissive power of a blackbody is given by Planck's law or the Planck distribution [1–4]:

$$E_{\lambda,b}(\lambda, T) = \pi I_{\lambda,b}(\lambda, T) = \frac{c_1}{\lambda^5 (e^{c_2/\lambda T} - 1)} \tag{7.5}$$

where $c_1 = 3.7418 \times 10^8$ W·µm⁴/m² and $c_2 = 1.4388 \times 10^4$ µm·K are called the first and second radiation constants, respectively. Equation (7.5) can be integrated over all wavelengths to obtain Equation (7.4).

At any specific wavelength, the higher the temperature, the greater the spectral emissive power. At any temperature, the emissive power approaches zero as $\lambda \to 0$, increases with wavelength until

it reaches a maximum, and then decreases to zero as $\lambda \to \infty$. The wavelength corresponding to the maximum emissive power λ_{max} can be determined by differentiating Equation (7.5) with respect to λ and setting the result to zero. The result is known as Wien's displacement law:

$$\lambda_{max} = c_3 / T \tag{7.6}$$

where $c_3 = 2897.8$ μm·K is sometimes called the third radiation constant. The fraction of emitted energy in the wavelength region from λ_1 to λ_2 is referred to as the blackbody band fraction and has the form

$$F_{\lambda_1-\lambda_2} = \frac{1}{\sigma T^4}\int_{\lambda_1}^{\lambda_2} E_{\lambda,b}\, d\lambda = \int_{\lambda_1 T}^{\lambda_2 T} \frac{c_1}{\sigma(\lambda T)^5 (e^{c_2/\lambda T} - 1)}\, d(\lambda T) \tag{7.7}$$

Figure 7.3a represents the Planck distribution for blackbody spectral emissive power with $E_{\lambda,b} / \sigma T^5$ as a function of λT. The band fraction of emitted energy in the region from 0 to λT is equal to the shaded area, which is expressed as $F_{0\to\lambda T}$ and shown in Figure 7.3b. About a quarter of the emitted energy is at wavelengths shorter than λ_{max}, and nearly 95% of the emitted energy is distributed between $0.6\lambda_{max}$ and $6\lambda_{max}$. The spectral distribution of solar radiation can be approximated as a blackbody at 5800 K. Therefore, $\lambda_{max} \approx 0.5$ μm, and the spectral region (95%) important for solar radiation is between 0.3 and 3 μm. For radiation from objects near room temperature, $\lambda_{max} \approx 10$ μm and the spectral region of importance (95%) is between 6 and 60 μm.

If $\lambda T \ll c_2$, the RHS of Equation (7.5) can be approximated as $c_1\lambda^{-5}e^{-c_2/\lambda T}$; this is known as Wien's approximate formula, which yields a relative error of less than 0.7% up to λ_{max}. If $\lambda T \gg c_2$, the RHS of Equation (7.5) is approximately equal to $c_1 T / c_2\lambda^4$, which is known as the Rayleigh-Jeans formula and is applicable only for very long wavelengths.

Blackbody radiation is achieved in an isothermal enclosure or cavity under thermodynamic equilibrium, as shown in Figure 7.4a. A uniform and isotropic radiation field is formed inside the enclosure. The total or spectral irradiation on any surface inside the enclosure is diffuse and identical to that of the blackbody emissive power. The spectral intensity is the same in all directions and is a function of λ and T given by Planck's law. If there is an aperture with an area much smaller compared with that of the cavity (see Figure 7.4b), λ the radiation field may be assumed unchanged and the outgoing radiation approximates that of blackbody emission. All radiation incident on the aperture is completely absorbed as a consequence of reflection within the enclosure. Blackbody cavities are used for measurements of radiant power and radiative properties, and for calibration of radiation thermometers (RTs) traceable to the International Temperature Scale of 1990 (ITS-90) [5].

7.3 RADIATIVE PROPERTIES OF SOLIDS

7.3.1 Emissivity

The ratio of the spectral emissive power of an object to that of a blackbody at the same temperature defines the spectral emissivity:

$$\varepsilon_\lambda(\lambda, T) \equiv \frac{E_\lambda(\lambda, T)}{E_{\lambda,b}(\lambda, T)} \tag{7.8}$$

The total emissivity is defined as and related to ε_λ by

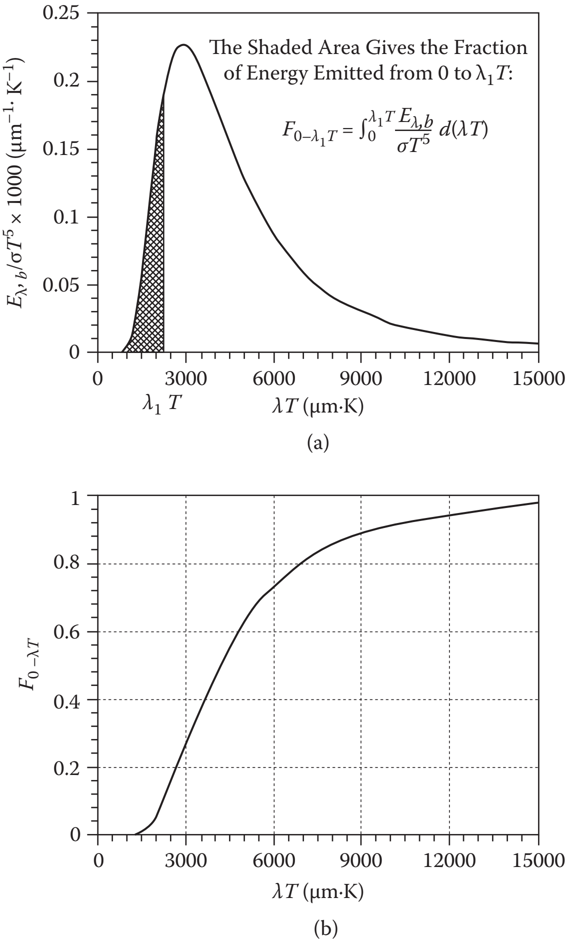

FIGURE 7.3 Blackbody characteristics: (a) Planck's law for spectral emissive power, and (b) band fraction for emission over the range from 0 to λT.

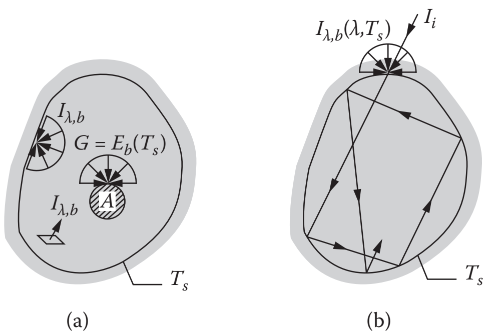

FIGURE 7.4 Blackbody characteristics for isothermal enclosures: (a) intensity is the same in all directions, and irradiation on any surface inside the enclosure is equal to the blackbody emissive power, and (b) emission through a small aperture approximates that of a blackbody, and the cavity acts as a perfect absorber.

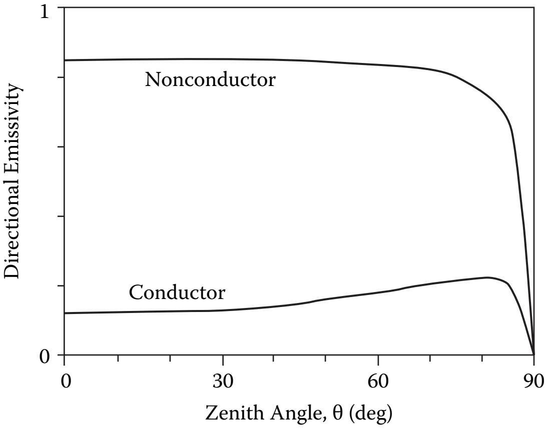

FIGURE 7.5 Directional distributions of the total directional emissivity for conductors (metals) and nonconductors (dielectrics).

$$\varepsilon(T) \equiv \frac{E(T)}{E_b(T)} = \frac{1}{\sigma T^4} \int_0^\infty \varepsilon_\lambda E_{\lambda,b}\, d\lambda \tag{7.9}$$

The ε_λ and ε defined above are hemispherical emissivities. The directional emissivities may be defined based on the ratio of the emitted (spectral or total) intensity to the blackbody (spectral or total) intensity. For a diffuse emitter, the emissivity is independent of the direction. For a *gray surface*, the emissivity is independent of wavelength, $\varepsilon = \varepsilon_\lambda$. In practice, the surface may be considered gray if the emissivity is independent of the wavelength over the spectral regions of irradiation and emission.

Many industrial materials have *spectrally selective* surfaces for which the emissivity is a complicated function of temperature, wavelength, and the direction of emission, and depends on the surface conditions. For perfectly smooth surfaces, the emissivity can be predicted from the electromagnetic wave theory [2–4]. Typical directional distributions of the total, directional emissivity are shown in Figure 7.5. For conductors (metallic materials), the emissivity is nearly constant for $\theta \le 40°$, increases to a maximum near 80°, and finally drops to zero. For nonconductors, the emissivity is nearly constant for $\theta \le 70°$ and decreases sharply to zero. The hemispherical emissivity is slightly higher (≤30%) than the normal emissivity for conductors and slightly lower (≤5%) than the normal emissivity for nonconductors. Diffuse emission is a good first-order approximation in many engineering applications, and the hemispherical emissivity may be assumed equal to the normal emissivity. The range of the total normal emissivities for a variety of materials near room temperature is listed in Table 7.1. The variation is mainly caused by the different types of materials and surface conditions. It can be seen that pure metals usually have a very low emissivity. Some spectrally selective materials that are highly reflecting in the visible may have a high emissivity (such as white paint and paper). The spectral and total normal emissivities for selected materials are shown in Figures 7.6 and 7.7 [1, 6]. The nature of surface finishing and coating can greatly affect the emissivity. A comprehensive compilation of radiative properties of solids is given by Touloukian and DeWitt [6].

Example 7.1

Assuming that ε_λ of stainless steel shown in Figure 7.6 is independent of temperature, how will its total emissivity ε change as the surface temperature increases?

TABLE 7.1
Ranges of the Total Normal Emissivity for Some Common Materials at 25°C

Material	ε_n
Highly polished metals, foils, and films	0.02–0.07
Polished metals	0.04–0.13
Unpolished metals	0.1–0.4
Oxidized metals	0.25–0.68
Oxides and ceramics	0.4–0.8
Graphite	0.76–0.94
Minerals and glasses	0.78–0.95
Vegetation, water, and skin	0.88–0.97
Special paints and anodized finishes	0.90–0.98

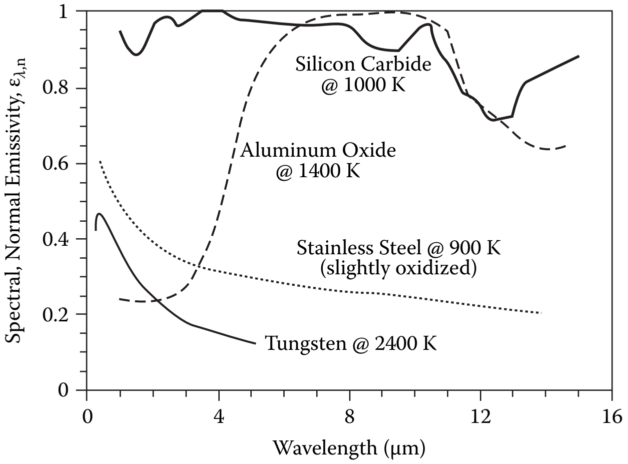

FIGURE 7.6 Spectral normal emissivity of selected materials. (Adapted from Incropera, F. P., and D. P. DeWitt, *Fundamentals of Heat and Mass Transfer*, 4th ed., Wiley, New York, 1996; and from Touloukian, Y. S., and D. P. DeWitt, *Thermal Radiative Properties*, vols. 7, 8, and 9, in *Thermophysical Properties of Matter*, TPRC Data Series, Y. S. Touloukian and C. Y. Ho, eds., IFI Plenum, New York, 1970–1972.)

Solution

As the temperature increases, the Planck distribution of the blackbody spectral emissive power will shift toward the short wavelength, so that more radiant power will be emitted at relatively shorter wavelengths. Using Equation (7.7), it can be estimated that at 400 K, less than 2% emitted power is at $\lambda < 4$ μm; whereas at 1000 K, more than 48% emitted power is at $\lambda < 4$ μm (see Figure 7.3b). Because the spectral emissivity decreases as the wavelength increases, the total emissivity will increase as temperature increases. The same reasoning can be used to explain the trends that the total emissivity of aluminum oxide decreases but that of tungsten increases as the temperature increases, as shown in Figure 7.7.

7.3.2 Absorptance, Reflectance, and Transmittance

When radiation is incident on an object, a portion of it is absorbed inside the material, another portion is reflected, and the remaining is transmitted. The absorptance α, reflectance ρ, or trans-

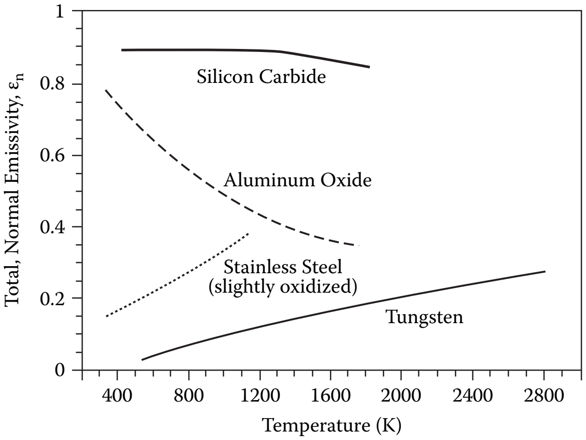

FIGURE 7.7 Temperature dependence of the total normal emissivity of selected materials. (Adapted from Incropera, F. P., and D. P. DeWitt, *Fundamentals of Heat and Mass Transfer*, 4th ed., Wiley, New York, 1996; and from Touloukian, Y. S., and D. P. DeWitt, *Thermal Radiative Properties*, vols. 7, 8, and 9, in *Thermophysical Properties of Matter*, TPRC Data Series, Y. S. Touloukian and C. Y. Ho, eds., IFI Plenum, New York, 1970–1972.)

mittance τ are defined, respectively, as the fraction of irradiation that is absorbed, reflected, or transmitted by the object. The radiative energy balance on the irradiated surface yields

$$\alpha + \rho + \tau = 1 \tag{7.10}$$

For an opaque object ($\tau = 0$), the reflectance and absorptance are also referred to as reflectivity and absorptivity in some literature. The subscript λ may be added to specify spectral properties. The total absorptance α is related to the spectral absorptance α_λ by

$$\alpha = \int_0^\infty \alpha_\lambda G_\lambda(\lambda) d\lambda \Big/ \int_0^\infty G_\lambda(\lambda) d\lambda \tag{7.11}$$

where $G_\lambda(\lambda)$ represents the spectral distribution of the irradiation. In general, the value of α depends on the spectral and directional distributions of the incident radiation (the radiative environment to which the surface is exposed) and the spectral absorptance. Equation (7.11) also holds for the reflectance or transmittance when α is replaced by ρ or τ.

Sometimes it is important to consider the direction of reflected irradiation exitent from a surface. A property called the bidirectional reflectance distribution function (BRDF) is used to specify the directional distribution of the reflected intensity for a specified direction of incident radiation [2–4]. A specular surface is a mirrorlike surface for which the incidence angle is equal to the reflection angle. For a diffusely reflecting surface, the reflected intensity is the same in all directions, and if perfectly reflective, the BRDF is $1/\pi$ sr^{-1}.

7.3.3 Kirchhoff's Law

Consider an object in a blackbody enclosure. Under thermodynamic equilibrium, the emitted radiant power $\varepsilon A_s E_b$ must equal the absorbed power $\alpha A_s G$, where A_s is the area of the surface. Because $G = E_b$, it follows that

$$\varepsilon = \alpha \tag{7.12}$$

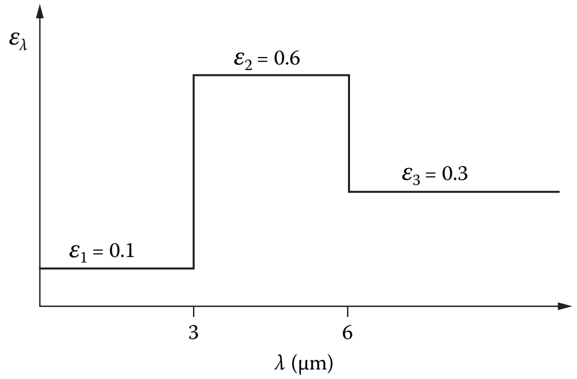

FIGURE 7.8 Example 7.2: spectral emissivity distribution of the spectrally selective surface.

It can also be shown that $\varepsilon_\lambda = \alpha_\lambda$ under the same condition [2]. These equalities between emissivities and absorptivities are known as Kirchhoff's laws. Because the absorptivity depends on the irradiation conditions, Kirchhoff's relations may not hold in general, except for the directional, spectral properties. It can be shown that $\varepsilon_\lambda = \alpha_\lambda$ if a surface is diffuse or diffusely irradiated. Furthermore, $\varepsilon = \alpha$ if the surface is diffuse-gray.

Example 7.2

Consider a hypothetical surface that is opaque and diffuse. At 300 K, its spectral emissivity ε_λ may be approximated with the wavelength dependence shown in Figure 7.8. Determine its total emissivity, ε, and the absorptivity for radiation from the sun, α_S, and a blackbody furnace at 2000 K, α_f.

Solution

The total emissivity can be calculated from the spectral emissivity using the Planck distribution; see Equation (7.9). Using Equation (7.7), it can be shown that at 300 K nearly 98% of the blackbody radiation is at wavelengths longer than 6 μm; therefore, the total emissivity at 300 K is equal to the spectral emissivity beyond 6 μm (see Figure 7.8). Hence, $\varepsilon \approx \varepsilon_3 = 0.3$. Because the surface is diffuse, from Kirchhoff's law, $\alpha_\lambda = \varepsilon_\lambda$. The total absorptivity can be calculated from Equation (7.11). The irradiation from the sun is proportional to the emissive power of a blackbody at 5800 K. Nearly 97% of the solar irradiation is at wavelengths below 3 μm; hence, the solar absorptivity is $\alpha_s \approx \varepsilon_1 = 0.1$ (see Figure 7.8). For a furnace at 2000 K, $G_\lambda \propto E_{\lambda,b}(\lambda, T)$; from Equation (7.11), we have

$$\alpha_f = \frac{1}{\sigma T^4}\int_0^\infty \varepsilon_\lambda E_{\lambda,b} d\lambda = \varepsilon_1 F_{0-\lambda_1 T} + \varepsilon_2 (F_{0-\lambda_2 T} - F_{0-\lambda_1 T}) + \varepsilon_3 (1 - F_{0-\lambda_2 T})$$

$$= 0.1 \times 0.7378 + 0.6 \times (0.9451 - 0.7378) + 0.3 \times (1 - 0.9451) = 0.2146\ .$$

where Equation (7.7) has been used to compute the band fractions. One can also use Figure 7.3b to obtain a rough estimate. Note that for spectrally selective surfaces (like the one given in this example), in general, $\varepsilon \neq \alpha$.

7.4 RADIATIVE ENERGY EXCHANGE BETWEEN SURFACES

7.4.1 Radiosity

The radiation exitent from an opaque surface can include emitted and reflected components. The *radiosity* is the sum of the emissive power and the portion of irradiation that is reflected by the

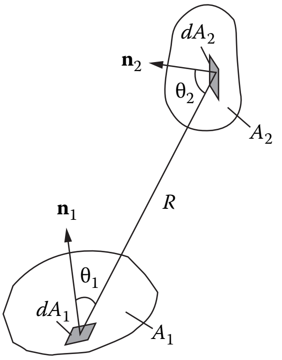

FIGURE 7.9 Definition of the view factor.

surface. The *total* radiosity is $J = \rho G + E$, and the *spectral* radiosity is $J_\lambda = \rho_\lambda G_\lambda + E_\lambda$. Radiosity is a useful concept in calculating radiation exchange between surfaces. Like E and G, J is also a hemispherical property.

7.4.2 The View Factor

Radiative exchange between diffuse-gray and opaque surfaces, including blackbodies, have many engineering applications. In the simplest case, the medium between the surfaces can be assumed *nonparticipating* (no absorption, emission, or scattering during propagation). The *view factor* (also called the configuration factor or shape factor) F_{ij} is defined as the fraction of radiation leaving surface i that is intercepted by surface j. For diffuse-gray surfaces with uniform radiosity, the view factor from A_1 to A_2 (see Figure 7.9) is

$$F_{12} = \frac{1}{A_1} \int_{A_2} \int_{A_1} \frac{\cos\theta_1 \cos\theta_2}{\pi R^2} dA_1 dA_2 \tag{7.13}$$

The view factor depends only upon the geometric arrangement of the surfaces, and satisfies the *reciprocity relation* $A_i F_{ij} = A_j F_{ji}$. The view factor must be between 0 and 1. In an enclosure consisting of N surfaces, the *summation rule* gives

$$\sum_{j=1}^{N} F_{ij} = 1$$

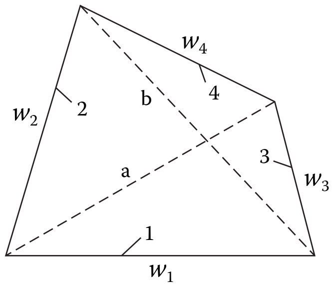
The term F_{ij} refers to the fraction of radiation that leaves surface i and is directly intercepted by surface i itself. For flat or convex surfaces, $F_{ij} = 0$; and for concave surfaces, F_{ij} is nonzero. Table 7.2 provides equations for calculating the view factors for some common configurations often encountered in practical applications [1, 2, 8]. The view factors for more complicated geometries can be found in [2].

7.4.3 Radiation Exchange between Blackbody Surfaces

If all surfaces are blackbodies, the net radiative heat-transfer rate from surface i to j is

$$q_{ij} = E_{bi} A_i F_{ij} - E_{bj} A_j F_{ji} = A_i F_{ij} (\sigma T_i^4 - \sigma T_j^4) \tag{7.14}$$

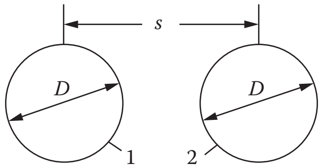
TABLE 7.2
View Factors for Some Simple Common Geometries



Long Strips (cross-strings method [8])

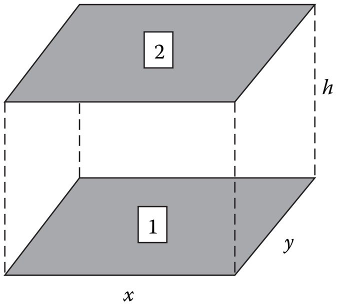
$$F_{12} = \frac{w_1 + w_2 - b}{2w_1}; \; F_{13} = \frac{w_1 + w_3 - a}{2w_1}$$

$$F_{14} = \frac{a + b - w_2 - w_3}{2w_1}$$



Long Cylinders of the Same Diameter

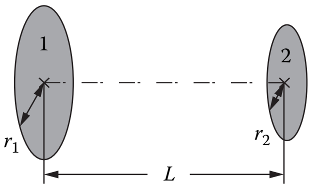
$$F_{12} = \frac{1}{\pi}\left[\sin^{-1}\left(\frac{D}{s}\right) + \sqrt{\left(\frac{s}{D}\right)^2 - 1} - \frac{s}{D}\right]$$



Aligned Parallel Rectangles

$$F_{12} = \frac{2}{\pi XY}\left[\ln\frac{AB}{\sqrt{1 + X^2 + Y^2}} + XB\tan^{-1}\frac{X}{B} + YA\tan^{-1}\frac{Y}{A} - X\tan^{-1}X - Y\tan^{-1}Y\right]$$

where $X = x/h$, $Y = y/h$, $A = \sqrt{1 + X^2}$, and $B = \sqrt{1 + Y^2}$



Coaxial Parallel Disks

$$S = 1 + \frac{1 + (r_2/L)^2}{(r_1/L)^2}$$

$$F_{12} = \frac{1}{2}\left[S - \sqrt{S^2 - 4\left(\frac{r_2}{r_1}\right)^2}\right]$$

Howell, *Thermal Radiation Heat Transfer*, 3rd ed., Hemisphere, Washington, 1992; and Hottel, H. C., and A. F. Sarofim, *Radiative Transfer*, McGraw-Hill, New York, 1967.

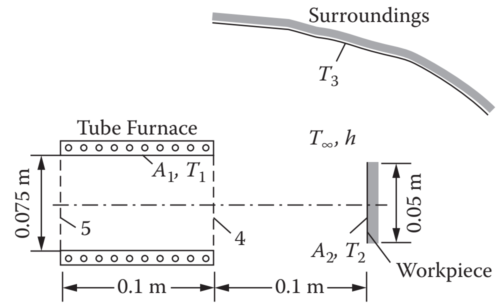


FIGURE 7.10 Example 7.3: tube furnace (1), workpiece (2), and surroundings (3) form a three-black-surface enclosure.

In an enclosure of N blackbody surfaces, the net radiative heat-transfer rate from surface i is

$$q_i = \sum_{j=1}^{N} q_{ij} = \sum_{j=1}^{N} A_i F_{ij} (\sigma T_i^4 - \sigma T_j^4), \quad i = 1, 2, \ldots, N \tag{7.15}$$

Given the geometry of the enclosure, if the temperatures of all the surfaces are known, Equation (7.15) can be used to determine the net radiative transfer from each surface. If the temperatures of k $(1 \le k \le N)$ surfaces and the net heat transfer from the remaining $(N - k)$ surfaces are known, Equation (7.15) may be solved to obtain the unknown temperatures and the net heat-transfer rates.

Example 7.3

An electrically heated tubular furnace with a black inner surface of uniform temperature T_1 = 1200 K irradiates a coaxial thin disk workpiece, as shown in Figure 7.10. The surface of the disk facing the furnace is painted black and the back side is well insulated. The furnace heater and the workpiece are placed in a large room with a uniform wall temperature T_3 (isothermal surroundings) of 300 K and air temperature T_∞ = 293 K. Determine the temperature of the disk, T_2, by (a) neglecting convective heat transfer and (b) including convective heat transfer, assuming the convective heat-transfer coefficient between the disk and the air is h = 10 W/m^2·K.

Solution

(a) The black surface of the furnace (1), workpiece (2) and surroundings (3) form a three-surface enclosure. Performing a radiative energy balance on the workpiece, $q_{1-2} - q_{2-3} = 0$, and using the reciprocity relation $A_1F_{12} = A_2F_{21}$, find $A_2F_{21}\sigma(T_1^4 - T_2^4) - A_2F_{23}\sigma(T_2^4 - T_3^4) = 0$. The view factor F_{21} may be calculated using the relation between two concentric disks (Table 7.2), $F_{21} = F_{24} - F_{25} = 0.086$, where 4 and 5 are the hypothetical circular surfaces at the right end and left end of the heating tube, respectively. Also, $F_{23} = 1 - F_{21}$. The result is T_2 = 655.6 K.

(b) The energy balance for surface 2 including convection is $q_{1-2} - q_{2-3} - q_{conv} = 0$, or

$$A_2F_{21}(\sigma T_1^4 - \sigma T_2^4) - A_2F_{23}(\sigma T_2^4 - \sigma T_3^4) - A_2h(T_2 - T_\infty) = 0$$

Solving by iteration, find T_2 = 601 K. Although convective heat loss is only about half of the radiative heat loss, it should not be neglected.

7.4.4 Enclosure with N Diffuse-Gray Surfaces—The Net Radiation Method

Consider an enclosure of N diffuse-gray, opaque surfaces, each surface being isothermal and having a uniform radiosity and irradiation. The radiative energy balance for the ith surface gives $q_i = A_i(J_i - G_i)$, where $J_i \equiv E_i + \rho_i G_i = \varepsilon_i E_{bi} + (1-\varepsilon_i)G_i$. Combining these two equations to eliminate G_i, one obtains

$$q_i = \frac{A_i \varepsilon_i}{1-\varepsilon_i}(E_{bi} - J_i) \tag{7.16}$$

The total radiation reaching surface i from the N-isothermal surfaces in the enclosure (including itself) is

$$A_i G_i = \sum_{j=1}^{N} A_j F_{ji} J_j = \sum_{j=1}^{N} A_i F_{ij} J_j$$

Therefore,

$$q_i = A_i\left(J_i - \sum_{j=1}^{N} F_{ij} J_j\right) = \sum_{j=1}^{N} A_i F_{ij}(J_i - J_j) = \sum_{j=1}^{N} q_{ij} \tag{7.17}$$

where q_{ij} is the net radiative heat-transfer rate from surface i to surface j.

If the surface temperature T_i is specified for surfaces i = 1, 2, …, k ($1 \le k \le N$) and the net radiative heat rate q_i is specified for surfaces $i = k+1, k+2, \ldots, N$, then Equations (7.16) and (7.17) may be rearranged as the following:

$$\begin{cases} \dfrac{\sigma T_i^4 - J_i}{(1-\varepsilon_i)/\varepsilon_i A_i} = \displaystyle\sum_{j=1}^{N} \frac{J_i - J_j}{1/A_i F_{ij}}, & i = 1, 2, 3, \ldots, k \\ \displaystyle\sum_{j=1}^{N} \frac{J_i - J_j}{1/A_i F_{ij}} = q_i, & i = k+1, k+2, \ldots, N \end{cases} \tag{7.18}$$

which gives N-linear algebraic equations that can be solved simultaneously for the N-unknown radiosities $J_1, J_2, \ldots, J_N$. The unknown q_i (i = 1, 2, …, k) and T_i ($i = k+1, k+2, \ldots, N$) can be calculated using Equation (7.18). The above equations may be rearranged in matrix format and solved by matrix inversion [2, 3].

If the temperature of each surface is specified, the spectral intensity leaving a surface is the sum of the emitted and the reflected intensities, therefore,

$$I_{\lambda,i} = \varepsilon_{\lambda,i} I_{\lambda,b} + (1-\varepsilon_{\lambda,i})\sum_{j=1}^{N} F_{ij} I_{\lambda,j}, \quad i = 1, 2, \ldots N \tag{7.19}$$

The N-linear algebraic equations given above can be solved for the spectral intensities $I_{\lambda,i}$. The foregoing treatment, the net-radiation method, is limited to opaque, diffuse-gray surfaces, which can be extended to include some specular surfaces using the *imaging method*. If the irradiation is not uniform, the *integration method* using differential surfaces is often used. In addition, the *Monte Carlo method*, which is a statistical method, can also be used to determine the radiative heat transfer between enclosure surfaces. Detailed discussions of these more complicated can be found in the literature [2–4, 7, 8].

7.4.5 The Network Representation

The radiative energy balances of Equations (7.16) and (7.17) can be represented in a network. Compared with an electric network, E_b and J_i are analogous to the potential, q_i and q_{ij} are analogous to the current, and $(1-\varepsilon_i)/A_i\varepsilon_i$ and $1/A_iF_{ij}$ are analogous to the resistances. The network analogy provides a useful way for visualizing radiation exchange in an enclosure and is a convenient tool for calculating the radiative exchange in an enclosure consisting of two or three surfaces. For an enclosure of two surfaces, using the *network method* as shown in Figure 7.11,

$$q_1 = -q_2 = q_{12} = \frac{\sigma T_1^4 - \sigma T_2^4}{\dfrac{1-\varepsilon_1}{\varepsilon_1 A_1} + \dfrac{1}{A_1 F_{12}} + \dfrac{1-\varepsilon_2}{\varepsilon_2 A_2}} \tag{7.20}$$

If surface 1 is a plane wall exposed to isothermal surroundings as shown in Figure 7.12a, then $F_{12} = 1$ and $A_1/A_2 << 1$. The net radiative heat-transfer rate from A_1 to its surroundings is

$$q_{\text{rad}} = q_1 = A_1\varepsilon_1\sigma(T_1^4 - T_{\text{sur}}^4) \tag{7.21}$$

Radiative heat transfer is often coupled with convective heat transfer to form the boundary conditions for conduction problems. A *radiation heat transfer coefficient* may be defined by $q_{\text{rad}} = A_1 h_{\text{rad}}(T_1 - T_{\text{sur}})$, where $h_{\text{rad}} = \varepsilon_1\sigma(T_1^2 + T_{\text{sur}}^2)(T_1 + T_{\text{sur}})$ is a strong function of the temperatures and emissivity. As a first-order estimate, h_{rad} may be compared with the convection heat transfer

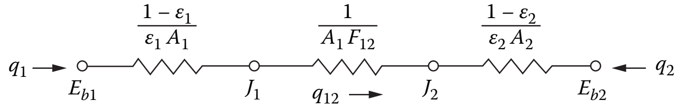

FIGURE 7.11 The radiation network for a two-surface enclosure.

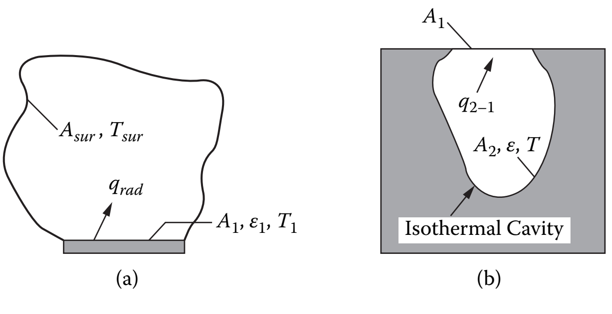

FIGURE 7.12 Applications of net radiation exchange between two surfaces: (a) a small, convex surface and large, isothermal surroundings; (b) an isothermal cavity radiating into cold, black surroundings.

coefficient (h) in a particular problem to see whether radiation heat transfer is significant. For a surface at 310 K, with an emissivity of 0.8 and the surroundings at 298 K, $h_{rad} \approx 5$ W/m^2·K, which is comparable with the values of h (2 to 10 W/m^2·K) due to natural convection of air in the same temperature range [1].

Another application of the two-surface enclosure is to determine the effective (apparent) emissivity of an isothermal cavity, as shown in Figure 7.12b. The effective emissivity is defined as the ratio of the radiant power from the cavity to that emitted by a blackbody of the same temperature with an area equal to the cavity opening. The radiation leaving surface 2 to the space above the cavity opening (surface 1) q_{2-1} may be obtained from Equation (7.20) by setting surface 1 as a blackbody at 0 K. Hence,

$$\varepsilon_{eff} = \frac{q_{2-1}}{A_1 \sigma T^4} = \frac{\varepsilon}{\varepsilon + (1-\varepsilon) A_1/A_2} = \frac{\varepsilon}{1-(1-\varepsilon)(1-A_1/A_2)} \tag{7.22}$$

As expected, the effective emissivity reaches unity as A_1/A_2 approaches zero. The effective absorptivity α_{eff} is equal to ε_{eff} and may be viewed as the ratio of the radiant energy absorbed by the cavity walls to that incident through the opening. Blackbody cavities have important applications in radiometry and radiation thermometry.

Example 7.4

In a petrochemical furnace as shown in Figure 7.13, a bank of tubes containing the process fluid is heated to $T_2 = 600$ K by placing the tubes between a large hot plate (with area A_1) and a refractory (insulated) wall ($A_3 = A_1$). The hot plate, with an emissivity of $\varepsilon_1 = 0.7$, is maintained at $T_1 = 1200$ K. The emissivity of the tube is $\varepsilon_2 = 0.5$. The diameter of each tube is $D = 50$ mm and the central distance between adjacent tubes is $s = 100$ mm. (a) Determine the heating rate that must be provided to the hot plate per unit surface area. (b) Determine the temperature of the refractory surface. (c) If the tubes are to be heated to $T_2' = 800$ K with the same heat-transfer rate, what is the required hot wall temperature T_1'?

Solution

Neglect convection heat transfer, and assume all surfaces are diffuse, gray, and of infinite extent. Since the bottom wall (A_3) is insulated, the net radiative heat flux at that surface must be zero. This type of surface is called a *reradiating surface*. The radiation network is shown in Figure 7.14. For an area of 1 m^2, $A_1 = A_3 = 1$ m^2, the number of tubes is $M = 10$, and the length of each tube is $L = 1$ m. Hence, $A_2 = M\pi DL = 1.57$ m^2 (the surface area of the tubes). If there were only one tube and the plates were infinitely large, the view factor between the tube and each plate would be 0.5.

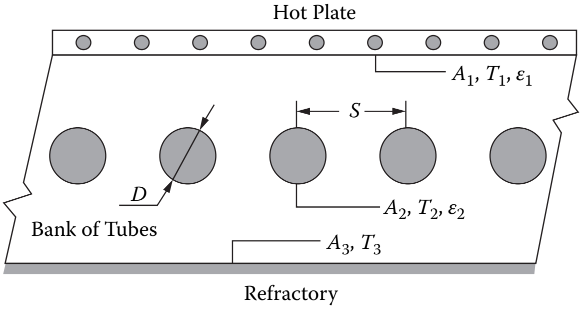

FIGURE 7.13 Example 7.4: hot furnace plate (1), tubes (2), and refractory wall (3) form a three-surface enclosure with a reradiating surface.

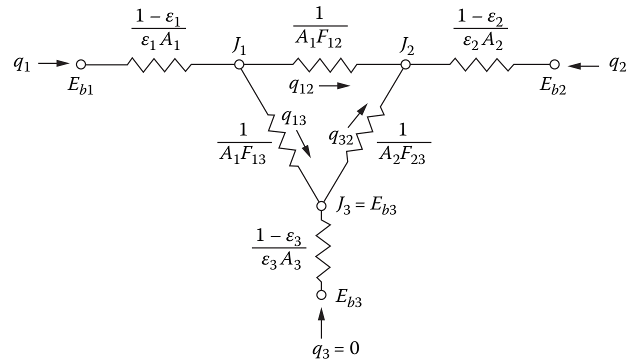

FIGURE 7.14 Network representation for a three-surface enclosure.

The view factor between the tube bank and each plate can be approximated by subtracting the view factor between two tubes from 0.5:

$$F_{21} = F_{23} = \frac{1}{2} - \frac{1}{\pi}\left[\sin^{-1}\frac{D}{s} + \sqrt{\left(\frac{s}{D}\right)^2 - 1} - \frac{s}{D}\right] = 0.4186$$

Therefore, $F_{12} = \frac{A_2}{A_1}F_{12} = 0.6576$ and $F_{13} = 1 - F_{12} = 0.3424$.

(a) $$q_1 = q_{12} = -q_2 = \frac{\sigma(T_1^4 - T_2^4)}{\frac{1-\varepsilon_1}{A_1\varepsilon_1} + \left(A_1F_{12} + \frac{1}{1/A_1F_{13} + 1/A_2F_{23}}\right)^{-1} + \frac{1-\varepsilon_2}{A_2\varepsilon_2}}$$

$$= \frac{5.67\times10^{-8}(1200^4 - 600^4)}{\frac{1-0.7}{0.7} + \left(0.6576 + \frac{1}{1/0.3424 + 1/(1.57\times0.4186)}\right)^{-1} + \frac{1-0.5}{1.57\times0.5}}$$

$= 50.14$ kW/m^2

(b) $J_1 = E_{b1} - q_1\left(\frac{1-\varepsilon_1}{A_1\varepsilon_1}\right) = 96.08$ kW/m^2, $J_2 = E_{b2} - q_2\left(\frac{1-\varepsilon_2}{A_2\varepsilon_2}\right) = 39.29$ kW/m^2

$$A_1F_{13}(J_1 - E_{b3}) = A_2F_{23}(E_{b3} - J_2)$$

yields $E_{b3} = 58.74$ kW/m^2 and $T_3 = 1009$ K.

(c) Because q_{12} and all the geometric parameters and emissivities have not changed, we have $T_1^4 - T_2^4 = T_1'^4 - T_2'^4$, which can be solved to obtain $T_1' = 1238.6$ K. That is to say, for the same heat transfer rate, only a 40 K temperature increase in T_1 will increase the tube temperature by 200 K.

Note that the emissivity value of the reradiating surface does not affect the results. If surfaces A_1 and A_2 are treated as blackbodies, $\varepsilon_1 = \varepsilon_2 = 1$, then the predicted net radiative heat transfer rate q_{12} would be 97.3 kW/m^2, which is almost twice the value calculated in part (a).

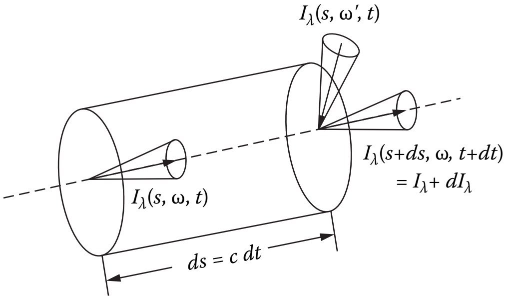

FIGURE 7.15 Radiative transfer in a participating medium.

7.5 GAS AND PARTICLE RADIATION

The above discussion assumes that the medium between surfaces does not participate in the thermal radiative process, which is a good approximation for nonpolar gases, such as Ar, N_2, and O_2. Polar gases, such as carbon dioxide, water vapor, and hydrocarbon gases, emit and absorb radiation in specific wavelength intervals (i.e., bands) over a wide range of temperatures. Gas molecules and aerosol in the atmosphere, pulverized coal in a combustor, and soot in flames can also scatter radiation. Radiative transfer in *participating media* is important in the study of the earth's radiation environment and in combustion processes. A brief summary of the radiative transfer equation and radiative properties of gases and particles is given here.

7.5.1 Radiative Transfer Equation

As shown in Figure 7.15, the spectral intensity in a participating medium, $I_\lambda = I_\lambda(s,\omega,t)$, depends on the location, the coordinate s, its direction (represented by the solid angle ω), and the time t. In a time interval dt, the beam travels from s to $s + ds$ ($ds = c\ dt$), and the intensity is (a) attenuated by absorption and scattering and (b) enhanced by emission and in-scattering. The macroscopic description of the radiation intensity is known as the *radiative transfer equation (*RTE) [4]:

$$\frac{dI_\lambda}{ds} = \frac{1}{c}\frac{\partial I_\lambda}{\partial t} + \frac{\partial I_\lambda}{\partial s} = \kappa_\lambda I_{\lambda,b}(T) - \beta_\lambda I_\lambda + \frac{\sigma_\lambda}{4\pi}\int_{4\pi} I_\lambda(s,\omega',t)\Phi_\lambda(\omega',\omega)d\omega' \quad (7.23)$$

where κ_λ and σ_λ are the absorption and scattering coefficients, respectively; $\beta_\lambda = \kappa_\lambda + \sigma_\lambda$ is the attenuation (or extinction) coefficient; and $\Phi_\lambda(\omega',\omega)$ is the *scattering phase function* ($\Phi_\lambda \equiv 1$ for isotropic scattering). The RHS of Equation (7.23) is composed of three terms: the first one accounts for the contribution of emission (which depends on the local temperature T); the second one is the attenuation by absorption and scattering; and the third one is the contribution of in-scattering from all directions (solid angle 4π) to the direction ω.

In most engineering applications, the transient term is negligible. The *single scattering albedo* is defined as $\Omega_\lambda = \sigma_\lambda / \beta_\lambda$. A dimensionless optical coordinate (sometimes called optical thickness) is often used, which is defined as

$$\zeta_\lambda = \int_0^s \beta_\lambda ds$$

The RTE in terms of the optical coordinate and the single scattering albedo is [2–4]

$$\frac{dI_\lambda}{d\zeta_\lambda} + I_\lambda = (1-\Omega_\lambda)I_{\lambda,b} + \frac{\Omega_\lambda}{4\pi}\int_{4\pi} I_\lambda(\zeta_\lambda,\omega')\Phi_\lambda(\omega',\omega)d\omega' \tag{7.24}$$

This is an integro-differential equation, and its RHS is called the source function. The boundary conditions also need to be specified. The integration of the spectral intensity over all wavelengths and all directions gives the radiative heat flux. Unless the temperature field is prescribed, Equation (7.24) is generally coupled with the thermal diffusion equation in a macroscopically stationary medium and with the energy conservation equation in a fluid with bulk movement. Under radiation equilibrium (steady state with no heat generation and without conduction or convection), the governing equation (energy equation) prescribes that the divergence of the radiative heat flux is zero.

Analytical solutions of the RTE rarely exist for applications with multidimensional and non-homogeneous media. Approximate models have been developed to deal with special types of problems, including Hottel's *zonal method* [8], the *differential and moment methods* (often using the spherical harmonic approximation), and the *discrete ordinates method*. The statistical model using the Monte Carlo method is often used for complicated geometries and radiative properties. Detailed discussions of these solution methods can be found in the literature [2–4, 7, 8] and are beyond the scope of this chapter. For an isothermal medium without scattering, integrating the RTE yields

$$I_\lambda(\zeta_\lambda) = I_\lambda(0)e^{-\zeta_\lambda} + I_{\lambda,b}(1-e^{-\zeta_\lambda}) \tag{7.25}$$

where $e^{-\zeta_\lambda}$ and $(1-e^{-\zeta_\lambda})$ may be regarded, respectively, as the transmissivity and emissivity of the gas along the path length 0 to s. Optically thin and optically thick limits refer to the cases when $\zeta_\lambda << 1$ (essentially transparent) and $\zeta_\lambda >> 1$ (essentially opaque).

As an example, consider a sphere of radius R with a black wall of temperature T_w filled with an isothermal gas at T_g, as shown in Figure 7.16. Neglect scattering and assume that the gas has a refractive index of 1 and an absorption coefficient κ that is independent of the wavelength (gray assumption). The spectral intensity at the wall is a function of angle θ. From Equation (7.25), we have $I_\lambda(\theta) = I_{\lambda,b}(T_w)e^{-2\kappa R\cos\theta} + I_{\lambda,b}(T_g)(1-e^{-2\kappa R\cos\theta})$. Since κ is not a function of the wavelength, a similar expression can be written for the total intensity by omitting the subscript λ. The heat flux on the wall can be obtained by integrating the intensity over the hemisphere:

$$q'' = \int_{\phi=0}^{2\pi}\int_{\theta=0}^{\pi/2} I(\theta)\cos\theta\sin\theta d\theta d\phi.$$

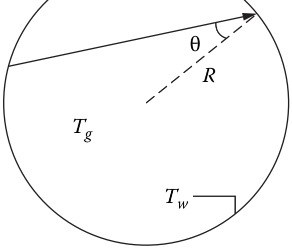

FIGURE 7.16 Example 7.5: an isothermal gas in a sphere.

The result is $q'' = \tau_g E_b(T_w) + \varepsilon_g E_b(T_g)$, where τ_g is regarded as the mean transmissivity, and $\varepsilon_g = 1 - \tau_g$ is the mean emissivity (which is the same as the mean absorptivity $\alpha_g = 1 - \tau_g$). The integration yields $\tau_g = 2(2\kappa R)^{-2}[1-(1+2\kappa R)e^{-2\kappa R}]$. The radiative heat-transfer rate from the gas to the wall is readily calculated from $q = 4\pi R^2(\varepsilon_g \sigma T_g^4 - \alpha_g \sigma T_w^4)$. In practice, the gas emits and absorbs at particular wavelength bands. Finding the mean total emissivity and absorptivity is important for first-order engineering heat-transfer calculations.

7.5.2 Radiative Properties of Gases and Particles

The molecular diameter of common gases is on the order of nanometers, much smaller than the wavelengths important for thermal radiation. Therefore, scattering by molecular gases is usually negligible in radiative heat transfer. When radiation travels through a cloud of gas, some of the energy may be absorbed. The absorption of radiant energy (or photons) raises the energy levels of individual molecules. Conversely, gas molecules may spontaneously lower their energy levels and emit photons. These changes in energy levels are called *radiative transitions*, which include bound-bound transitions (between nondissociated molecular states), bound-free transitions (between non-dissociated and dissociated states), and free-free transitions (between dissociated states).

Bound-free and free-free transitions usually occur at very high temperatures (greater than about 5000 K) and are in the ultraviolet and visible regions. The most important transitions for radiative heat transfer are bound-bound transitions between vibrational energy levels coupled with rotational transitions. The photon energy (or frequency) must be exactly the same as the difference between two energy levels if the photon is to be absorbed or emitted; therefore, the quantization of the energy levels results in discrete spectral lines for absorption and emission. The rotational lines superimposed on a vibrational line give a band of closely spaced spectral lines, called the vibration-rotation spectrum. In addition to the natural line broadening due to Heisenberg's uncertainty principle, collision and Doppler effects are two other reasons for line broadening, although the resulting lines are often still very narrow, on the order of 0.05 cm^{-1}. Wavenumber (in cm^{-1}), which is the inverse of wavelength, is often used to describe the spectral lines. The shape and width of each line depend on the temperature and pressure of the medium. The Lorentz profile is commonly used to define the shape of these lines for most engineering applications. More elaborated discussions on the absorption and emission mechanisms can be found in the literature [2–4]. A detailed treatment on the radiative properties of gases was given by Tien [9].

The large number of quantum states in polyatomic gases can produce spectral lines that are spaced very close to each other; some lines may overlap as a consequence of broadening. The results are called vibration-rotation bands. Band models are therefore developed to facilitate the computation of the total radiative properties. In a narrow-band model, the absorption coefficients of individual lines are added up in a spectral interval of 50 cm^{-1} or so. Narrow-band models are much simpler than the line-by-line calculation, yet still require a large database and significant computational effort. The wide-band models, on the other hand, predict the total absorption and emission over an entire vibrational band. Typical wide-band models are the box model and the exponential wide-band model. Among other gases, water vapor (H_2O) and carbon dioxide (CO_2) are the major species that participate in radiative transfer, both in the atmosphere and in combustion furnaces. The four most important bands for H_2O are centered at wavelengths of 1.38 μm (7250 cm^{-1}), 1.87 μm (5350 cm^{-1}), 2.7 μm (3760 cm^{-1}), and 6.3 μm (1600 cm^{-1}). For CO_2, the major bands are at 2.7 μm (3715 cm^{-1}), 4.3 μm (2349 cm^{-1}), and 15 μm (667 cm^{-1}). For CO, the major absorption band is at 4.7 μm (2143 cm^{-1}). Detailed formulations and parameters for various gas species can be found in the literature [2–4].

For heat-transfer calculations in many engineering applications, only the spectrally integrated (i.e., total) gas emissivity and absorptivity are needed in the calculation. For isothermal gases, the band emissivity can be integrated considering the blackbody intensity distribution at the gas temperature. If two absorbing gases appear together, the integration can be performed separately

and the total emissivities should be added and then subtracted by the contribution of the overlapping bands; hence,

$$\varepsilon_{a+b} = \varepsilon_a + \varepsilon_b - \Delta\varepsilon_{ab} \tag{7.26}$$

where subscripts *a* and *b* represent two different gases, typically H_2O and CO_2, and $\Delta\varepsilon_{ab}$ is the contribution due to overlapping bands (which is about 2.7 μm for H_2O and CO_2). A similar expression can be obtained for the total absorptance. However, the integration must be weighted over the Planck distribution at the wall temperature. Notice that the total emissivity is a function of the gas temperature, pressure, partial pressure, and path length; and the total absorptivity is also a function of the wall temperature. Most heat transfer textbooks present the total emissivity and absorptivity of H_2O and CO_2 in charts [1, 2], an approach first introduced by Hottel [8]. New charts and equations have also been proposed. A summary can be found in the textbook by Modest [4]. For nonisothermal gases, the zonal method is widely employed for calculating radiative heat transfer in combustion chambers [2, 8].

Small particles are important for radiative transfer in atmosphere and combustion chambers [2–4]. Soot particles ranging from 5 to 100 nm in size are formed during a combustion process and emit thermal radiation (often stronger than the emission from combustion gases) in a continuous spectrum over the infrared and some visible regions. In pulverized-coal combustion furnaces, coal, char, and fly ash particles are important, as are soot particles. Particles can also scatter electromagnetic waves or photons, causing a change in the direction of propagation. In the early 20th century, Mie developed a theory for a spherical particle based on Maxwell's electromagnetic wave equations, known as the *Mie scattering theory*, which can be used to predict the scattering-phase function. In the case when the particle sizes are small compared with the wavelength (Rayleigh limit), the formulation reduces to the simple expression obtained earlier by Rayleigh. In the Rayleigh limit, the scattering efficiency is inversely proportional to the wavelength to the fourth power. This factor explains why the sky is blue and why the sun appears red at sunset. The absorption efficiency, on the other hand, is proportional to the inverse of the wavelength. The scattering phase function is symmetric as far as forward and backward scattering is concerned, and is nearly isotropic [2–4]. Soot particles generally fall in the Rayleigh limit. For spheres whose diameters are much greater than the wavelength, diffraction theory and geometric optics based on specular surface or diffuse surface can be applied [4]. If the scattering by one particle is affected by the presence of other particles, the scattering is called dependent scattering and requires more complicated treatments. Detailed discussions of particle properties and scattering theory can be found from [2–4] and references therein.

7.6 RADIATION THERMOMETRY

Radiation thermometry (or pyrometry) is a subject that involves determining the temperature of an object from measurement of its exitent intensity. A radiation thermometer (RT) is a radiometer calibrated to indicate the temperature of a blackbody, as shown in Figure 7.17a. RTs have been used in high-temperature furnaces, glass processing, steel processing, crystal growth, aluminum manufacturing, and thermal imaging [10]. The application of RTs to high-temperature furnaces is addressed in [11]. A more recent review on surface temperature measurements using optical techniques is given by Zhang [5]. When an RT is used to measure the temperature of a real surface, as shown in Figure 7.17b, two issues arise. The first is the unknown emissivity of the surface and the second is the influence of the surrounding radiation. Various methods have been developed to deal with these problems, including the creation of a blackbody cavity on the surface, the two-color method, and the use of a controlled reference source [5, 10, 11]. The development of optical

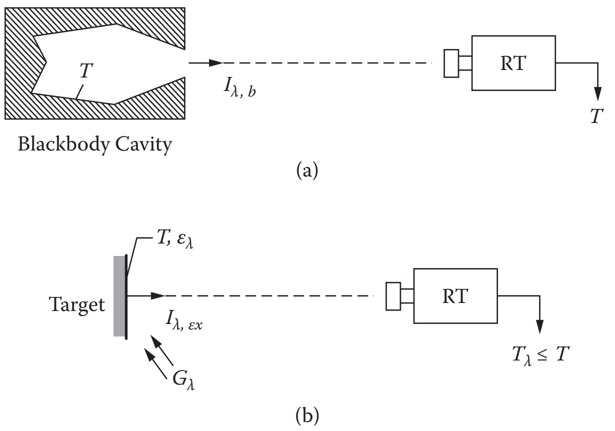

FIGURE 7.17 Radiation thermometry: (a) calibration against a blackbody cavity; (b) measurement of a real surface.

fibers has allowed radiometric temperature measurement for surface locations otherwise inaccessible by imaging radiometers.

The *measurement equation* of a spectral radiation thermometer may be approximated as

$$S_\lambda = C_\lambda L_{\lambda,ex}(\lambda) \tag{7.27}$$

where S_λ is the detector output signal, $L_{\lambda,ex}(\lambda)$ is the *exitent spectral radiance*,* and C_λ is an instrument constant that is independent of the target material and temperature. The *radiance temperature* T_λ is defined by the following equation:

$$L_{\lambda,b}(\lambda, T_\lambda) = L_{\lambda,ex}(\lambda) \tag{7.28}$$

For a freely radiating target (i.e., with cold black surroundings), the exitent spectral radiance is due only to the emission by the target (see Figure 7.17), therefore,

$$L_{\lambda,ex}(\lambda) = L_{\lambda,e}(\lambda, T) = \varepsilon'_\lambda \; L_{\lambda,b}(\lambda, T) \tag{7.29}$$

where ε'_λ is the directional spectral emissivity, and $L_{\lambda,b}(\lambda, T)$ is the blackbody spectral radiance given by Planck's law, Equation (7.5). By combining Equations (7.28) and (7.29) and applying Wien's approximate formula, one obtains the temperature equation that relates the surface temperature to the radiance temperature as follows:

$$\frac{1}{T} = \frac{1}{T_\lambda} + \frac{\lambda}{c_2} \ln \varepsilon'_\lambda \tag{7.30}$$

The effect of the emissivity uncertainty on the temperature accuracy decreases as λ decreases. However, the wavelength at which $L_{\lambda,b}(\lambda, T)$ is a maximum is given by Wien's displacement law.

* Although the concept of radiance is the same as the intensity defined in Equation (7.3), it is commonly used in radiation thermometry. Therefore, both the term radiance and its symbol L are retained here.

In practice, the choice of operating wavelength also depends on the surrounding radiation. Therefore, it is an important issue to select the operating wavelength.

Example 7.5

For a surface at T = 1800 K with an emissivity of 0.6, what are the radiance temperatures at λ = 0.65 μm and 1.5 μm? If a conical hole is formed with a half-cone angle of 15°, what is the effective emissivity and the radiance temperature at λ = 0.65 μm?

Solution

From Equation (7.30), $T_\lambda \approx$ 1728 K at λ = 0.65 μm and 1643 K at λ = 1.5 μm. If the emissivity is not taken into consideration, the error would be 1800 − 1728 = 72 K, or 4% for a radiation thermometer at λ = 0.65 μm, and 157 K or 8.7% for an RT at λ = 1.5 μm. If a cavity is formed, assuming that the surface is diffuse, the effective emissivity can be approximated by Equation (7.22). Because the half-cone angle is 15°, A_1/A_2 = sin 15° and ε_{eff} = 0.853. The radiance temperature based on the effective emissivity is $T_{\lambda=0.65\ \mu\text{m}} \approx$ 1777 K. The error in RT will be reduced to 23 K or 1.3%. The effective emissivity for a specular surface would be even larger in this case, which would result in a smaller difference between T_λ and T.

If the target is not a blackbody and the surrounding radiation is not negligible, $L_{\lambda,ex}(\lambda)$ is the sum of the emitted and reflected spectral radiances:

$$L_{\lambda,ex}(\lambda) = L_{\lambda,e}(\lambda, T) + L_{\lambda,r}(\lambda) \tag{7.31}$$

The reflected spectral radiance depends on the distribution of the surrounding radiation incident on the target and the bidirectional reflectance distribution function of the target, and except for well-controlled environments or in some limited cases, $L_{\lambda,r}(\lambda)$ is difficult to determine.

For flame or gas temperature measurements, the exitent radiance is proportional to $L_{\lambda,b}(1 - e^{-\zeta_\lambda})$, where ζ_λ is the optical thickness. The emission from the surface may transmit through the gas and needs to be taken into consideration [11]. Although RTs can be used to measure temperatures for high-temperature surfaces and flames with uncertainties ranging from a few kelvin to a few tens of kelvin, great care must be taken in the calibration and operation of RTs. Calibration is usually done with high-temperature blackbody furnaces. In the measurement, the field of view and the angle of incidence need to be correctly chosen. The alignment needs to be carefully performed. Background radiation and other radiation sources should be avoided.

8.1 INTRODUCTION

Mass can be transported in various ways, for example by truck, aircraft, or barge. Here the context is quite different; we shall use the term "mass transfer" to characterize the movement of molecules under the influence of a concentration gradient. Of special concern will be molecular movement across a phase boundary. The primary applications of such interphase transfer will involve gas-liquid, vapor-liquid, liquid-liquid, and fluid-solid transfer for absorption/stripping, distillation, extraction, and adsorption. The principles described can easily be extended to other operations such as leaching and solids drying.

Common to all the above example applications is the relationship known as Fick's first law:

$$J_i = -D_i \frac{\partial C_i}{\partial z} \tag{8.1}$$

where

J_i = a molar mass flux of species i, g-moles/(s − cm^2)

C_i = concentration of species i, g-moles/cm^3
Z = distance, cm
D_i = a proportionality constant, called the *diffusion coefficient* for species i, cm^2/s

Equation (8.1) is basic and states that the rate of diffusion of a molecule, in mixture with others, moves at a rate directly proportional to its concentration gradient and the cross section through which it diffuses, and is inversely proportional to the distance through which it must travel. It implies steady-state diffusion.* The negative sign in Equation (8.1) is simply to make the flux positive, since the concentration gradient is negative. Variations of Equation (8.1) can be used to allow concentration expressed in mole fraction or mass fraction, for example,

$$J_i = -C_m D_i \frac{\partial y_i}{\partial z} \tag{8.1a}$$

where

J_i = molar mass flux of species i, g-moles/(s·cm^2)
C_m = average total concentration, total g-moles/cm^3
z = distance, cm
y_i = mole fraction of species i (g-moles i/total g-moles)
D_i = proportionality constant, the *diffusion coefficient* for species i, cm^2/s

The value of D depends upon the conditions of transport. For the often-used case of diffusion under nonturbulent conditions, *molecular diffusion* prevails, and D is a *molecular diffusion coefficient*.† As such, its value depends on temperature, pressure, relative size of molecules involved, and in some cases, whether all molecules, including i, are polar. If turbulent conditions prevail, we have an *eddy diffusion coefficient*, usually designated by the symbol ε. The models used in this chapter do not involve the turbulent case, largely because it lacks a firm basis for estimation, i.e., degrees of turbulence are not easily evaluated.

Equation (8.1) has its counterparts for heat flux (Fourier's equation) and momentum flux. Evaluation of D_i is relatively simple for binary systems, i.e., species i moving through, say, species j. If i is moving through several components that can be grouped as a single pseudo component, evaluation of D_i is straightforward. However, if all species in the mixture are diffusing at different rates (and in different directions), one must use the Maxwell-Stefan relationships, which are beyond the coverage of the present chapter. Taylor and Krishna [1] provide extensive coverage of multicomponent diffusion.

8.2 MOLECULAR DIFFUSION COEFFICIENTS

8.2.1 Gases—Binary Mixtures

Diffusion coefficients for some binary gas mixtures have been measured and are reported in various compendia, such as *Perry's Handbook* [2]. Of concern here are the models available for *estimating* the coefficients, or for extrapolating the values of measured coefficients. A number of predictive models have been presented for the case of binary gas mixtures. The models are based on experimental data, where the movement of one component is measured under carefully controlled laminar conditions. A model combining both accuracy and ease of use is due to Fuller et al. [3]:

---

* Fick's second law deals with transient diffusion, not covered in this chapter.

† The terms *diffusion coefficient* and *diffusivity* are synonymous. The former will be used here.

$$D_{ij} = \frac{1.0\left(10^{-3}\right)T^{1.75}}{P\left[\left(\Sigma v\right)_i^{1/3} + \left(\Sigma v\right)_j^{1/3}\right]^2}\left(\frac{1}{M_i} + \frac{1}{M_j}\right)^{1/2} \tag{8.2}$$

where

D_{ij} = gaseous diffusion coefficient, cm^2/s
T = absolute temperature, °K
M = molecular weight
P = absolute pressure, atm
Σ_v = diffusion volume, the sum of atomic volumes in each molecule; values obtained from Table 8.1.

Equation (8.2) shows that the coefficient is inversely proportional to pressure and proportional to the 1.75 power of absolute temperature. It shows that the relative sizes of the molecules are also important. Equation (8.2) is reported to predict values within ±7% for nonpolar and polar molecules. In general, it is derived from the kinetic theory of gases.

For more careful (and more tedious) work, the model of Hirschfelder-Bird-Spotz [4] is recommended. It involves the Lennard-Jones potential between diffusing species, and that potential can be corrected slightly when both species are polar, using the method of Brokaw [5]. For engineering work, Equation (8.2) is normally adequate. According to the kinetic theory, the gas diffusion coefficient is independent of concentration.

TABLE 8.1
Atomic and Molecular Diffusion Volumes for Equation (8.2)

Atomic and Structural Diffusion Volume Increments, *v*

C	16.5	(Cl)	19.5
H	1.98	(S)	17.0
O	5.48	Aromatic ring	−20.2
(N)	5.69	Heterocyclic ring	−20.2

Diffusion Volumes, Σ*v*, for Simple Molecules

H_2	7.07	CO_2	26.9
D_2	6.70	N_2O	35.9
He	2.88	NH_3	14.9
N_2	17.9	H_2O	12.7
O_2	16.6	(CCl_2F_2)	114.8
Air	20.1	(SF_6)	69.7
Ar	16.1	(Cl_2)	37.7
Kr	22.8	(Br_2)	67.2
CO	18.9	(SO_2)	41.1

Note: Atoms and molecules in parentheses indicate very few data available.

Example 8.1

Estimate the gaseous diffusion coefficient for methanol diffusing through water vapor at 25°C and 1.0 atm pressure.

Solution

Equation (8.2) is used, with the following values:

T = 298°K
M_i = 32.0 (methanol)
M_j = 18.1 (water)
P = 1.0 atm
Σv_i = 16.5 + 4(1.98) + 5.48 = 29.9 (Table 8.1)
Σv_j = 12.7 (Table 8.1)

By Equation (8.2),

$$D_{ij} = \frac{1.0\left(10\right)^{-3}\left(298\right)^{1.75}}{1.0\left[\left(29.9\right)^{1/3}+\left(12.7\right)^{1/3}\right]^2}\left(\frac{1}{32.0}+\frac{1}{18.1}\right)^{0.5} = 0.213 \text{ cm}^2/\text{s}$$

8.2.2 Liquids—Binary Mixtures

The liquid phase is less predictable than the gas phase, and methods for predicting diffusion coefficients do not have the support that gases have from the kinetic theory of gases. The Stokes-Einstein relationship forms the basis for modeling:

$$D_{ij}^{L} = \frac{kT}{4\pi r_i \mu_j} \tag{8.3}$$

Wilke and Chang [7] modified this relationship to develop a *dimensional* relationship for the dilute case, i.e., low concentrations of i in j:

$$D_{ij}^{LO} = \frac{7.4\left(10^{-8}\right)\left(\phi_j M_j\right)^{1/2} T}{V_i^{0.6}\mu_j} \tag{8.4}$$

where

D_{ij}^{LO} = liquid diffusion coefficient for dilute solute i in solvent j, cm²/s
ϕ_j = correction factor for associated liquid solvent; ϕ = 1.0 for nonassociated liquids, = 2.4 for water, 1.9 for methanol, and 1.5 for ethanol
M_j = molecular weight of solvent j
T = absolute temperature, °K
μ_j = viscosity of solvent, mPa·s (centipoise)
V_i = molar volume of solution at normal boiling point, cm³/g-mole

Values of V_i may be estimated by means of the LeBas parameters given in Table 8.2.

TABLE 8.2
LeBas Additive Volumes for Wilke-Chang Equation (8.4)

	Increment (cm^3/g-mole)
Carbon	14.8
Hydrogen	3.7
Oxygen (except where noted below)	7.4
in methyl esters and ethers	9.1
in ethyl esters and ethers	9.9
in higher esters and ethers	11.0
in acids	12.0
joined to S, P, N	8.3
Nitrogen	
doubly bonded	15.6
in primary amines	10.5
in secondary amines	12.0
Bromine	27.0
Chlorine	24.6
Fluorine	8.7
Iodine	37
Sulfur	25.6
Ring	
three-membered	−6.0
four-membered	−8.5
five-membered	−11.5
six-membered	−15.0
naphthalene	−30.0
anthracene	−47.5

Note: The additive volume procedure should not be used for simple molecules. Instead, use the following values:

H_2	14.3	SO_2	44.8	COS	51.5	O_2	25.6
NO	23.6	Cl_2	48.4	N_2	31.2	N_2O	36.4
Br_2	53.2	Air	29.9	NH_3	25.8	I_2	71.5
CO	30.7	H_2O	18.9	CO_2	34.0	H_2S	32.9

For solute-solvent mixtures that are ideal, values of intermediate concentrations can be estimated on the following basis:

$$D_{ij}^{L} = x_i\, D_{ji}^{LO} + x_j\, D_{ij}^{LO} \tag{8.5}$$

Thus, the two infinite-dilution coefficients are calculated, and intermediate values of the coefficient are based on a linear relationship based on mole fractions. A 50-50 molar mixture would have a coefficient of

$$\frac{D_{ij}^{LO} + D_{ji}^{LO}}{2}$$

For non-ideal liquid mixtures, the Vignes [8] relationship should be used:

$$D_{ij}^{L} = \left(D_{ij}^{LO}\right)^{x_j} \left(D_{ji}^{LO}\right)^{x_i} \left(1 + x_i \frac{d \ln \gamma_i}{d x_i}\right) \tag{8.6}$$

For an ideal-liquid mixture, this equation shows a linear plot of ln *D* vs. molar concentration. The term γ_i is the liquid-phase activity coefficient, and the term $d \ln\gamma_i/dx_i$ is the slope of the conventional plot of the logarithm of the activity coefficient versus mole fraction (see Figures 12.7 and 12.9 in Chapter 12, or see Chapter 4). Thus, for the value of the liquid diffusion coefficient of a concentrated binary mixture *i-j*, Equations (8.5) or (8.6) should be used, depending on ideality of the solution.

When water is the solute, diffusing at very low concentration through a solvent, the dimensional relationship by Sitaraman et al. [9] gives a somewhat better fit than Equation (8.4):

$$D_{ij}^{LO} = 16.8(10^{-10})\left(\frac{M_j^{0.5}\lambda_j^{0.333}T}{\mu_j V_i^{0.5}\lambda_i^{0.3}}\right)^{0.93} \tag{8.7}$$

where

λ_i and λ_j = latent heats of vaporization of the solute and solvent, respectively, at their normal boiling points, J/kg

μ_j = viscosity of the solute, cP

and other terms are the same as for Equation (8.4). Special relationships apply when an organic is diffusing through an ionic solution; for such a case, consult Hirschfelder et al. [4] or Reid et al. [6]

Example 8.2

For a liquid solution of 10 mole-% methanol in water, calculate the diffusion coefficients for each component. Temperature is 25°C, pressure is 1.0 atm, viscosity of the methanol is 0.55 cP, and viscosity of water is 0.95 cP.

Solution

Let *i* be methanol and *j* be water. The infinite-dilution coefficient for methanol in water is computed using Equation (8.4). Values of terms are

Association parameters ϕ = 2.6 for water and 1.9 for methanol
Molecular weights M = 18.1 for water and 32.0 for methanol
Molecular volumes (Table 8.2): for methanol = 14.8 + 4(3.7) + 7.4 = 37.0; for water = 18.9

1. Methanol in water

$$D_{ij}^{LO} = \frac{7.40(10)^{-8}\left[(2.6)(18.1)\right]^{1/2}(298)}{(37)^{0.6}(0.95)} = 1.824(10)^{-5}\ \text{cm}^2/\text{s}$$

2. Water in methanol

$$D_{ji}^{LO} = \frac{7.40(10)^{-8}\left[(1.9)(32.0)\right]^{1/2}(298)}{(18.9)^{0.6}(0.55)} = 5.36(10)^{-5} \text{ cm}^2\text{/s}$$

3. 10% methanol
   Because the mixture is nonideal, a relationship between composition and activity coefficient is needed. An estimate, based on van Laar coefficients A_{ij} = 0.36 and A_{ji} = 0.22,

$$\ln \gamma_i = \frac{0.83}{\left[1 + 1.627\, x_i/x_j\right]^2}$$

from which, for x_i = 0.10,

$$\partial \ln \gamma_i / x_i = -2.0275$$

and for 1 + x_i,

$$(d\ln\gamma_i/dx_i) = 1 + 0.10\ (-2.0275) = 0.7972$$

Finally, by Equation (8.6),

$$D_{ij,x_i=0.10}^{L} = \left[1.824(10)^{-5}\right]^{0.9}\left[5.36\left(10^{-5}\right)^{0.1}\right](0.7972) = 1.624(10)^{-5} \text{ m}^2\text{/s}$$

Note: For a simple molar average of infinite-dilution coefficients,

$$D_{ij}^{L} = 2.19(10)^{-5} \text{ cm}^2\text{/s}$$

8.2.3 Gases—Multicomponent Mixtures

As mentioned earlier, prediction of the coefficient for species *i* diffusing through a mixture of *j*,*k*,*l*,… depends on the diffusion characteristics of the other components. For the special case where *i* is diffusing through other components that are not diffusing, the Wilke [10] relationship may be used:

$$D_{i-mixture} = \frac{1 - y_i}{\sum_{j}^{n} \frac{y_j}{D_{ij}}} \tag{8.8}$$

The components *j*,*k*,*l*,… are considered to be a "stagnant barrier mixture."

Equation (8.8) provides a good approximation for dilute cases, even if the barrier mixture is not "stagnant." For more rigorous approaches, the text by Taylor and Krishna[1] should be consulted.

8.2.4 Liquids—Multicomponent Mixtures

If the mixture is ideal, or nearly so, a modification of the Vignes equation (8.6) may be used, considering the mixture $j,k,l,\ldots$ as a pseudo component. Thus, for a ternary ideal mixture i,j,k,

$$D^{LO}_{i-mixture}\,\mu_{ijk} = \left(D^{LO}_{ij}\,\mu_j\right)^{x_j}\left(D^{LO}_{ik}\right)^{x_k} \tag{8.9}$$

For, say, a ternary non-ideal mixture, activity-coefficient data must be available. In such a case, the result of Equation (8.9) can be multiplied by $(1+x_i(\partial \ln \gamma_i / \partial x_i))$ as in the Vignes equation (8.6). One should recognize, however, that activity-coefficient data for mixtures with more than two components are scarce; the best source for such data is the Gmehling series [11].

8.2.5 Diffusion through Porous Solids

For a gas diffusing through the very small pores of an adsorbent or solid catalyst, a form of Fick's equation (Equation (8.1)), called the slab equation, may be used:

$$J_i = -\frac{D_{ki}}{z_o}\left(C_{i2} - C_{i1}\right) = \frac{D_{ki}}{RT}\left(\frac{(p_1 - p_2)_i}{z_o}\right) \tag{8.10}$$

where

z_o = length of pore traveled, cm
R = gas constant, 82.057 (atm·cm^3)/ (g-moles·°K)
T = absolute temperature, °K
p_i = partial pressure of i, obtained from concentration using the gas law:

$$C_i = \frac{n_i}{V} = \frac{p_i}{RT} \tag{8.11}$$

and D_{ki} is the *Knudsen diffusion coefficient* for species i, so called because, in the very small and crooked pores, the molecules collide more frequently with the pore wall than with each other. Thus, the value of this coefficient depends more on the pore geometry than on the diffusing species:

$$D_{ki} = D_k = 2/3\, r_e\left(\frac{8\,RT}{\pi M_i}\right)^{0.5} = 9700\, r_e \sqrt{\frac{T}{M_i}}\ \text{cm}^2/\text{s} \tag{8.12}$$

with r_e being the effective pore radius, cm.

The pore size may be known, or it can be estimated:

$$r_e = \frac{2\,\varepsilon}{S\,\rho_p} \tag{8.13}$$

where

ε = fraction voids in solid particle
S = total surface area of solid, cm^2/g
ρ_p = particle density, g/cm^3

A correction for D_k is needed for the usual case of a pore that is very crooked, called the "tortuosity factor" τ:

$$D_{k,eff} = D_k \frac{\varepsilon}{\tau} \tag{8.14}$$

This factor has an observed range of 1 to 7. A good average is $\tau = 4$.

For larger pore sizes, molecular diffusion may play a role, and the molecular diffusion and Knudsen coefficients can be combined:

$$\frac{1}{D_{i,eff}} = \frac{1}{D_i} + \frac{1}{D_{k,eff}} \tag{8.15}$$

where $D_i = D_{ij}$ = coefficient determined by Equation (8.2) and $D_{k,eff}$ is obtained from Equation (8.14).

Example 8.3

Propane (mol. wt. = 44) is diffusing through nitrogen in the pore structure of 4 × 6-mesh Sorb-Tech activated carbon. Temperature is 298°K. Assume a tortuosity factor of 4. The carbon has the following properties [12]:

Surface area = 1096 m^2/g = 1.096×10^7 cm^2/g
Bulk density = 0.49 g/cm^3
Internal void fraction = 0.543
Particle density = 1.00 g/cm^3

Solution

First, the effective pore radius is estimated by Equation (8.13):

$$r_e = \frac{2(0.543)}{1{,}096(10)^7(1.00)} = 0.99(10)^{-10} \text{ cm}$$

Next, the Knudsen coefficient is calculated by Equation (8.12):

$$D_{ki} = 9.7(10)^3\, 0.99(10)^{-10} \sqrt{298/44} = 25.0(10)^{-7} \text{ cm}^2\text{/s}$$

The coefficient is then corrected for tortuosity by Equation (8.14):

$$D_{ki,eff} = 25.0(10)^{-7} \frac{0.543}{4} = 3.40(10)^{-7} \text{ cm}^2\text{/s}$$

By Equation (8.2), the molecular diffusion coefficient for propane in nitrogen is 0.113 cm^2/s. Because $D_i >> D_{ki,eff}$, it is clear that Knudsen diffusion controls.

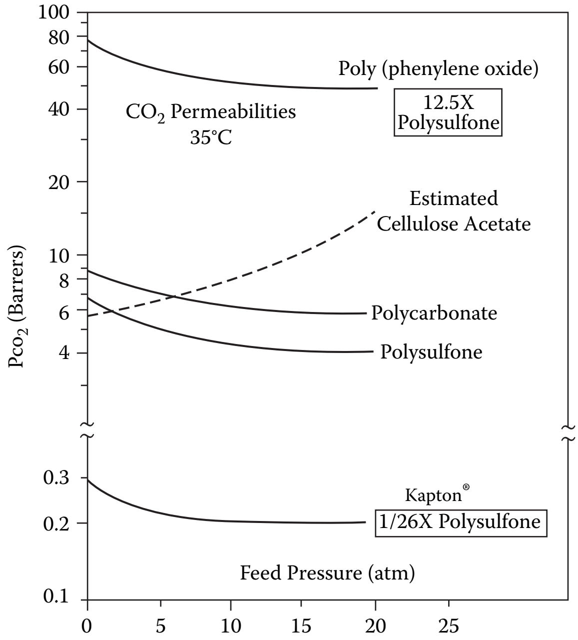

FIGURE 8.1 Permeabilities for carbon dioxide passing through several membrane materials. (From Fair, J. R. *Chem. Proc.* 52 (10): 81 (1989). With permission.)

8.2.6 Gases—Diffusion through Membranes

Again, Fick's law is used, with the length term equal to the membrane thickness. The diffusion coefficient is usually called a *permeability* and is measured by observing the flux J_i for a given membrane material coupled with a known pressure difference on either side of the membrane. For a semipermeable membrane, the permeability P is a function of both a mobility term and a solubility term, i.e., $P = DS$. Because the separating power of a membrane is based on different values of P for each component, it follows that the selectivity term α_{ij} is

$$\alpha_{ij} = \frac{P_i}{P_j} = \frac{D_i}{D_j}\frac{S_i}{S_j} = \left(\frac{\text{mobility}}{\text{selectivity}}\right)\left(\frac{\text{solubility}}{\text{selectivity}}\right) \tag{8.16}$$

To indicate the influence of the membrane material on a diffusing species, Figure 8.1 shows permeabilities for carbon dioxide moving through different membranes under the influence of a pressure-driving force [13]. The permeability is calculated from measured flux:

$$P_{CO_2} = \frac{\text{Std. cm}^3\text{ diffusing}}{\text{s} - \text{cm}^2 - \text{cm Hg driving force}}$$

Researchers in membrane technology have adopted the special permeability unit called the Barrer:

$$1.0\,\text{Barrer} = \frac{10^{10}\left(\text{cm}^3\text{ @ STP}\right)\left(\text{cm}\right)}{\text{cm}^2\left(\text{sec}\right)\left(\text{cm Hg}\right)}$$

In some cases, two or more different materials are sandwiched to form the membrane. A combined permeability follows the same style as Equation (8.15).

8.3 MASS TRANSFER AT A PHASE BOUNDARY

For molecules approaching a phase boundary (gas-liquid, liquid-liquid, gas-solid, liquid-solid), movement is represented by Fick's law (Equation (8.1)) or, more practically, the slab equation [Equation (8.10)]. Examples of application are

1. A species in a *gas mixture moving to a boundary with a liquid* where, if the species is soluble in the liquid, the species moves across the phase boundary and into the liquid. This is a type of unidirectional mass transfer found in absorption separations.
2. A species in a *liquid mixture moving to a boundary with an immiscible liquid* where, if soluble, the species passes into the immiscible liquid. This is unidirectional mass transfer found in liquid-liquid extraction separations.
3. A species in a *gas mixture moving to a boundary with a solid* where, if appropriate, it moves into the structure of the solid. The solid can be an adsorbent or a catalyst, for example. Diffusion within the pore structure may be a consideration. Transfer may be unidirectional or counterdiffusional, for example, if products are leaving a solid catalyst.
4. A species in a *liquid mixture moving to a boundary with a vapor* and passing countercurrently to another species, leaving the vapor and passing into the liquid. This is often equimolar counterdiffusion, as found in distillation.

For the counterdiffusion steady-state case, as in distillation, the slab equation is

$$J_i = \frac{D_i}{z_o}\left(C_{i1} - C_{i2}\right) = \frac{D_i}{RT\,z_o}\left(p_{i1} - p_{i2}\right) = \frac{D_i\;P}{RT\,z_o}\left(y_{i1} - y_{i2}\right) = \frac{D_i^L\;C_i}{z_o}\left(x_{i1} - x_{i2}\right) \tag{8.17}$$

where the partial-pressure driving forces denote a gas and the mole-fraction driving forces denote a gas (y) or liquid (x).

For unidirectional steady-state mass transfer, as in absorption, adsorption, and stripping,

$$J_i = \frac{D_i}{z_o}\left(\frac{C_{i1} - C_{i2}}{C_{jm}}\right) = \frac{D_i\,P}{RT\,z_o}\left(\frac{p_{i1} - p_{i2}}{p_{jm}}\right) = \frac{D_i\;P}{RT\,z_o}\left(\frac{y_{i1} - y_{i2}}{y_{jm}}\right) = \frac{D_i^L\;C_i}{z_o}\left(\frac{x_{i1} - x_{i2}}{x_{jm}}\right) \tag{8.18}$$

where C_{jm}, p_{jm}, y_{jm}, and x_{jm} include all components other than i in the mixture. The differences between Equations (8.17) and (8.18) should be noted carefully. For "lean gas" or "lean liquid" cases, where the concentration of the diffusing component i is very low, the fluxes have about the same value. The difference has to do with the assignment of a stationary diffusional plane (equimolar transfer) or a moving plane (unidirectional transfer) and the phenomenological derivation of the two modes; this is beyond the scope of the present work. Flux designations of J and N are sometimes used to denote the difference. For the derivations, the reader may consult works of Pigford et al. [14], Hines and Maddox [15], or other basic texts on mass transfer.

Given Equations (8.17) and (8.18), the question arises as to how they can be applied to practical operations such as those noted (distillation, absorption, adsorption, etc.). The problem is in assigning a value to the distance z_0. The driving force can be calculated, and the diffusion coefficient can be estimated, as just discussed. The determination of z_0 is the basis for several theories, discussed in the following sections.

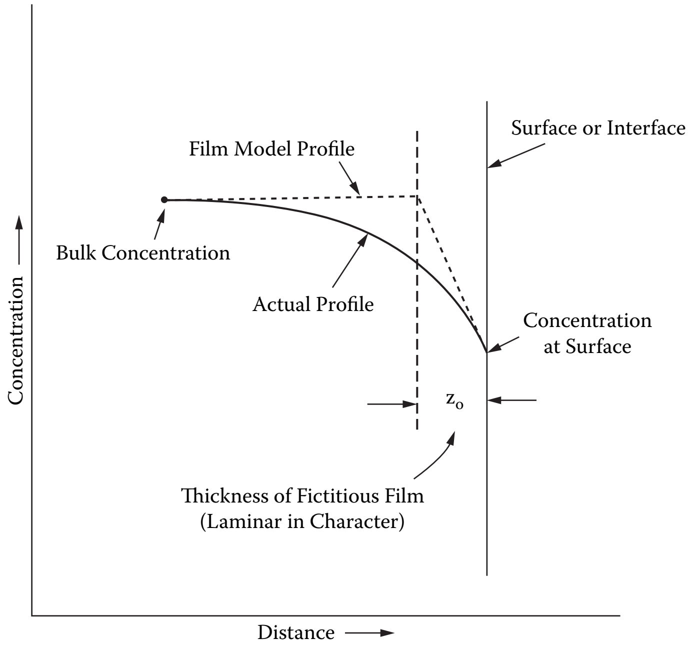

FIGURE 8.2 Elements of the film theory.

8.3.1 Stagnant-Film Model

This model, developed by Whitman [16] in 1923, is still used. The assumption is that adjacent to the interface there exists a thin film that is laminar in character and through which transfer is by molecular diffusion only. In this film, the entire concentration driving force exists, i.e., outside the film, in the bulk fluid, the concentration is constant at some steady state. Flow outside the film may be laminar or turbulent, but inside the film, flow conditions are completely laminar. Figure 8.2 shows the elements of the theory.

It is possible in some cases to measure the thickness of the film, which is akin to the boundary layer in turbulent flow. In most cases, however, this is not practical, if indeed possible. Accordingly, the quotient D/z_0 is simply called a *mass transfer coefficient*. Equations for the different mass transfer coefficients are shown in Table 8.3.

The coefficient is subject to certain variables, not all quantifiable:

1. The coefficient increases or decreases according to the variables affecting the diffusion coefficient, Equations (8.2) or (8.4).
2. The film is subject to the fluid mechanics of the bulk mixture. For example, high bulk fluid velocities can thin the film and thus increase the value of the coefficient.

Even if the flow of the bulk fluid is laminar, there is still considered to be a separate film at the interface.

One must be very careful about the units used. Those shown in Table 8.3 are typical, but many other combinations can be used.

8.3.2 Penetration Model

In searching for a more realistic model than one containing a "fictitous film," Higbie [17] proposed the elimination of the film idea and replacing it with an unsteady-state model that permits turbulent conditions adjacent to the interface. Sometimes called the "Higbie model," it contains the following elements:

TABLE 8.3
Mass Transfer Coefficient Definitions

	Driving Force	Equimolar	Unidirectional	Units	Typical Units
Gases	p	$k'_g = \frac{D_{ij}P}{RTz_o}$	$k_g = \frac{D_{ij}P}{RTz_o p_{jm}}$	$\frac{\text{moles}}{\text{time-area-pressure}}$	$\frac{\text{gm-moles}}{\text{s-cm}^2\text{-atm}}$
Gases	y	$k'_y = \frac{D_{ij}P}{RT\,z_o}$	$k_y = \frac{D_{ij}P}{RTz_o y_{jm}}$	$\frac{\text{moles}}{\text{time-area-molefraction}}$	$\frac{\text{gm-moles}}{\text{s-cm}^2}$
Gases	C	$k'_c = \frac{D_{ij}}{z_o}$	$k_c = \frac{D_{ij}P}{z_o p_{jm}}$	$\frac{\text{moles}}{\text{time-area-moles/volume}}$	$\frac{\text{gm-moles}}{\text{s-cm-gm}^2\ \text{moles/cm}^3} = \frac{\text{cm}}{\text{s}}$
Liquids	C	$k'_L = \frac{D^L_{ij}}{z_o}$	$k_L = \frac{D^L_{ij}}{z_o x_{jm}}$	$\frac{\text{moles}}{\text{time-area-moles/volume}}$	$\frac{\text{gm moles}}{\text{s-cm-gm}^2\ \text{moles/cm}^3} = \frac{\text{cm}}{\text{s}}$
Liquids	x	$k'_x = \frac{D^L_{ij}C_i}{z_o}$	$k_x = \frac{D^L_{ij}C_i}{z_o x_{jm}}$	$\frac{\text{moles}}{\text{time-area-mole fraction}}$	$\frac{\text{gm moles}}{\text{s-cm}^2}$

- There are no films.
- Eddies bring "packets" of material to the interface, where they are exposed for a short time.
- All exposure times are the same.
- Mass transfer occurs only during exposure.

While Higbie proposed the model only for the liquid phase, it has been extended to include the gas phase. To satisfy Fick's theory, Higbie assumed that, at the time of exposure, the transfer process involved only molecular diffusion or, alternatively, the packets assumed a laminar character as they approached the interface. The net result of Higbie's model provides the flux equation:

$$J_i = 2\left(C_{iB} - C_{i,\text{int}}\right)\sqrt{\frac{D_{ij}}{\pi\theta_i}} \tag{8.19}$$

where

J_i = flux of i, g-moles/s·cm^2 of interface
$C_{i,\text{B}}$ = bulk concentration of i, g-moles/cm^3
$C_{i,\text{int.}}$ = interfacial concentration of i, g-moles/cm^3
D_{ij} = molecular diffusion coefficient, cm^2/s
π = 3.1416…
θ_i = exposure time of i at the interface, s

Thus, the mass transfer coefficient is $2\sqrt{D_{ij}/\pi\theta_i}$, cm/s.

One apparent advantage of this model is that it predicts a dependence of flux on the one-half power of the diffusion coefficient, which is closer to reality than the first power for the molecular diffusion model. And it is more realistic, in that eddy-type packets are considered. However, it does not have an application advantage, since there is little physical basis for estimating the exposure

time, let alone a range of exposure times, just as there is little experimental support for the stagnant film of finite thickness.

8.3.3 Surface Renewal Model

This model, proposed originally by Danckwerts [18], is an extension of the penetration model. Whereas Higbie assumed that all exposure times were the same, Danckwerts provided for a range of times, based on probability theory. After a given exposure, the surface (interface) was renewed, leading to the name of the theory. The elements of the model are

- There are no films.
- Eddies bring packets to the interface, remaining there for a variety of times.
- The surface (interface) is renewed on the basis of fluid flow and geometry.
- Mass transfer occurs only during exposure.

The flux equation by this model is

$$J_i = \left(C_{iB} - C_{i,\text{int}}\right)\sqrt{S\,D_{ij}} \tag{8.20}$$

where S is the fractional surface renewal rate, s^{-1}; and the mass transfer coefficient is $\sqrt{S\,D_{ij}}$, cm/s. In reality, the difference between the penetration and surface-renewal models is the factor of 2 in the flux equation. The models are used interchangeably, with little attempt to predict the range of exposure times. Use of these models is described in the following section.

8.4 MASS TRANSFER ACROSS A PHASE BOUNDARY

The practical applications provided here all involve two phases, with molecules transferring between them. Thus, there are two resistances to transfer, plus possibly a third resistance at the interface itself. We have just discussed transfer within a phase and ending at a phase boundary, such as an interface. It is necessary to couple individual phase resistances to characterize the overall transfer process. The first attempt at this, and indeed a lasting one, was presented by Lewis and Whitman [19] as the *two-film theory*. More recently it has been called simply the *two-resistance theory*, eliminating the requirement that transport in each phase be handled by the film concept.

8.4.1 Two-Film Model

To describe this model, let us assume that a species is transferring from a gas phase to a liquid phase, as in gas absorption. Figure 8.3 diagrams the process. If the transfer flux is based on a unit area of interface, we may write the total flux equation as follows:

$$J_i = k_{y,i}\left(y_{ib} - y_{i,\text{int}}\right) = k_{x,i}\left(x_{i,\text{int}} - x_{ib}\right) \tag{8.21}$$

[gas] [liquid]

where

J_i = mass flux of i, g-moles/s·cm^2 interfacial area
k_x, k_y = mass transfer coefficients for gas and liquid, respectively, defined in Table 8.3
y_{ib} = mole fraction of i in the bulk gas phase
$y_{i,\text{int}}$ = mole fraction of i in the gas, at the interface
$x_{i,\text{int}}$ = mole fraction of i in the liquid, at the interface

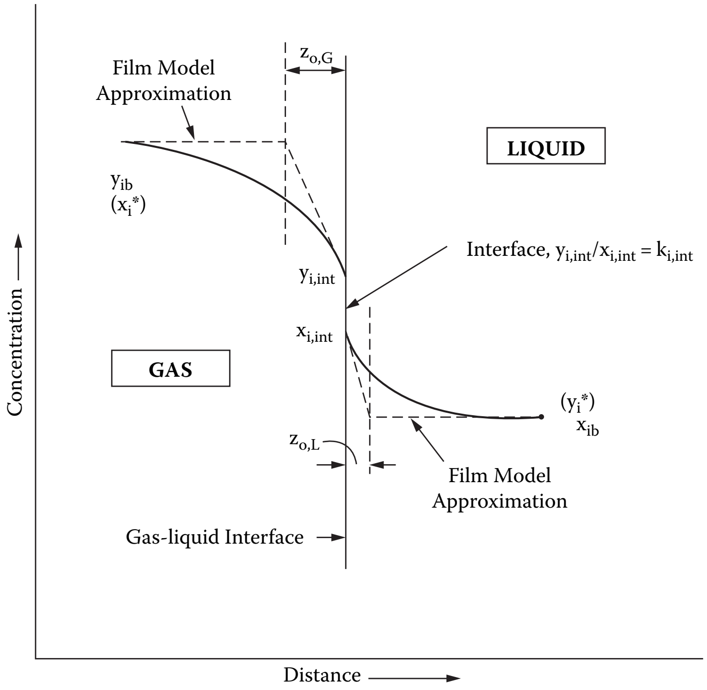

FIGURE 8.3 Two-film theory applied to unidirectional flow, gas to liquid.

x_{ib} = mole fraction of i in the bulk liquid

To make Equation (8.21) tractable for design purposes, it is necessary to make the assumption that *thermodynamic equilibrium exists at the interface*, i.e., $y^*_{i,\text{int}}/x_{i,\text{int}} = K_i$ or $y_{i,\text{int}}/x^*_{i,\text{int}} = K_i$, where K_i is the conventional thermodynamic equilibrium ratio and the asterisks denote an equilibrium composition. Note that the equilibrium designation depends on the concentration units used. For example, if gas concentrations are in partial pressures and liquid compositions are in molar concentrations, a Henry's law coefficient, $H_i = p^*_{i,\text{int}}/C_{i,\text{int}}$, must be used.

It is also expedient to define a fictitious liquid composition in equilibrium with the bulk gas concentration, i.e., $x_{ib}^* = y_{ib}/K'$, and to define a fictitious gas composition in equilibrium with the bulk liquid composition, $y_i^* = K''x_{ib}$. Because the K value is composition dependent, values of K, K', and K'' will not necessarily be the same. Figure 8.4 illustrates this difference on a y versus x plot.

The assumption of interfacial equilibrium permits definition of overall mass transfer relationships for transferring species i:

$$J_i = K_{ox}\,(x_i^* - x_{ib}) \tag{8.22a}$$

$$= K_{oy}\,(y_{ib} - y_i^*) \tag{8.22b}$$

where

K_{ox} = overall coefficient based on liquid concentrations
K_{oy} = overall coefficient based on gas concentrations

These expressions cover the overall concentration change, bulk to bulk, and take into account the total resistance to mass transfer offered by both phases. They are useful in that they eliminate the need for interfacial concentrations, which are rarely available and are difficult if not impossible to

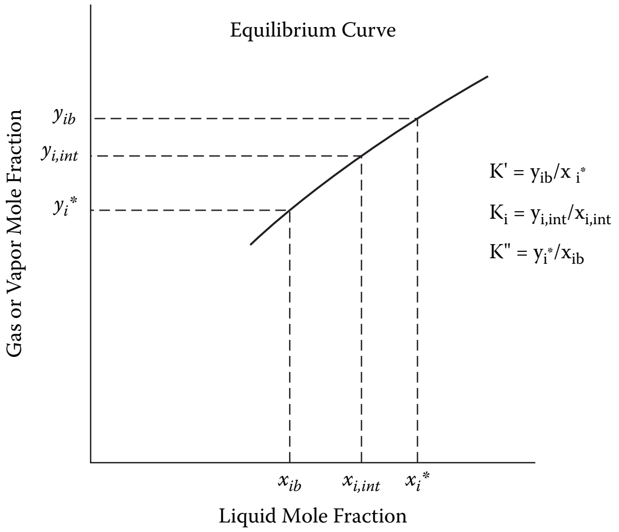

FIGURE 8.4 Variation of K values for interphase transfer, binary system.

measure or to predict. However, they do not deal with the individual mass transfer characteristics of the individual phases. For most engineering calculations, knowledge of the contributions of the phases to mass transfer are needed, obtainable from the following relationship for transferring species i:

$$\frac{1}{K_{ox}} = \frac{1}{K_i k_y} + \frac{1}{k_x} \tag{8.23}$$

$$\frac{1}{K_{oy}} = \frac{1}{k_y} + \frac{K_i}{k_x} \tag{8.24}$$

Equations (8.23) and (8.24) are equivalent and represent a series resistance expression:

$$R_{\text{total}} = R_{\text{gas}} + R_{\text{liquid}}$$

When essentially all of the resistance is on the gas side of the interface, $k_x >> k_y$, and $K_{oy} \approx k_y$ or $K_{ox} \approx k_y K_i$. A well-known example of pure gas-phase resistance is the humidification of dry air with pure water. Because there is no concentration gradient in the liquid, the interface concentration equals the vapor pressure of water at the temperature under consideration. Thus the only driving force is $p^{\text{vap}} - p_b$, where p_b = partial pressure of water in the air, equivalent to the humidity. Many distillation separations have most of the resistance in the vapor phase.

Conversely, when essentially all of the resistance is on the liquid side, $K_{oy} \approx k_g/K_i$ or $K_{ox} \approx k_x$. For test work, this situation is simulated by the stripping of oxygen from water by air. Because of the limited solubility of oxygen in water, the value of K_i is very high, and the first term on the right-hand side of Equation (8.23) is essentially zero. This is the situation for many strippers, where the solute is relatively insoluble in the solvent.

Equations (8.22)–(8.24) and their associated discussion refer to a single diffusing component. Further, they are based only on one set of symbols from those given in Table 8.3. Equations with other symbols are included in Table 8.4.

TABLE 8.4
Gas-Liquid Mass Transfer

$$J_i = k_g\left(p_{ib} - p_{i,\text{int}}\right) = k_x\left(x_{i,\text{int}} - x_{ib}\right)$$

$$\frac{1}{K_{og}} = \frac{1}{k_g} + \frac{H_i}{k_x} \qquad H_i = \text{Henry's law coefficient,} = p_{ib}/x_{ib}$$

$$\text{or } \frac{1}{K_{oL}} = \frac{1}{H_i k_g} + \frac{1}{k_x}$$

$$J_i = k_y\left(y_{ib} - y_{i,\text{int}}\right) = k_c\left(C_{i,\text{int}} - C_i\right)_L$$

$$\frac{1}{K_{oy}} = \frac{1}{k_y} + \frac{H_i'}{k_c} \qquad H_i' = \text{Henry's law coefficient} = y_{ib}/C_{ib}$$

$$\text{or } \frac{1}{K_{oL}} = \frac{1}{k_y H_i'} + \frac{1}{k_c}$$

$$J_i = k_y\left(y_{ib} - y_{i,\text{int}}\right) = k_x\left(x_{i,\text{int}} - x_{ib}\right)$$

$$\frac{1}{K_{oy}} = \frac{1}{k_y} + \frac{K_i}{k_c} \qquad K_i = \text{Equilibrium ratio} = y_{ib}/x_{ib}$$

$$\text{or } \frac{1}{K_{ox}} = \frac{1}{k_y K_i} + \frac{1}{k_x}$$

8.4.2 Interfacial Area

The mass flux is based on a unit cross-sectional area, for example, at the interface. For a few simple contacting geometries the interfacial area may be known, and some of these are discussed later. For most situations, particularly when significant turbulence is present, the area is not known, and methods for its estimation are unreliable. In such cases, the area is coupled with the mass transfer coefficient to form a *volumetric mass transfer coefficient.*

8.4.3 Volumetric Coefficients, Gas-Liquid

When the mass transfer coefficient is combined with the interfacial area per unit volume, a volumetric mass transfer coefficient results with typical units,

$$k_y a \text{ or } k_x a = \frac{\text{gm moles}}{\text{s} - \text{cm}^2 - \text{mole fraction}} \times \frac{\text{cm}^2}{\text{cm}^3} = \frac{\text{gm moles}}{\text{s} - \text{cm}^3 - \text{mole fraction}}$$

The two-film, or two-resistance, model then results:

$$\frac{1}{K_{ox}a} = \frac{1}{K_i k_y a} + \frac{1}{k_x a} \tag{8.25}$$

$$\frac{1}{K_{oy}a} = \frac{1}{k_y a} + \frac{K_i}{k_x a} \tag{8.26}$$

where a is the interfacial area per unit volume.

For design purposes, representative expressions for total transfer, considering resistance of both phases, are

Absorption, gas to liquid:

$$N_i = K_{oy,i}a\left(y_i - y_i^*\right) = K_{ox,i}\, a\left(x_i^* - x_i\right) \tag{8.27}$$

Stripping, liquid to gas:

$$N_i = K_{oy,i}\, a\left(y_i^* - y_i\right) = K_{ox,i}\, a\left(x_i - x_i^*\right) \tag{8.28}$$

In Equations (8.27 and 8.28), N_i is the total moles/time of i transferred, and a is the effective interfacial area at the phase boundary. Individual phase resistances are handled by Equations (8.25) or (8.26).

Distillation, equimolar counterdiffusion:

$$N_i = K_i' a\left(y_i - y_i^*\right) \tag{8.29}$$

By convention, distillation calculations are based on the gas (vapor) phase, since usually most of the resistance is in that phase. Note also that since components are diffusing in both directions, the coefficient has a slightly different definition (see Table 8.3 for the individual mass transfer coefficients, which are primed). Further, the equilibrium ratio is replaced by the slope of the equilibrium curve, m. The overall coefficient is, then,

$$K_{oy}' a = \frac{1}{\dfrac{1}{k_{oy}' a} + \dfrac{m}{k_x' a}} \tag{8.30}$$

For a binary mixture, a typical y^*, x graph is shown in Figure 8.5. It is clear that with a change in location within the distillation column, the slope varies, being relatively large at the bottom. The liquid-side resistance to mass transfer is thus greater at the bottom than at the top, since the $m/k'_x a$ term represents the liquid-phase resistance.

8.4.4 Volumetric Coefficients, Liquid-Liquid

For two immiscible liquids in contact, a phase boundary occurs, and it is possible to transfer a solute I between them. The analogy between liquid-liquid and gas-liquid systems is apparent, and the equations for gas-liquid mass transfer apply. The phase with the lower density is called the

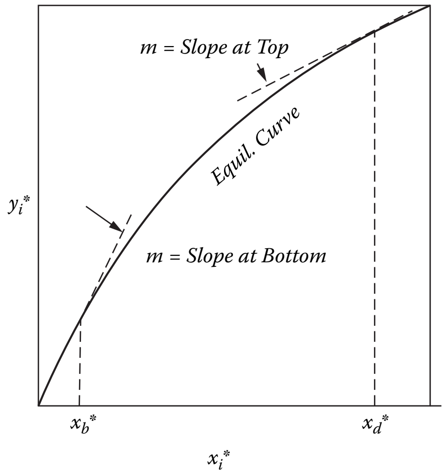

FIGURE 8.5 Representative equilibrium curve for binary distillation.

light phase, and the phase with the higher density is called the *heavy phase*. In design work, especially for liquid-liquid extraction, a distinction can be made between the dispersed phase and the continuous phase and between the extract (solvent) phase and the raffinate phase. These latter distinctions need not enter into the present discussion. For convenience in the analogy, we shall designate the light phase as the y-phase and the heavy phase as the x-phase.

Diffusion coefficients for the phases are calculated by methods given earlier. For the two-film model, equilibrium at the interface is assumed. In some cases, the interfacial area may be estimated, e.g., if a minor phase is dispersed such that discrete drops of a given size may be assumed, and if the fractional holdup of that phase (in the other phase) can be determined, then the use of volumetric coefficients is not necessary. Although such instances are relatively rare, and are related to the type of contactor used, they can be handled in the same fashion as gas-liquid mass transfer.

The liquid-liquid equivalents of Equations (8.27) and (8.28) are

Light phase to heavy phase:

$$N_i = K_{oy,i}a\left(y_i - y_i^*\right) = K_{ox,i}\,a\left(x_i^* - x_i\right) \tag{8.31}$$

Heavy phase to light phase:

$$N_i = K_{oy,i}\,a\left(y_i^* - y_i\right) = K_{ox,i}\,a\left(x_i - x_i^*\right) \tag{8.32}$$

and, with subscripts L and H (light and heavy) substituted for y and x,

$$\frac{1}{K_{oL,i}a} = \frac{1}{K_{L/H,i}\,k_{L,i}a} + \frac{1}{k_{H,i}a} \tag{8.33}$$

$$\frac{1}{K_{oH,i}a} = \frac{1}{k_{L,i}\,a} + \frac{K_{L/H,i}}{k_{H,i}\,a} \tag{8.34}$$

In Equations (8.33) and (8.34), the term $K_{L/H,i}$ is called an equilibrium *distribution coefficient*, and is often carried in terms other than mole fractions. (See Chapter 10 on liquid-liquid extraction.) The point to be made here is that the analogy between gas-liquid and liquid-liquid systems applies. However, one must be very careful in converting between sets of units (concentrations or mass fractions versus mole fractions) as well as in phase designations. Many designers call the *y* phase the solvent (or extract) phase, with transfer from the *x* phase to the *y* phase, with the stripping analogy in gas-liquid contacting. However, the solvent phase is often the light phase.

Designers of extraction equipment often use mass concentration units, which requires that the equilibrium ratio be expressed in the same units. An equivalent of Equations (8.31) and (8.32), using movement from continuous to dispersed phases, is

$$M_{i,c\to d} = K_{OL,cont}\, a\left(C'_{i,cont} - C'^{*}_{i,cont}\right) \tag{8.35}$$

where

M = g/(s-cm^3) transferred
a = interfacial area, cm^2/cm^3
$K_{OL,cont}$ = overall coefficient for the diffusing species (i.e., solute), cm/s
C' = mass concentration in bulk continuous phase, g/cm^3
C'^* = continuous phase concentration in equilibrium with bulk dispersed phase, i.e., $C'^* = m_{cd}\, C'_{\text{disp}}$
m_{cd} = equilibrium distribution coefficient, g/g

Example 8.4 has been included to help clarify the extraction adaptation of the gas-liquid relationships.

Example 8.4

Acetone is being removed from water by contacting with toluene in a packed extraction column. Water is the continuous [heavy] phase, and toluene is the dispersed [light] phase. Calculate the overall mass transfer coefficient for this process.

Data:
Continuous phase: density = 0.994 g/cm^3, viscosity = 0.92 cP, molecular weight ≈ 18 (lean solution)
Dispersed phase: density = 0.860 g/cm^3, viscosity = 0.54 cP, molecular weight ≈ 92 (lean solution)
Molecular weight of solute = 58
Distribution coefficient (equivalent to equilibrium ratio) = $C_{\text{disp}}/C_{\text{cont}} = 0.67$

Solution

Seibert and Fair [20] have found, for the system in question and for the particular packing type and flow rates, effective interfacial area = a = 1.46 cm^2/cm^3, and the following phase mass transfer coefficients:

$k_{L,\text{cont}} = 4.20 \times 10^{-3}$ cm/s
$k_{L,\text{disp}} = 9.81 \times 10^{-3}$ cm/s

Because concentrations are used, the equilibrium ratio is also in terms of concentrations. Thus,

$$K_{oL,cont} = \frac{1}{k_{L,cont}} + \frac{1}{m_{DC}\ k_{L,disp}} = \frac{1}{4.20\times10^{-3}} + \frac{1}{0.67\left(9.81\times10^{-3}\right)} = 2.56\times10^{-3}\ \text{cm}/\text{s}$$

$$K_{oL,cont}a = (1.46)\left(2.56\times10^{-3}\right) = 3.73\times10^{-3}\ \text{s}^{-1}$$

8.4.5 Evaporation of Spills

An important application of mass transfer principles deals with the evaporation of a hazardous liquid after an inadvertent spill. Here, the liquid must vaporize and diffuse through the adjacent air. The slab equation (Equation (8.17)), with partial-pressure driving force, may be used:

$$J_i = \frac{D_{ij}}{RT\ z_o}\left(p_{i1} - p_{i2}\right) = \frac{k_{ci}}{RT}\left(p_i^{sat} - p_{i2}\right) \tag{8.36}$$

where k_{ci} is a mass transfer coefficient for the liquid transferring into the air. If the evaporating liquid is relatively pure, there is no liquid-side resistance to mass transfer. The driving force is thus the vapor pressure of the liquid, and the downstream partial pressure can be neglected. The flux J_i is the amount of liquid evaporated per unit time per area of the spill.

Studies of water evaporation have shown the mass transfer coefficient to be a simple function of wind velocity U_j [21]:

$$k_{water,g} = 0.67U_j^{0.78} \tag{8.37}$$

By film theory, the wind velocity affects the film thickness z_0 in Equation (8.36).

For liquids other than water, the U.S. Environmental Protection Agency recommends the simple ratio [22]:

$$\frac{k_{ci}}{k_{water,gas}} = \left(\frac{M_{water}}{M_i}\right)^{1/3} \tag{8.38}$$

which is an approximation of the diffusion coefficient ratio in Equation (8.36).

A final design equation then results:

$$J_i = \frac{0.67U_j^{0.78}\left(18/M_i\right)^{1/3}\ p_i^{sat}}{RT} \tag{8.39}$$

which of course can be simplified by combining the constant terms. If the amount and area of the spill are known, Equation (8.39) can be used to determine the time required for essentially complete vaporization.

Example 8.5

A leak of toluene generates a spill area of 3.0 m^2. The temperature is 32°C, and the average wind velocity is 0.5 m/s. What is the rate of evaporation of the toluene?

Data:

Toluene mol. wt. = 92, and its vapor pressure = 40 mm Hg, or 0.053 atm.

Solution

By Equation (8.39),

$$J_i = \frac{0.67(0.5)^{0.78}(18/92)^{1/3}\,0.053}{(82.057 \times 305.2)} = 4.79 \times (10^{-7})\,\frac{\text{gm}-\text{moles}}{\text{s}-\text{cm}^2}$$

For 3×10^4 cm^2 and converting to familiar units, rate of evaporation = 0.175 lb/min.

8.5 SUMMARY

This chapter deals with the diffusional transfer of mass to and across a phase boundary. In particular, gas-liquid, gas-solid, and liquid-liquid phase combinations have been considered. Process applications include absorption, stripping, distillation, extraction, adsorption, and the diffusional aspects of chemical reactions on a solid surface. For steady-state transfer operations, the rates of mass transfer can be correlated by variations of Fick's first law, which states that the rate is directly proportional to the concentration driving force and the extent of interfacial area, and inversely proportional to the distance of movement of the mass to the interface.

To make Fick's law tractable for engineering calculations, several theories, or models, have been discussed. Their application usually introduces some empiricism, since distance of diffusion and extent of interfacial area are usually indeterminate. For most calculations, the time-tested film model is appropriate, not because it represents with validity the physical situation, but rather because it is supported by a wealth of experience as well as the ready availability of data, particularly molecular diffusion coefficients. The penetration and surface-renewal models have specialized applications and also depend on empirically derived parameters.

Not all possible applications of mass transfer theory have been discussed, and multicomponent systems have been treated as pseudo binary or ternary systems. To delve deeper, the reader should consult specialized books, some of which are listed in the References section.

NOMENCLATURE

a	interfacial area, s^{-1}
c_m	mean concentration, g-moles/cm^3
C	concentration, g-moles/cm^3
C_m	average total concentration, g-moles/cm^3
D	molecular diffusion coefficient of gas, cm^2/s
D^L	molecular diffusion coefficient, liquid phase, cm^2/s
D^{LO}	molecular diffusion coefficient of liquid at infinite dilution, cm^2/s
H	Henry's law coefficient, *p*/*x* or *y*/*C*
i	diffusing species *i*
j	diffusing species *j*
J	diffusion flux for unidirectional transfer, g-moles/s·cm^2
k	diffusing species *k*
k	Boltzmann constant, Equation (8.3)
K	overall mass transfer coefficient

K gas-liquid or vapor-liquid equilibrium ratio
l diffusing species *l*
m slope of equilibrium line
M molecular weight
N diffusion flux for equimolar transfer, g-moles/$cm^2 \cdot s$
p partial pressure, atm
P total (absolute) pressure, atm
r pore radius, cm
R gas constant
s seconds
S fractional surface renewal, s^{-1}
S total surface area of solid, cm^2/g (Equation (8.13))
T absolute temperature, °K
V molar volume, cm^3/g-mole
x liquid mole fraction
y gas or vapor mole fraction
z diffusion distance, cm
z_0 thickness of film, cm

Greek letters

γ thermodynamic activity coefficient
ε internal void fraction of solid
θ exposure time, s
λ latent heat of vaporization, J/kg (Equation (8.7))
μ viscosity, cP
π 3.1416…
ρ Density, g/cm^3
Σ_v diffusion volume (Equation (8.2))
τ tortuosity factor, dimensionless
ϕ correction factor for liquid association (Equation (8.4))

Subscripts

b bulk basis
eff effective
G gas
i component *i*
int interface basis

9.1 INTRODUCTION AND OVERVIEW

9.1.1 Turbulent, Transitional, and Laminar Mixing

It has been estimated that well over 70% of all mixing is done under turbulent conditions. Turbulent mixing occurs in pipelines, liquid jets, impingement devices, mixing vessels, tee-junctions, static mixers, pumps and orifices, and anywhere turbulence can be created. Eddy interactions lead to turbulent mixing in low-viscosity fluids. Large, high-energy eddies become smaller as a result of viscous-energy dissipation. During this process, regions of segregation are reduced in both size and intensity by the eddy motion. This process is normally fast. In turbine-equipped baffle-stirred vessels, turbulent mixing develops at impeller Reynolds numbers (Re), ($D^2N\rho/\mu$) ≥ 10^4. Turbulent mixing is faster than transitional-flow mixing and is orders of magnitude faster than laminar mixing. Virtually all gas-gas mixing occurs under turbulent conditions. Commonly used units of power intensity are kW/m^3 or hp per 1000 gal.

At transitional flow conditions, larger diameter impellers are used to improve mixing times, but they require more power than equivalent mixing rates under turbulent conditions. Baffles improve mixing rates for Re > 300, but have the opposite effect for Re below this point. Helical ribbon-, anchor-, and gate-type impellers are commonly used at the low end of the transitional flow range.

Laminar mixing is a two-stage process: (1) Discrete layers or lumps of fluid are stretched by mechanically induced shear. The more they are stretched, the thinner they become. (2) Diffusion decreases the concentration gradients between adjacent, yet still distinct layers. Laminar mixing is slower, and much more energy demanding, than turbulent or transitional mixing. If complete stretching does not occur throughout the fluid, uniformity will not be achieved. Stirred vessels containing impellers are used for viscosities of up to 50,000 cP. At higher viscosities, equipment used includes extruders (single and twin screw), kneaders, Banbury mixers, and static mixers. Gear pumps are used to move material through static (motionless) mixers. Good mixing demands that all of the fluid be exposed to the stretching process. Power is measured in terms of horsepower/pound.

9.1.2 Process Effects

Mixing enables a chemical reaction or a physical process to be carried out efficiently, thereby achieving a desirable result. Rapid local mixing, created by turbulence, often affects the yield from a set of chemical reactions. Segregation, due to poor mixing, can lead to lower yields and formation of undesirable by-products. Sometimes, simple changes, such as relocating the feed point, can lead

to an improved performance. In cases where reaction rates are very fast, such as in reaction injection molding (RIM), impinging jet mixers create the rapid mixing needed for producing high-quality products. Mixing helps promote desirable rates of polymer chain growth for polymerizations. Many exothermic reactions, such as nitration and emulsion polymerization reactions, are operated by continuous reagent/feed addition. Such processes require rapid mixing to avoid local segregation that could lead to undesirable side reactions. Neutralization reactions often form solid precipitates. Conditions of locally high supersaturation, due to inadequate mixing, lead to the formation of hard-to-filter fine particles. This can be prevented by introducing reagents to the impeller region, where local mixing rates are fast.

For two-phase systems, mixing promotes faster mass transfer by creating higher interfacial area due to smaller bubbles or drops. Turbulence also helps reduce the boundary-layer resistance around drop or bubble surfaces, leading to faster mass transfer.

For solid-liquid systems, agitation provides solids suspension, either by maintaining movement at the bottom of a vessel, or by maintaining a desired level of uniformity throughout the vessel.

Agitation is required for blending, where the process objective is to promote homogenization of a fluid to a desired degree of uniformity, often in a specified time. The rate of approach to uniformity is an exponential process. Complete uniformity takes a very long time. In practice, one sets specifications to typically 95 or 99% uniformity, based on the process requirements.

The subjects discussed in this chapter are described more fully in the *Handbook of Industrial Mixing* [1].

9.1.3 Equipment and Design

It is important to match mixing equipment capabilities with process requirements. While it is desirable to have an optimum design and operating conditions for every step in the process sequence, it is seldom practical to do so. For example, specialty and pharmaceutical processes require the use of multipurpose reactors. An important consideration is to understand how less-than-ideal equipment will function in all stages of operation.

Documenting mixing performance data is vital to future troubleshooting. During the life of the equipment, modifications of both processes and equipment are common. For example, increased production requirements could lead to higher process concentrations and viscosity. Under such conditions, mixing may become inadequate, leading to regions of stagnation. Documented performance conditions for the original process are useful for diagnosing how the process responds to new conditions. A simple design or operational change can often meet the new challenge.

Mixing intensities vary greatly throughout a stirred vessel. While turbulent mixing can exist in the impeller region, transitional or laminar-flow conditions can exist elsewhere. Energy dissipation near the impeller is 40–50 times greater than in other regions (see Zhou and Kresta [2]). Common practice introduces feed to the surface of the liquid. While this avoids plugging problems and feed-pipe stagnation, it places the feed in a weakly mixed region.

Computational fluid dynamics or CFD (also known as computational fluid mixing, CFM) was introduced to the chemical process industries in the late 1980s. CFD/CFM is a numerical technique for solving fluid relationships such as conservation, transport, and the Navier-Stokes equations. Commercial CFD software enables one to predict the effects that geometry, feed location, physical properties, and operating conditions have on conditions in the vessel. Typical results predict velocity profiles, rates of energy dissipation, concentrations, and flow streamlines as they would occur in the vessel. This tool enables one to appreciate the good and bad features for each considered design. CFD simulations are based on assumptions. Some are low risk, but some impose high risk. Experimental validation is important particularly for nontrivial applications. Validation is advisable. Published velocity profile data can often help to validate results. At the time of this writing, CFD is weak in its ability to model large-scale turbulence and multiphase flow.

9.2 SYMBOLS, DIMENSIONLESS GROUPS, AND TERMS USED IN MIXING

9.2.1 Common Symbols Used in Mixing

Symbol	Significance	Units	
		Metric	English
a	Interfacial area of drops, bubbles, and solids per unit volume	cm^2/cm^3	ft^2/ft^3
B	Baffle width	m	ft
c_p	Specific heat at constant pressure	J/(kg·°K)	Btu/(lb·°F)
C	Impeller clearance, distance between lower tip of the impeller and the bottom of the vessel	m	ft
c_{B0}	Initial concentration of B	mol/m^3	
d	Diameter of dispersed phase particle, drop, or bubble	m	ft
d_{32}	Sauter mean drop or bubble diameter	m	ft
d_j	Jet diameter	m	ft
D	Impeller diameter (diameter swept out by the impeller)	m	ft
H	Height of liquid measured from the bottom of the tank	m	ft
h	Film heat-transfer coefficient, often accompanied with subscripts i, j, o, (inside, jacket, outside)	$J/(s{\cdot}m^2{\cdot}°K)$	$Btu/(h\ {\cdot}ft^2{\cdot}°F)$
k	Thermal conductivity	W/(m·°K)	Btu/(ft·°F)
k_2	Specific reaction rate constant	various	
k_La	Volumetric mass transfer coefficient	s^{-1}	
M_i	Mass transfer rate for species (i)	g mole/s	lb mole/s
N	Impeller speed	s^{-1}	rpm
N_{JS}	Impeller speed to just suspend particles (all solids move)	s^{-1}	rpm
n_B	Number of blades on the turbine hub		
P	Power drawn by the impeller	kW	hp
P_G	Power drawn by the impeller under gassing conditions	kW	hp
Q	Volumetric gas flow rate, liquid flow rate	m^3/s	ft^3/s
S	Spacing between impellers	m	ft
T	Tank inside diameter	m	ft
τ_r	Reaction time	s	
τ_m	Mixing time	s	
V	Volume of contents in a vessel	m^3	gal
V_j	Jet velocity	m/s	ft/s
W	Impeller blade width	m	ft
X_S	Selectivity variable for chemical reactions for s		
F	Holdup, often used with subscripts g, s to designate gas, solid, etc.	fraction, sometimes %	
s	Interfacial or surface tension	N/m	lb_f/ft
D	Molecular diffusivity	m^2/s	ft^2/s
µ	Dynamic viscosity	Pa·s	cP
u	Kinematic viscosity	m^2/s	ft^2/h
r	Density	kg/m^3	lb/ft^3
H	Henry's law constant		

9.2.2 Common Dimensionless Groups Used in Mixing Correlations

Name	Symbols	Significance
Reynolds number	$\mathrm{Re} = D^2N\rho/\mu$	Ratio of inertial to viscous stress; defines turbulent, transitional, and laminar-flow regimes; a correlating parameter for flow-sensitive terms in mixing
Power number	$\mathrm{Np} = P/\rho N^3D^5$	A function of the impeller Reynolds number and impeller type; Np is constant at $\mathrm{Re} > 10^4$; increases with decreasing Re in the laminar region
Flow number	$\mathrm{Nq} = Q/ND^3$	Ratio of actual impeller flow to an idealized flow
Fourier number	$\mathrm{Fo} = \mu\theta/\rho T^2$	Used to correlate mixing times; also referred to as the vessel Reynolds number
Gas flow number	$\mathrm{Fl}_G = Q/ND^3$	Ratio of gas to idealized liquid flow
Dämköhler number	$\mathrm{Da} = \tau_M/\tau_R$	Ratio of mixing time to reaction time
	$\mathrm{Da} = k_2c_{BO}/E$	Half life of a reaction to the rate of engulfment
Capillary number	$\mathrm{Ca} = \tau \cdot r_D/\sigma$	Ratio of fluid stress on a drop to its interfacial resistance
Froude number	$\mathrm{Fr} = N^2D/g$	Ratio of centrifugal to gravity forces; used for vortex definition and in gas-liquid mixing correlations
Nusselt number	$\mathrm{Nu} = hD/k$	Used with Re and Pr to correlate heat-transfer data
Prandtl number	$\mathrm{Pr} = c_p\mu/k$	Ratio of convective to conductive heat transfer
Weber number	$\mathrm{We} = N^2D^3\rho/\sigma$	Ratio of inertia to surface/interfacial forces for gas-liquid and immiscible L-L systems; used to correlate bubble/drop size

9.2.3 Significance of Commonly Used Mixing Terms

Power Number, Np: The power number, Np, sometimes referred to as Po, is a measure of the relative drag of the impeller. Streamline curved blades, like hydrofoils and retreat-curve impellers, have less drag than flat blades; consequently, their power numbers are lower than those for flat-blade impellers. Power numbers of some of the more popular impellers are given in Table 9.1. The calculation of power from impeller diameter, speed, and liquid density is given by Equation (9.1).

Flow Number, Nq: The magnitude of the flow number is a measure of an impeller's ability to produce flow. The larger the flow number, the greater is the flow. The total impeller flow consists of the direct discharge flow plus entrained flow. Most reported flow numbers include both flows. Equation (9.3) shows the use of Nq in calculating the total discharge flow.

Mixing time, θ_M: Mixing time, θ_M, is the time it takes to mix initially segregated materials to a specified degree of uniformity. For example, it takes 60% longer to mix to 99% uniformity than to mix to only 95%. Mixing times can be calculated from the methods described in Section 9.4. For certain reactions, it is important to have mixing times shorter than reaction times. The Dämköhler number, Da, is the ratio of mixing to reaction times and is further described in Section 9.5.

Impeller Reynolds number, Re, N_{Re}*, and vessel Reynolds number, Re*: The impeller and vessel Reynolds numbers are the ratios of inertia to viscous forces. They are indicators of flow conditions: turbulent, laminar, or transitional. They are used to correlate other quantities such as the power number, Figure 9.1, and the inside heat-transfer coefficients shown by Equation (9.85).

Micro-Mixing: Micro-mixing is the smallest scale of mixing. In terms of dimensions, it is at or below the Kolmogoroff microscale that can be calculated by Equation (9.9). Micro-

TABLE 9.1
Characteristics of Commonly Used Impellers

Model	Flow Pattern	No. of Blades	Features	Np	Nq	Supplier
HE-3	Highly axial	3	Efficient turbulent flow, blending, and suspending of solids; efficient pumping impeller in gas-liquid systems	0.23–0.33	0.54	Chemineer
CD-6/BT-6	Highly radial	6	Effective gas dispersing impeller; BT-6 handles higher gas flows	2.7–3.7	0.72	Chemineer
Maxflow T	Between high-efficiency HE-3 and 45° PBT	3, 4, or 6	High solidity reduces cavitation tendency in gas-handling applications; good pumping in the presence of gas	0.4–0.9 depends on pitch, D/T, and no. of blades	…	Chemineer
Mark II	Axial	3 or 6	High solidity reduces cavitation tendency; highly effective blending in side-entering mode	0.22–0.75 depends on pitch and D/T	…	Chemineer
R-100 D-6	Highly radial	5 or 6	Commonly used for gassing; prone to cavitate; also used for making dispersions and emulsions	5.75	0.8	Lightnin Chemineer
A-200 P-4, P-6	Mixed flow	4	Good for viscous mixing, general blending operations; more shear than the hydrofoils	1.0–1.3	0.72–0.82	Lightnin Chemineer
A-310	Highly axial	3	High pumping, efficient, available in many materials of construction, side-entering version is the A-312	0.30	0.56	Lightnin
A-315	Highly axial	4	High solidity makes this a good gas-dispersing impeller; high pumping circulates gas-liquid mixture throughout vessel	0.75	0.73	Lightnin
A-320	Highly axial	3	Good for high-viscosity applications, often interchanging with A-200, more axial than the A-200, but somewhat dependent on Reynolds number	0.65	0.68	Lightnin
R-510	Weak radial	6	A bar turbine that produces high shear for dispersing and shredding operations; similar in use to the R-500, bars are mounted on a disc with alternate blade on top and bottom of disc	0.61	…	Lightnin

Continued

TABLE 9.1 ***(Continued)***
Characteristics of Commonly Used Impellers

Model	Flow Pattern	No. of Blades	Features	Np	Nq	Supplier
R-500	Weak radial	many	Very high shear, effective in dissolving polymers, forming solutions; removes boundary-layer resistance	0.17–0.3	…	Lightnin
Curved Blade turbine	Highly radial	6	Lower shear rate than straight blade; not commonly used today	3.91	0.82	Various
Propeller 1.5/1.0 Pitch	Strong axial	3	Efficient, costly, heavy compared with HE-3 and A-310	0.87/0.35	0.77/0.44	Various
Curved Blade Turbine	Radial	4	Good pumping due to broad blades; a glassed steel impeller	1.7–1.4	0.54	Pfaudler
Retreat-curve impeller (RCI)	Radial	3	Used with glass-lined equipment; usually at bottom of vessel and with large D/T ratios; effective general-purpose impeller; can be used for limited gas dispersion, with good baffling	0.5–0.3	0.24	Pfaudler DeDietrich Tycon
Vertical-blade turbine	Radial	2 + 2	Similar to vertical pitch flat-blade design; glassed steel, overlapping hub design	2.7	0.65	Pfaudler
Turbofoil	Axial	4	A glassed hydrofoil, similar to HE-3 or A-310, except has four blades	0.4–0.3	0.48	Pfaudler

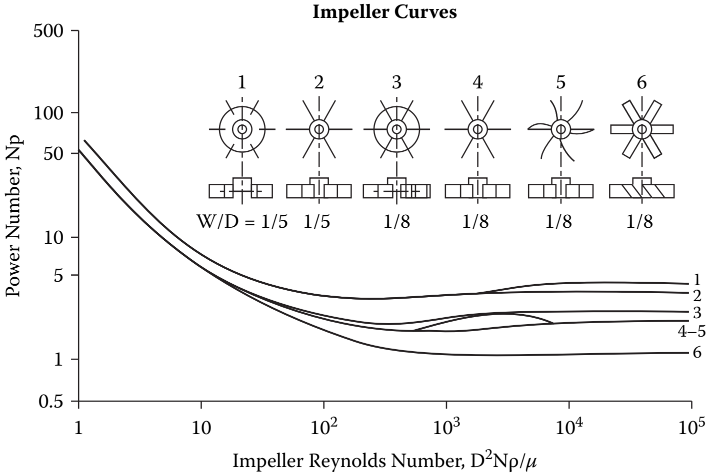

FIGURE 9.1 Reynolds number vs. power number for six turbine impellers. (Modified from Rushton et al., 1980. With permission.)

mixing is the scale involved with kinetically controlled chemical reactions. Effective micro-mixing usually requires high-energy input.

Meso-Mixing: Meso-mixing is a term used to describe the intermediate scale of mixing between micro-mixing and macro-mixing. More specifically, it is the turbulent exchange between turbulent impeller flow and the surrounding fluid. Refer to Figure 9.9.

Macro-Mixing: Macro-mixing is distributive mixing caused by large-scale flows. It is analogous to convective mixing. The rapid blending in a stirred vessel is due to macro-mixing.

9.3 STIRRED TANKS: EQUIPMENT AND FUNCTION

9.3.1 Impellers and Their Characteristics

This section describes mixer geometry: impellers (types listed in Figure 9.3), the number required, their characteristics, importance of location, vessel shape, and effects of baffles. An example is given to show a basic calculation of mixer power and flow.

Impellers available in the pre-1960 era would have been limited to four- and six-blade disc turbines (also known as radial-flow turbines or RFT or Rushton turbines), the four- and six-blade 45° pitch blade turbines (PBT), the four- and six-blade flat-blade turbines (FBT), and the three-blade retreat-curve impellers (RCI).

While these older impeller types are still used, numerous hydrofoil designs are now available. These contoured blade hydrofoils, originally developed by R. Weetman, require much less power and produce nearly axial flow, two big advantages they have over the older designs. True axial flow is desirable, since it permits more efficient top-to-bottom mixing or turnover. Hydrofoils are also specialized for different applications, such as viscous fluid mixing, gas-liquid mixing, as well as low-viscosity turbulent mixing. They are ideally suited for flow-dominated applications such as multiphase suspension and blending. They work well with other impellers.

Recent designs used for gas-liquid mixing include the Scaba and Chemineer's BT-6 and CD-6 originating from the work of Professors J. M. Smith and A. Bakker. The forward-facing cup-shaped blades delay the onset of cavitation, thus enabling more power to be delivered for dispersion. Other impeller designs include sawtooth blades such as the Lightnin R-500, used to produce high shear rates in low-viscosity fluids; Ekato's INTERMIG design for moderately high-viscosity blending; and the older helical and anchor designs for high-viscosity mixing.

9.3.2 Power

Figure 9.1 is a log-log plot of the power number, Np, vs. the Reynolds number for several impellers in a fully baffled vessel. A few important features are noted here:

- In the laminar region ($1 \le Re \le 10$), the power number decreases linearly with increasing Reynolds number.
- In the transition region ($10 \le Re \le 10{,}000$), the power number decreases more gradually, and for some impellers, it then begins to increase, while for others, it continues to decrease with increasing Reynolds number.
- In the fully turbulent region ($Re \ge 10{,}000$), power numbers are constant, but design dependent.

There is a different power number for each impeller, reflecting its unique shape and drag-producing characteristics. The power number values given in Table 9.1 are only applicable for turbulent flow. Manufacturers offer a variety of impellers, the characteristics of which are given in Table 9.1.

The power requirement for a single impeller operating in a baffled vessel can be calculated from

$$P = Np \cdot \rho \cdot N^3 D^5 \tag{9.1}$$

In English units, Equation (9.1) becomes

$$HP = Po \cdot \rho\left(lb \cdot ft^{-3}\right) \cdot N^3\left(s^{-1}\right) \cdot D\left(ft\right) / 32.2\left(ft \cdot s^{-2}\right) \cdot 550\left(ft - lb \cdot hr^{-1}\right) \tag{9.1a}$$

In metric units, Equation (9.1) becomes

$$kW = Np \cdot \rho \cdot \left(kg \cdot m^{-3}\right) \cdot N^3\left(s^{-1}\right) \cdot D^5\left(m\right) / 1{,}000 \tag{9.1b}$$

In practice, the Reynolds number must first be determined to obtain the power number. The impeller Reynolds number is defined for stirred vessels and given by

$$\mathrm{Re} = \frac{D^2 N \rho}{\mu} \tag{9.2}$$

Example 9.1

Determine the power needed to agitate a fluid using a Rushton impeller, given the specific gravity of the liquid is 1.0, the tank diameter is 3.0 m, the height of liquid is 3.0 m, the impeller diameter is 1.0 m, the speed is 1.0 s^{-1}, and the liquid viscosity is 1.0 cP.

Solution

Substituting the Reynolds number in Equation (9.2), Re = $(1.0^2)(1)(1{,}000)/0.001 = 10^6$. Flow is therefore fully turbulent. The power number for a Rushton impeller, the top curve in Figure 9.1, is Np = 5.0. The density = 1000 kg/m^3, and the power is

$$P_{\text{Rushton}} = 5.0(1000)(1.0^3)(1.0^5)/1000 = 5.0 \text{ kW}$$

If a 45° PBT is selected (line 6, Figure 9.1) at a Re = 10^6, the power number is 1.3. The power is

$$P_{45°PBT} = 1.3(1000)(1.0^3)(1.0^5)/1000 = 1.3 \text{ kW}$$

Zhou and Kresta [2] have determined the energy distribution for different impellers. They reported the dissipation rates in the impeller region to be 38.1% for the A-310, 43.4% for the Rushton turbine, and 70.5% for the 45° PBT of the total energy input to the impeller.

9.3.3 Multiple Impellers

Many applications benefit from the use of two or more impellers. Multiple impellers are commonly used in tall vessels, where $H/T \geq 1.2$. The upper impellers are often hydrofoils, and the selection of the lower turbine depends on the application. For example, gas-liquid and liquid-liquid dispersion applications frequently combine hydrofoils in the upper position and disc turbines in the lower position. The practice of placing several radial discharging disc turbines at equal intervals on the shaft leads to compartmentalization and poor turnover. Two or more axial-flow turbines, such as hydrofoil types, are often used for blending of low-viscosity homogeneous materials. Multiple 45° pitch blade turbines can be used for viscous blending. Low-viscosity blending in square-shaped vessels can normally be done using a single impeller. Multiple impellers are generally not used for solids suspension applications.

Multiple impellers need not be the same size or type. For example, in gas-liquid applications, a good practice is to assign 75% of the energy to gas dispersion and 25% to circulation. Using this power allocation, the assumption of additive power and values of Np enables one to calculate the respective impeller diameters.

Power calculation is more complicated for certain multiple impeller configurations. The power demand is less than additive if one impeller "receives flow" from an adjacent impeller. Frequently, multiple axial or mixed-flow impellers are used to create better flow distribution. The effects of impeller spacing, blade angle, number of blades, the degree of baffling, as well as the effect of Reynolds number on the power number are given by Bates [3] and shown in Figure 9.2. The ordinate is the ratio of two impellers to that of a single flat-blade turbine, and the abscissa is the impeller spacing.

With reference to Figure 9.2, observe that the power demand for multiple radial impellers spaced at one or more impeller diameters apart is additive, but at closer spacing, power is greater than the sum of each impeller. This is due to flow interference. As mentioned earlier, the total power demand for multiple mixed-flow impellers is complex.

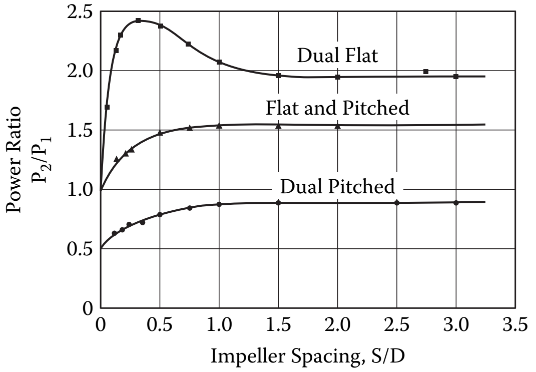

FIGURE 9.2 Effect of dual turbine spacing on power. (Modified from Bates et al., 1963. With permission.)

9.3.4 Flow Discharge

The discharge flow rate from most impellers is expressed in terms of the flow number N_q. Values are given in Table 9.1. The flow number, Nq, is defined by

$$Nq = \frac{Q}{ND^3} \tag{9.3}$$

where Q represents the total flow (direct + entrained) in m^3/s (ft^3/s), N is the speed in s^{-1}, and D is the impeller diameter in m (ft).

Flow rate calculations can be used to estimate the mean circulation time, τ_C, of fluid in the vessel. It is the liquid volume divided by the impeller flow rate. A rule of thumb is that the approximate mixing time, τ_M, is three to four times the mean circulation time, τ_C.

The flow rate resulting from complementing dual impellers is not significantly greater than for a single impeller. The performance improvement comes from better flow distribution. The mean circulation time is the time a particle takes to complete a circuit in the vessel. Every vessel has a distribution of circulation times. Multiple impellers reduce the circulation time distribution (see Section 9.4).

Figure 9.3 shows many of the impellers listed in Table 9.1.

9.3.5 Baffles

Baffles are used to convert tangential to axial flow and are required for all stirred-tank turbulent-flow applications. They are optional for transitional-flow conditions ($10 \leq Re \leq 10{,}000$) and should never be used for laminar-flow applications. Within the transitional-flow range, a good rule of thumb is to use some baffling for $300 \leq Re \leq 1000$ but not below 300. Baffles are required for most low-viscosity, multiphase applications.

The standard fully baffled vessel consists of four equally spaced vertical plates, T/12 to T/10 wide, and set away from the wall a distance of T/72 to T/90. Baffle lengths extend from near the liquid surface to the bottom of the straight wall. Baffles reaching the surface create eddies, which are helpful for engulfing addition streams or floating solids. Surface eddies also lead to incorporation of headspace gases, which sometimes need to be prevented. Short baffles located in the impeller region can substitute for full-length designs. Baffles used with glass-lined equipment include the beavertail, finger, "h," "d," and fin baffles. These are shown in Figure 9.4. One or two of these baffles are normally suspended from top openings on the vessel. Care must be taken to avoid excessive drag and fluctuating loads that could damage the glass lining of the support nozzle.

The demand for instrumentation, feed inlets, vent lines, relief systems, and inspection ports places a heavy demand on nozzle availability for baffles. Baffling often becomes secondary to these other process needs. While two baffles generally improve mixing rates by as much as 20% over single baffles, surprisingly good mixing can be achieved with one "h," "d," or fin-type baffle. The baffles shown in Figure 9.4 usually come equipped with temperature-sensing provisions. The degree of baffling can be varied by changing the baffle angle relative to flow, thus creating a variable flow resistance. Less conventional baffle designs include 90° angle-shaped baffles welded to the vessel walls.

Short top-entering baffles located at a distance 2/3R and extending to mid-depth convert angular to axial momentum; their submergence affects mixing. The optimum depth for suspended baffles is from 1/3 to 2/3 of the total liquid depth. Deeper penetration suppresses overall momentum and results in poorer mixing. Shallower penetration fails to convert enough tangential to axial momentum. Applications requiring changing liquid levels or operation at low liquid levels are often equipped with one deep and one shallow baffle. Similar arguments also hold for wall-attached baffles.

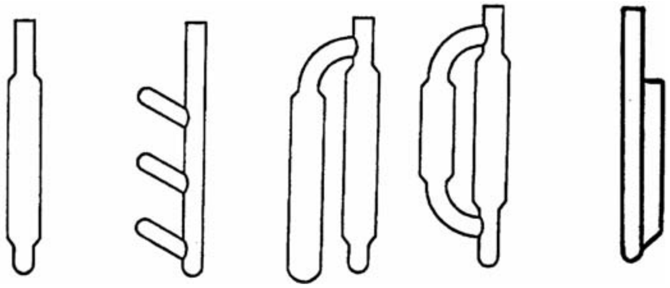

FIGURE 9.4 Baffles used in glass steel vessels (L-R): flattened pipe (Beavertail), finger, "h," "d," and fin.

9.3.6 Vessel Shape

The optimal vessel design is a dish-bottom tank having an *H/T* of approximately 1.2. Flat-bottom tanks, particularly larger storage vessels, can be used for simple mixing applications, but the flat-bottom tank is prone to develop dead zones in the corners. Also, the flat bottom is not conducive to redirecting the flow upward. Similarly, cone-bottom tanks should be avoided except for certain solids applications. Tall, slender vessels are used to increase gas residence time and to reduce wall thickness of pressure vessels. A major disadvantage is that tall vessels require long shafts requiring larger shaft diameters or use of steady bearings. Good circulation can be a problem for these designs. Draft tubes can promote good circulation, but require a constant level in the tank. Single impellers can be effectively used, coupled with optimum baffling, to provide good mixing in tanks up to 2:1 *H/T*. Harvey [4] shows that multiple different-size 45° PBTs can be optimized to improve mixing in transitional flow fluid applications.

9.3.7 Mechanical Considerations

The torque required of a mixer is

$$torque\left(N \cdot m\right) = \frac{P\left(kW\right) \cdot 10^3}{2\pi N\left(s^{-1}\right)} \tag{9.4a}$$

$$torque\left(in \cdot lb\right) = \frac{63{,}000 \cdot \left(HP\right)}{N\left(\min^{-1}\right)} \tag{9.4b}$$

The head developed by an impeller is

$$head \propto \frac{P}{Q} \tag{9.5}$$

where the head is in N/m^2 (lb/ft^2), *P* is in N·m/s (ft-lb/min), and *Q* (the impeller discharge flow) is in m^3/s (ft^3/min).

Impeller size (*D/T* ratio) influences whether flow or turbulence governs the process of mixing. Oldshue [5] shows, for equal process results, that impeller diameter affects power and torque characteristics, as shown in Figure 9.5. The values for power and torque are normalized to the values for an impeller with *D/T* = 0.333.

D/T ratios can be in the range of 0.2 to 0.7, but commonly they are 0.3 to 0.5. At equal power, large impellers rotate more slowly and require large gearboxes compared with smaller impellers.

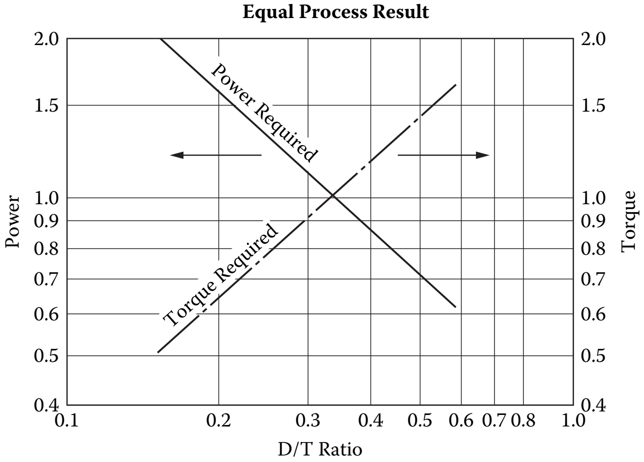

FIGURE 9.5 Typical curve of power decreasing while torque increases with *D/T.* (From Oldshue, J. Y., 1983.)

Large impellers create more flow and relatively less turbulence than small impellers. Small impellers display the opposite effects. There is a minimum cost of mixing (operating vs. capital) associated with the selection of *D/T.* This minimum is usually found at 0.35 to 0.45.

A complete mechanical design should include a calculation of the critical speed. When the operating speed is close to or exceeds the critical shaft speed, vibrations can lead to mechanical instabilities and severe equipment damage. For more information, see the chapter by King [6] in *Mixing in the Process Industries* or the chapter by Dickey and Fasano in the *Handbook of Industrial Mixing* [1].

9.3.8 Bottom Clearance

The clearance, expressed as "C" or as a ratio C/T or C/D, is the distance from the bottom edge of an impeller to the bottom of the vessel. C/D for an impeller in the middle is 0.5. General-purpose vessels used for multiple operations use an impeller placed very close to the bottom of the tank. This enables solids to be handled more efficiently as well as loading and unloading operations. When the impeller is some distance from the bottom, a small impeller "tickler" can help solve mixing problems with settling solids.

Impeller clearance affects total discharge flow and its direction. For example, when axial-flow impellers are placed close to the bottom, they produce a radial discharge. Upward-angled, retreat-curve impellers are always located at the bottom of the vessel, where they produce strong radial flow and produce good circulation while handling level changes and solids effectively.

Impeller clearance also affects power draw, as is shown in Figure 9.6 for six-blade Rushton, PBT, and flat-blade turbines.

9.3.9 The Vendor's Role

In the authors' experience, the vendor can play a valuable and often underappreciated role in supplying broad mixing experience. It is important to establish a trusting yet confidential relationship early on. Competitive vendor proposals serve to confirm designs and cost, but they are only as accurate as the information supplied to them. Industrial in-house mixing technology is important to validate vendor proposals. The vendor is often valuable in proposing new designs and in troubleshooting. Modern equipment suppliers are sophisticated in their knowledge of mixing, often possessing CFD tools and providing in-house experimental facilities for the benefit of their customers.

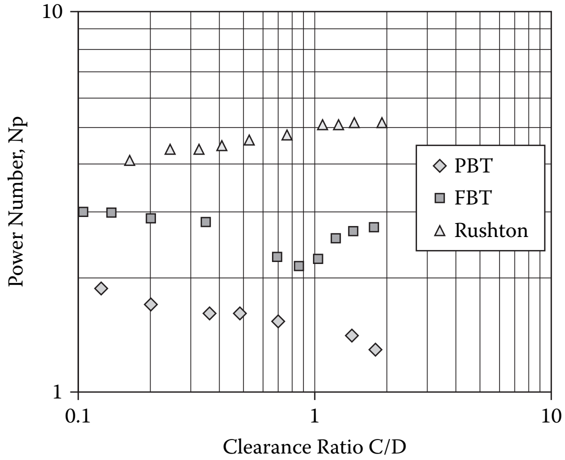

FIGURE 9.6 Effect of clearance on power. (From Bates et al., 1963).

9.4 BLENDING

9.4.1 Introduction and Scope

Blending is the mixing of different, but miscible, fluids. The topics that are discussed in this section include: fluid properties (rheology), mixing mechanisms, equipment used, and the energy required to mix to a certain degree of uniformity in a given time. This section emphasizes the stirred tank, but blending is also done in static mixers and by jet mixing. These topics are discussed in Sections 9.9 and 9.10 in this chapter. The kinetics of blending is discussed as well as how blend time is related to design, impeller selection, and operation.

The fluid viscosity is one of the primary considerations when selecting an impeller. Turbine-type impellers are used for fluid viscosity of up to 50,000 cP. Smaller diameter turbines are used for low-viscosity fluids; larger ones for higher viscosity applications. Beyond 50,000 cP, the helical ribbon impeller, screw/draft tube designs, gate types, paddles, and anchors are used. While gates, paddles, and anchors are considerably less expensive than the helical ribbon or screw/draft tube designs, they are less able to produce good top-to-bottom flow, essential for good mixing.

9.4.2 Turbulent, Transitional, and Laminar Flow Blending

Blending is all about creating a specified degree of homogeneity from initially segregated materials in a given time. The *degree of mixing* is a term used to describe the quality of the result. For example, θ_{95} refers to the time it takes to reach 95% uniformity, and θ_{99} the time to reach 99% uniformity. Higher degrees of uniformity require longer mixing times. An example is given later in this section.

Turbulent and laminar mixing are quite different. Turbulent mixing takes place by three mechanisms: turbulent eddy motion, bulk or convective flow, and molecular diffusion. Laminar flow has no eddies to assist in mixing. Laminar mixing first depends on creating very thin layers between initially unmixed components, followed by molecular diffusion.

Efficient laminar mixing requires that very thin layers of fluid be well distributed throughout the vessel. Laminar mixing is slow and can take orders of magnitude longer to reach an equivalent state of uniformity than turbulent mixing.

In designing blending systems, it is important to establish whether conditions will be turbulent, transitional, or laminar. Turbulent mixing occurs at impeller Reynolds numbers greater than 10^4.

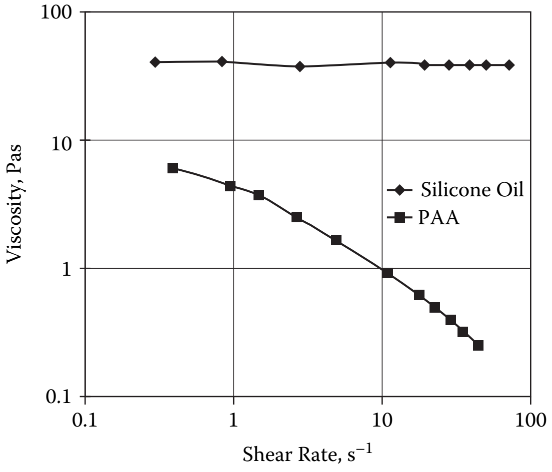

FIGURE 9.7 Typical viscosity shear rate curves for Newtonian silicone fluid and non-Newtonian polyacrylamide. (From Ulbricht et al., 1986.)

Mixing times are normally short. If the Reynolds number lies between 10 and 10^4, conditions are referred to as transitional. Mixing times will be longer than at turbulent conditions, but short compared with laminar flow conditions. At a Reynolds number of <10, conditions are laminar. While stirred tanks using proprietary devices can be used at these conditions, one ought to consider using a motionless mixer.

While many process fluids are Newtonian, some are non-Newtonian (as seen in Figure 9.7). For such cases, it is not sufficient to use a single value for viscosity to determine the impeller Reynolds number. Concentrated slurries are typically non-Newtonian and particle-size dependent. They are frequently shear-thinning. Dilatant behavior seldom occurs. If the system is simply shear thinning, it is usually possible to describe its rheological behavior with a simple power-law relationship:

$$\tau = k\gamma^n \tag{9.6}$$

where n is the flow behavior index and k is the viscosity at a shear rate of 1.0 s^{-1}.

Metzner [8] determined that the mean shear rate, $\bar{\gamma}$ (s^{-1}), for a stirred tank in the transitional to laminar regime can be determined by the Metzner-Otto equation:

$$\bar{\gamma} = KN \tag{9.7}$$

where K values are found in Table 9.2, and N is the speed in s^{-1}.

Shear-thinning fluids can cause a number of problems. Near the impeller zone, where shear rates are high, the apparent viscosity is low and the region is well mixed. Further from the impeller, shear rates are much lower, the apparent viscosity is higher, and the fluid is often stagnant. Caverns, shown in Figure 9.8 (regions of well-mixed fluids in a stagnant matrix), can develop yield-stress fluids. The shape of the cavern depends on the discharge pattern of the impeller.

Cavern formation, shown in Figure 9.8, is very real and highly undesirable. It can be avoided by better distribution of the shear stress (using multiple impellers), thus creating lower local effective viscosity and higher circulation rates throughout the vessel.

TABLE 9.2
Constants in the Metzner-Otto Equation

Impeller Type	Mean Shear Rate Constant, *K*
Propeller	10
Rushton turbine	12
Flat-blade turbine	12
Pitch-blade turbine	12
Anchor	25
Helical ribbon	30

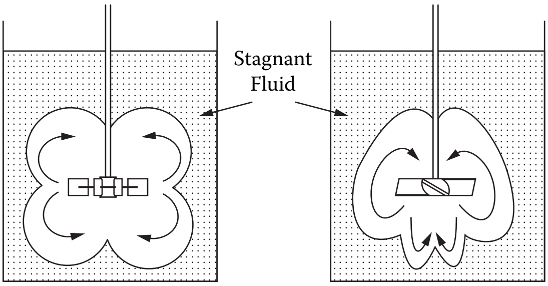

FIGURE 9.8 Shape of cavity in a shear-thinning suspension. (From Wichterle et al., 1981.)

Recent advances in commercial CFD software have enabled this problem to be modeled. The diameter and height of caverns have been correlated:

$$\left(\frac{D_c}{D}\right)^3 = N_P \cdot \left(\frac{\rho \cdot N^2 D^2}{\tau_y \pi^2 \left(1/3 + H_c / D_c\right)}\right) \tag{9.8}$$

where D_C and H_C are the cavern diameter and height and τ_y is the yield stress. The value of H_C/D_C for a Rushton turbine was found to be 0.4 [9].

Example 9.2

Calculate the impeller Reynolds number for a power-law fluid with k = 1.5 poise, n = 0.7, and density = 1000 kg/m^3. Assume the vessel diameter is 2 m, and the impeller, a 45° PBT, is 0.7 m in diameter. The operating speed is 90 rpm. Determine the nature of flow.

Solution

The mean shear rate constant *K*, for a 45° PBT, from Table 9.2 is 12. The mean shear rate at 90 rpm is 12 (90/60) = 18 s^{-1}. The viscosity is defined as the shear stress/shear rate and is $\mu = k\gamma^{(n-1)}$ for a power-law fluid. For the problem at hand, this becomes 1.5 (18)$^{-0.3}$ = 0.630 poise (0.063 kg/m·s). The Reynolds number is 0.7^2 (90/60) 1000/0.063 = 11,666. The flow is fully turbulent in this example.

9.4.3 The Nature of Turbulent Flow

Large eddies are produced when an impeller passes through a low-viscosity liquid. These eddies are close to the impeller tip and are similar in size to the blade width. Figure 9.9 shows the energy $E(k)$ as a continuous function of wave number (k), along with terms commonly used in turbulent mixing. Large eddies depend on how the turbulence is generated. Smaller eddies do not. Eddy size,

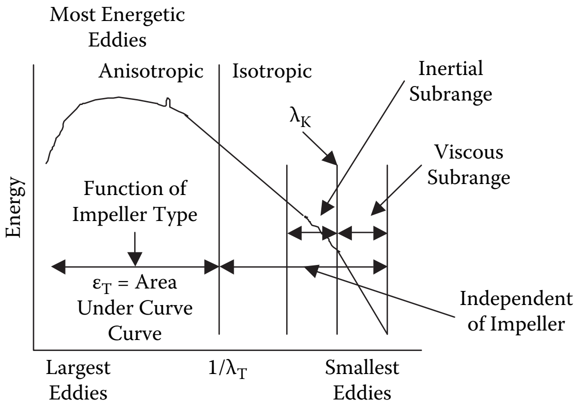

FIGURE 9.9 Turbulence energy spectrum, with λ_T as the length scale.

λ, is inversely proportional to wave number, *k*. The size and energy content of these eddies decrease with increasing distance from the impeller tip.

The Kolmogoroff scale can be calculated from

$$\lambda_k = \left(\frac{\nu^3}{\varepsilon_T}\right)^{1/4} \tag{9.9}$$

where λ_k is the Kolmogoroff length scale, ε_T is the local energy dissipation rate, and ν is the kinematic viscosity. For a power input of 1 kW/m^3 (5 hp/1000 USG), λ_k is about 30 μ. This value is an effective size for many fast chemical reactions.

The energy distribution in a stirred vessel is not uniform. As mentioned earlier, investigators have shown dissipation rates near the impeller to be 10 to 50 times greater than the vessel average.

Figure 9.10 shows energy-dissipation contours for four impellers. The numbers represent fractions of the average energy input. It is important to understand energy distribution because it affects all processes requiring intensive mixing. This includes fast multipath chemical reactions, bubble and drop dispersion, and solids dissolution. Subsequent sections review these topics.

9.4.4 Shear Rates

The highest shear rates in a mixing vessel are close to the blades. Local impeller shear rates are proportional to tip speed (π*DN*) and are impeller specific. Disc turbines produce higher shear rates than propellers or hydrofoils (Figure 9.11). Certain applications, such as gas dispersion, require high shear rates while suspension polymerization requires a low shear rate. The vessel average shear rate, as described by the Metzner and Otto equation (9.7), is dependent on rotational speed, not tip speed.

9.4.5 Flow Patterns

Figure 9.12 shows the idealized flow patterns for radial- and axial-flow turbines. The radial-flow turbine (R-100, D-6, or Rushton) (Figure 9.12, upper left) creates two completely separate circulating zones. Shear is very high in the impeller discharge region, and the impinging discharge flow divides at the wall, forming the two zones. The axial-flow turbine (Figure 9.12, upper right) would include propellers and hydrofoils (A-310, A-315, A-320, HE-3, Maxflow T, etc.). This impeller creates a

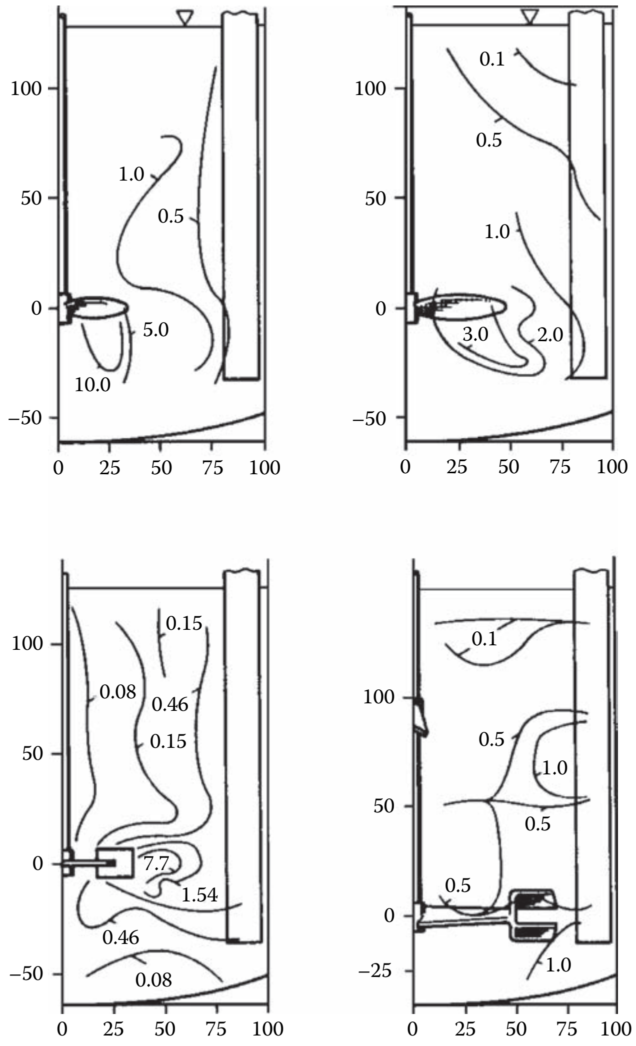

FIGURE 9.10 Energy contours for different impellers (L-R): (top) small propeller, large propeller; (bottom): Rushton turbine, Ekato-MIG. (From Todtenhaupt et al., 1991.)

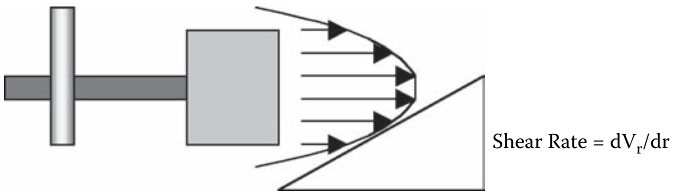

FIGURE 9.11 Typical velocity profile of the discharge flow from a disc turbine.

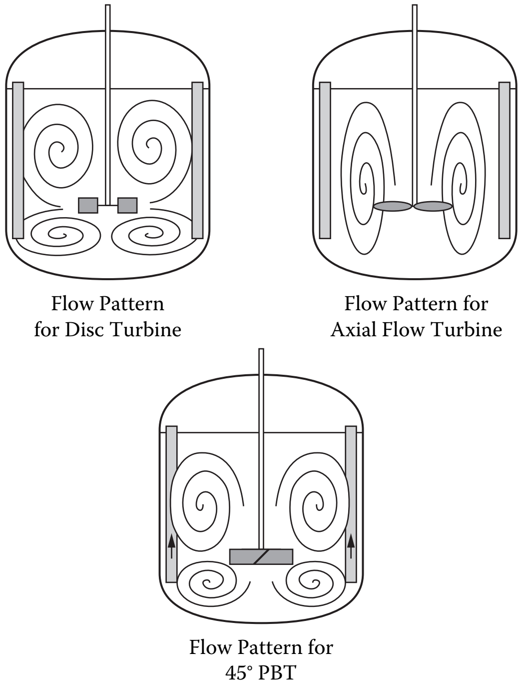

FIGURE 9.12 Typical flow patterns for radial, axial, and 45° pitch blade turbines.

desirable top-to-bottom single-flow loop pattern. The shear rate in the impeller region is much lower than the radial-flow turbine at comparable tip speeds. Flow distribution is good, and there is no flow stagnation anywhere. The 45° PBT (Figure 9.12, bottom) produces a downward and outward flow discharge angle. It also produces fairly high shear. The returning flow from the bottom zone (at the wall) helps to feed the upper zone and create fairly good top-to-bottom turnover, but not as good as for true axial impellers, since there are two distinct circulation regions that develop. Flow in the center region directly below the PBT is upward. This creates a conically shaped, poorly mixed region under the impeller and can occasionally lead to processing problems. In the above discussion, all vessels are fully baffled. Flow pattern information helps determine the best-feed point location.

Viscosity, hence Reynolds number, affects the performance of axial-flow impellers. The discharge angle (measured from the horizontal) decreases with increasing viscosity, causing flow patterns to change. Propellers discharge flow in a similar pattern to the 45° PBT as shown in Figure 9.13, but in a more vertical direction. The flow discharge angle becomes increasingly more radial with decreasing impeller Reynolds number.

Flow discharge angles are important for multi-impeller configurations. If flow from adjacent impellers fails to "communicate," separate circulation zones develop. This is seldom desirable. Harvey [4] shows the effect of multiple impellers on flow patterns in Figure 9.14. CFD analyses are shown on the left, and experimental laser Doppler flow measurements are shown on the right.

Experimental and CFD results are in close agreement. Observe that impeller 2 is able to capture flow from impeller 3 above it. Had impeller 3 been larger, its discharge would have extended beyond the suction region of impeller 2, and flow would be less. Both impeller size and spacing are important variables that affect flow pattern.

9.4.6 Mixing Time—Turbulent and Transitional Flows

Mixing-time considerations are important for analyzing competing chemical reactions, polymerizations, and precipitations. While data are available on the effect of speed on mixing time, design

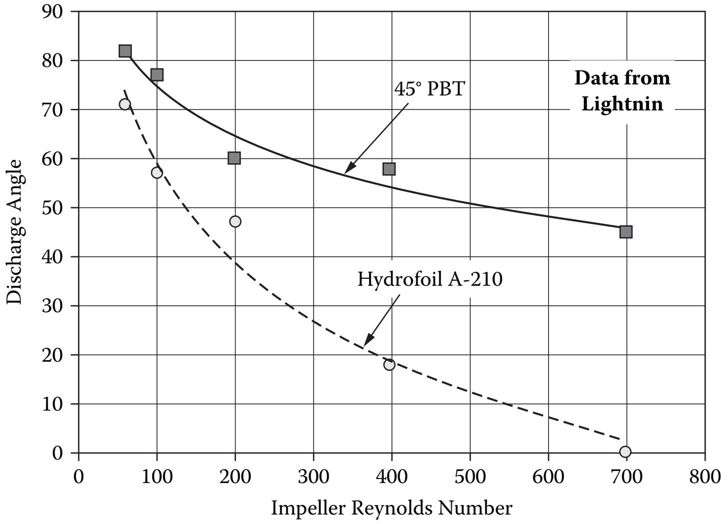

FIGURE 9.13 Flow discharge angles for two Lightnin viscous flow impellers.

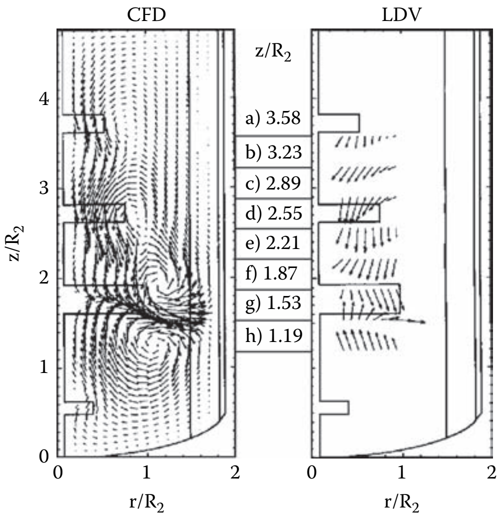

FIGURE 9.14 Experimental and CFD modeling of a series of 45° PBTs for fluids in the transition region. (From Harvey et al., 1997.)

details are usually lacking. For example, the effects of multiple impellers, clearance, spacing, and baffle design on mixing time are not well known, but the effects of speed, impeller diameter, and impeller type are better understood.

Many investigators have found that, under turbulent conditions, mixing is complete after three to four turnovers. This is shown schematically in Figure 9.15.

The mean circulation time (assuming the turbulent flow discharge, Q, from an impeller is $Q = \mathrm{Nq}ND^3$, the tank shape is $T = H$, its volume is V_R, and D/T is constant) is

$$\theta_C = \frac{V_R}{Q} \propto \frac{T^3}{N_q N D^3} \tag{9.10}$$

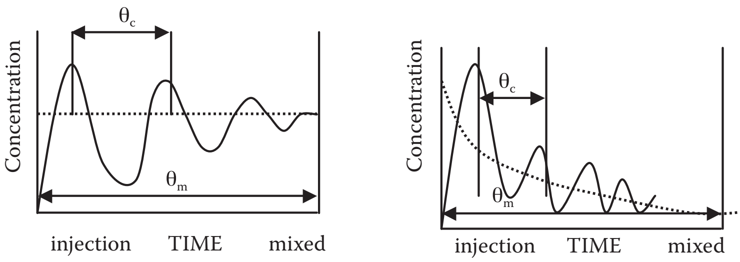

FIGURE 9.15 Typical tracer-time curves for batch and continuous stirred vessels.

For scale-up, if *D*/*T* = constant and the same impeller type is selected,

$$\theta_C = \frac{1}{N_q N \left(\frac{D}{T}\right)^3} = \text{constant} \cdot \frac{1}{N} \tag{9.11}$$

$$\theta_C N = \text{constant} \tag{9.12}$$

Thus, for scaling turbulent flow cases, the product of mixing time and speed is constant. Industrial scale-up is seldom done using constant mixing time as a criterion, because power demand is usually too high.

This does not apply for transitional flows. Work at BHRG's FMP program reported by Grenville [12] shows that Re, Fo, and Np can be arranged to correlate mixing times for fluids in the turbulent and transitional flow regimes. Data were taken from mixing-time experiments in vessels from 0.3 to 2.67 m in diameter, using different impeller types and sizes. These included a 45° PBT and diameters of (T/3 and T/2), a flat-blade turbine of diameter of (T/3), and a hydrofoil of diameter of (T/2). For Re > 200, power numbers and $N\theta$ were constant, as in Equation (9.12). In the transition region, $N\theta \propto Re^a$, where $a = -1.0$ for the FBT and PBT, and −0.84 for hydrofoils. The correlations represent a large amount of data and are given by Equations (9.13) to (9.15).

At turbulent conditions:

$$Np^{1/3} Re = \frac{5.2}{F_o} \tag{9.13}$$

where $F_O = \mu\theta/\rho T^2$, and the relative standard deviation is ±10%. F_O is the Fourier number, also referred to as the vessel Reynolds number.

In the transition flow region,

$$Np^{1/3} Re \sqrt{F_o} = 184 \tag{9.14}$$

Here the relative standard deviation is ±17.4%

At the crossover point,

$$Re_{crossover} = \frac{6{,}370}{Np^{1/3}} \tag{9.15}$$

These equations enable one to calculate θ_{95}, or the time to mix to 95% completion. If more uniformity is desired, for example, 99% complete, it will require 1.6 times longer, as shown by

$$\frac{\theta_{99}}{\theta_{95}} = \frac{\ln(0.01)}{\ln(0.05)} = 1.6 \tag{9.16}$$

There are some interesting conclusions from this work. At equal power input and impeller diameter D, mixing time is impeller independent. Impellers with a low power number, such as A-310 or HE-3, must operate at higher speeds to attain comparable power to a higher-power-number impeller. Higher speeds mean lower torque and a smaller, less costly design.

Example 9.3

Addition polymerization requires that monomer groups be added to a core polymer containing reactive ends. If the chain ends see low monomer concentration, end groups will be short; but if locally high concentrations are encountered, end groups will be long. Quality considerations demand uniformity of chain length of the end groups. Rapid monomer mixing is essential. Kinetic studies showed the half-life of the addition reaction to be ≅5.0 minutes. The pre-polymer is dissolved in a solvent, the viscosity at the operating conditions is 1000 cP, and fluid behavior is Newtonian. The reactor is 6 ft in diameter × 8 ft high, with top and bottom elliptical heads. The active average volume is 1160 gal. The viscosity remains constant during end-group addition. Design a mixing system to give 99% complete mixing in 1.0 min, or at 20% of the reaction half-life.

Solution

Equations (9.11) to (9.13) must be solved iteratively. An equation solver (or spreadsheet) provides a convenient way to do this. First, a Lightnin A-320 impeller is selected. (A 45° PBT could also have been a reasonable first choice.) Choose D = 28 in. so that $D/T \approx 0.4$. The height of liquid is 72 in. and the volume including the elliptical head is 1162 USG. A single impeller is selected, since the H/T is 1.0. Assume a speed; determine the Re and the crossover point for transitional flow (Equation (9.15)) and the mixing time θ_{99}. The trial-and-error solution using a spreadsheet is shown in Table 9.3.

We are mainly interested in numbers in the last (eighth) column. A speed of 145 rpm was selected to give a 99% mixing time (valid for the transitional region) in just under a minute. Had the Reynolds number been higher than values in the sixth column, the correlation for turbulent flow (column 7) would have been used. The power requirement is 2.58 hp. The volumetric based power is 2.22 hp/1000 gal.

TABLE 9.3
Solution to Problem 3

Speed (rpm)	HP	HP/1000 gal	Re	Re Trans	θ_{95} (min) Turb	θ_{95} (min) Trans	θ_{99} (min) Trans

9.4.7 Mixing Time—Laminar Flow

Laminar mixing takes place at Re < 10. The process tasks are the same for turbulent and transitional flow. Other important process requirements might include the ingestion of solids and powders. Since viscosities and power input are very high, there is lots of energy to aid in the dispersion of agglomerates. Impellers used include anchor, screw, and gate-type and helical ribbon designs, each having many design variables such as blade width, wall clearance, pitch angle, and single- or double-flight helical ribbon.

Equation (9.17) gives the general form of the power equation described by Tatterson in *Fluid Mixing and Gas Dispersion in Agitated Tanks* [13]:

$$N_P = \frac{C(n)}{\text{Re}}$$
$$C(n) = Bk^{n-1} \tag{9.17}$$

where C is a function of n, the flow behavior index for a power-law fluid; Re is the Reynolds number; and B and k values are given in Table 9.4.

Mixing times depend on geometry, speed, and rheology, in the general form of Equation (9.18)

$$N\theta_M = k_M \tag{9.18}$$

where k_M is referred to as the mixing or homogenization number.

Straight lines in Figure 9.16 indicate that k_M is constant. Lines for the ribbon are virtually identical, while those for the paddle are quite different. Nagata [14] explains the difference as follows. CMC is a pseudoplastic fluid, and TiO_2, a slurry, is a Bingham plastic. The ribbon impeller produces effective axial flows, but less shearing action. A large axial flow is necessary to maintain particles in a proper suspended state. The paddle creates mostly tangential motion, not conducive for solids suspension, and creates slippage planes in the slurry. Shear stress cannot be transferred to fluid elements effectively, and mixing times are long. We conclude that while paddles and anchors are simple to construct, they are ineffective mixers compared with helical impellers. However, they are helpful in promoting improved heat transfer at the wall. This is discussed in Section 9.11.

9.5 REACTIVE MIXING

This section discusses the mixing of reagents to produce a chemical reaction within a single phase, with a brief introduction to reactive mixing in multiphase systems. The latter is a rather complex subject, and a detailed treatment is beyond the scope of this section.

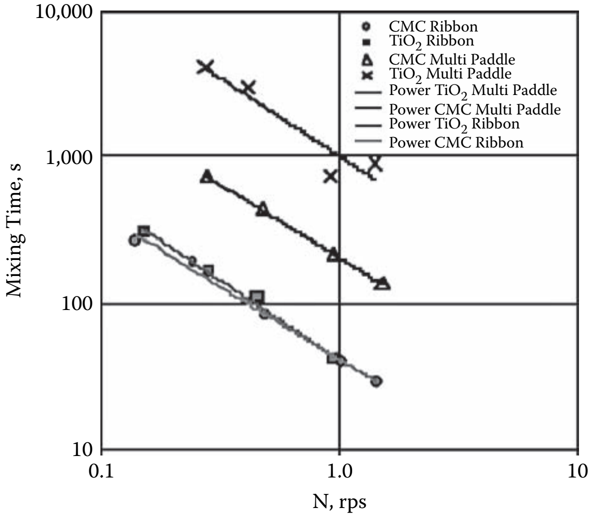

FIGURE 9.16 Comparison of the mixing time for ribbon and multistage paddle in non-Newtonian liquids. (From Nagata, 1975.)

9.5.1 Introduction

The challenges of mixing of fluids during reaction are important for fast reactions in homogeneous systems as well as for all multiphase systems. There are two issues involved: degree of segregation and timing. The degree of segregation refers to whether mixing occurs on the microscopic level (mixing at the molecular level in the limit) or the macroscopic level (mixing of clumps or globs of fluid). The second issue refers to how fast or slow is the change in the degree of segregation from the initial (feed) state to the final (exit) state, i.e., whether the macrofluid (glob of fluid) reaches its ultimate size early or late as it flows through the reactor. Since both macro-mixing and micro-mixing vary with reactor size, the following three undesirable effects are typically observed upon scale-up of mixing sensitive reaction systems:

1. Reduced reaction rates and conversion
2. Reduced selectivity
3. Reduced product quality (increased impurity levels)

Since mixing is very efficient on a laboratory scale, the detrimental effects of mixing observed on larger scales generally come as an unwanted surprise.

9.5.2 Fundamental Concepts in Reactive Mixing

When two miscible reactant fluids A and B are mixed, it is normally assumed that the two streams first form a homogeneous mixture that then reacts. This is true if, and only if, the chemical reaction is slower (say requiring more than 100–400 s) than the mixing time (typically 0.1 s to 50 s in a well-designed turbulent reactor). Mixing time is strongly dependent on scale. When the half-lives of the two processes are similar in magnitude, or when mixing is slower than reaction, mixing and reaction proceed simultaneously, not consecutively. Reaction occurs in localized zones. As the intrinsic reaction rate increases, the sizes of the reaction zones shrink to a plane. Only a small part of the reactor volume is used for reaction. For example, in any proton transfer reactions in aqueous phase (half-life of less than a millionth of a second), the reaction takes place in a very small volume,

as may be visually observed in acid-base neutralization reactions. Indeed, acid-base reactions with suitable indicators are often used to determine mixing times and flow patterns.

A single reaction is rarely the case in practice. Usually, the reaction systems are quite complex, with several products, intermediates, and undesired by-products. However, all reaction schemes can be ultimately analyzed in terms of series/parallel reactions.

Parallel reactions:

$$A \rightarrow R \ (\text{Product})$$

$$\text{A} \rightarrow \text{S} \quad (\text{By-product})$$

For reactions in parallel, the concentration level of reactant is the key to the control of product distribution. A high reactant concentration favors the reaction of higher order or the one with the larger reaction rate constant.

Series reactions:

$$A \rightarrow R \rightarrow S$$

For reactions in series, the mixing of fluids of different compositions is the key to formation of intermediate. The maximum possible amount of all intermediates is obtained if fluids of different compositions and at different stages of conversion are not allowed to mix. Thus, a plug-flow reactor will always give a much higher yield of the intermediate R than a CSTR.

Series-parallel reactions:

$$A + B \xrightarrow{k_1} R \ (desirable)$$

$$B + R \xrightarrow{k_2} S \ (undesirable)$$

Series-parallel reactions can be analyzed in terms of their constituent series reaction and constituent parallel reactions. Hence, as far as A, R, and S are concerned, this scheme may be viewed as the series reaction above. On the other hand, this scheme may be viewed as a parallel reaction with respect to B. Thus, the concentration level of B has no effect on the product distribution. When R is the desired product, the best way of contacting A and B is to react A uniformly, while adding B any convenient way.

Once a working reaction scheme is determined, it is possible to determine the optimal contacting for favorable product distribution, as illustrated by Levenspiel [15]. Figures 9.17 and 9.18 from [15] illustrate the contacting patterns for various combinations of high and low concentrations in noncontinuous and continuous flow operations. Here we are concerned about influencing the reactor performance by primarily changing the bulk contacting pattern on a macro scale for relatively slow reactions. We will return to fast reactions and micro-mixing later.

The contacting pattern is not the only issue that determines the batch, semi-batch, or continuous mode of reactor operation. Sometimes, heat transfer and control of exothermic reactions may require

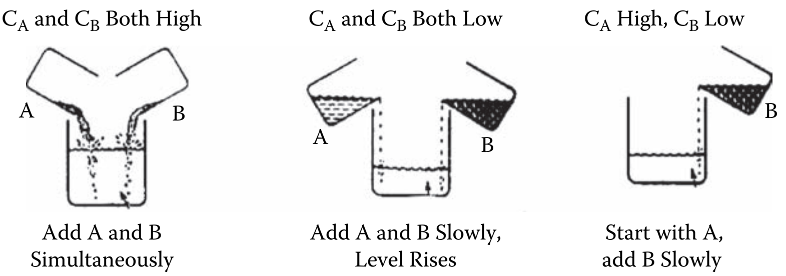

FIGURE 9.17 Contacting patterns for various combinations of high and low concentrations of reactants in noncontinuous operations. (From Levenspiel, 1972.)

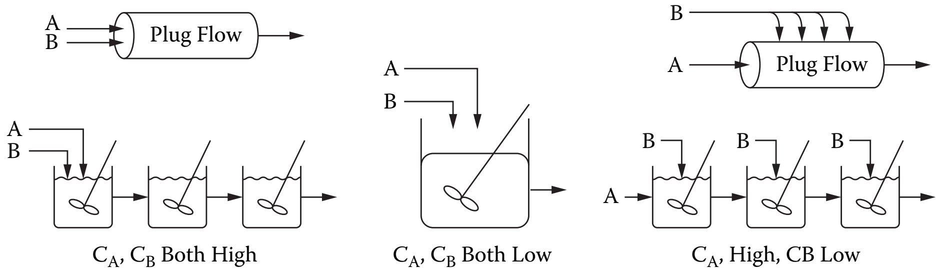

FIGURE 9.18 Contacting patterns for various combinations of high and low concentration of reactants in continuous flow operations. (From Levenspiel, 1972.)

a semi-batch mode of operation. At other times, safety considerations may require very little buildup of a potentially dangerous intermediate.

If kinetics are known for all the reactions (a rare occasion in practice), it is possible to predict the yield and selectivity in ideal reactors or their combinations. Please refer to any reaction engineering textbook for more information on this subject.

9.5.3 Macro-Mixing and Micro-Mixing

Turbulence can be conceptualized as the transfer of kinetic energy from large eddies (on the order of the size of the impeller blade width) to successively smaller eddies. The smaller eddies originally in the inertial sub-range disintegrate further into the viscous sub-range, and eventually all energy is dissipated into heat. This subject is dealt with more fully in the discussion on blending in Section 9.4.

Macro-mixing is mixing that is associated with the length scales larger than the viscous sub-range. Macro-mixing is visible, a result of flow rate, fluid motion, and convection. Flow patterns, circulation cells, and back-mixing regions are macro-mixing phenomena. The residence-time distribution (RTD) is related to macro-mixing.

Micro-mixing is mixing associated at length scales in the viscous sub-range or smaller. Molecular diffusion and turbulence intensity are important micro-mixing parameters. In reality, there is no sharp distinction between these two types of mixing. The names macro- and micro-mixing are conceptualizations of processes that take place simultaneously, and on all scales. Intense micro-mixing without macro-mixing (or vice versa) does not lead to an effective mixing process.

9.5.4 Ideal Flow Patterns in Reactors and Residence-Time Distribution (RTD)

Common practice is to model reactors as some combination of elementary and idealized building blocks, such as

- Continuous stirred-tank reactors (CSTRs)
- Plug-flow reactors (PFRs) with or without axial dispersion
- Dead volumes
- Bypass flows
- Recycle flows
- Inlets and outlets

When can a reactor be considered an ideal CSTR? A rule of thumb is that a stirred tank can be considered ideal when the mixing time is less than about 20% of the mean vessel residence time and, for reacting systems, less than about 5% of the characteristic reaction time.

Residence-time distribution (RTD) is a useful concept in characterizing the macro-mixing in a continuous flow system. However, it does not describe micro-mixing. If the flow pattern in a mixer is known, the residence-time distribution (RTD) can be calculated, and there is no need to measure it. The practice, however, is to measure the RTD and then attempt to deduce the flow pattern from it. An RTD measurement shows the correlation between the concentration of a reactant at two locations of the stirred vessel, typically the inlet and the outlet. An RTD measurement will result in information on:

- Bypass flow rate
- Dead volume
- Active CSTR and PFR volumes

An RTD measurement does not reveal details of the flow patterns within the vessel, or the sequence of the flow through the various regions. For complex geometries, an RTD measurement can be useful in determining the presence of stagnation. There are limitations on when to use RTD measurements to predict the specific flow patterns or the reactor performance. For example, the sequence of a CSTR and PFR cannot be determined from an RTD measurement alone. Swapping locations of a CSTR and a PFR in series will result in the same RTD. However if a non-first-order reaction takes place in a CSTR and a PFR in series, the resulting conversion does depend on sequence. RTD is not sufficient to predict the reactor performance except in the case of first-order reactions. In a reaction scheme with any other order, the reactor performance is determined not only by the length of time that a fluid element spends in the vessel, but also by its surrounding environment during its travel from inlet to outlet.

Quantitative information on the flow pattern can also be determined by direct flow visualization, although this method is limited to optically transparent liquids, sufficient light, suitable flow followers, and adequate observation points. Direct observation provides information about recirculation (back-mixing), short circuits, and dead zones.

Computational fluid dynamics (CFD) has emerged as a very valuable tool in modeling the real flow patterns in chemical reactors. It represents a quantum leap from the idealized reactor models or their modifications, such as the tanks-in-series or axial-dispersion models to account for non-idealities. It has the potential to account for flow and reactions inside a reactor in their entirety. CFD has been used successfully to predict the flow patterns and reactor performance in the case of reactions involving macro-mixing effects.

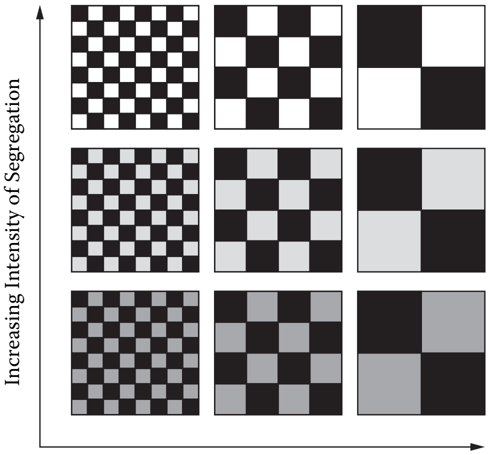

FIGURE 9.19 Scale and intensity of segregation.

9.5.5 Micro-Mixing and Segregation

Each feed stream to a reactor usually contains only one reactant, and the large portions of fluid thus introduced must be broken down rapidly so that each reactant can be dispersed to encounter the others and react. The large turbulent eddies break down the fluid elements to successively smaller sizes until a size is reached when the inertial forces are unlikely to reduce it further, and the energy decays due to viscous action. Based on work presented in the literature [16–20], it is possible to make an estimate of the size of agglomerates.

For example, Kolmogoroff's length scale, λ_k, represents the eddy size that is associated with the boundary between the inertial and viscous subranges and is defined by

$$\lambda_k = \left(\upsilon^3 \big/ \varepsilon_T \right)^{1/4} \tag{9.19}$$

where ε_T is the local energy dissipation rate expressed as power per unit mass, and ν is the kinematic viscosity.

For a typical power input of 1 kW/m^3 (P/V = 5 hp/1000 gal) with a waterlike fluid (ν of 0.009 cm^2/s) in a stirred reactor, λ_k is 30 μm. Note that this is the scale at which molecular diffusion dominates, and a 30-μm (micron) diameter sphere still contains 4×10^{14} molecules of water!

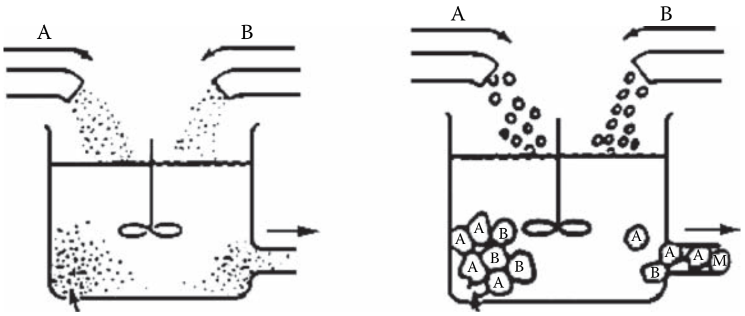
The *scale of segregation* effectively measures the size of unmixed regions. As mixing proceeds, the scale of segregation is reduced, due to liquid motion.

The *intensity of segregation* measures the concentration variations in the mixture. As mixing proceeds, the intensity of segregation is reduced, due to diffusion (Figure 9.19).

Consider two limiting cases to help explain the effect of segregation on a single reaction: Feed streams containing reactants A and B are available, each first as a micro-fluid (free to mix) and then as a macro-fluid (segregation maintained) [15]. Micro-fluids A and B behave in the expected manner and reaction occurs. However, upon mixing of macro-fluids, no reaction takes place because molecules of A cannot contact molecules of B (except at the interface, which has a zero volume in this idealization). These two situations are illustrated in Figure 9.20.

9.5.6 Micro-Mixing and Selectivity

If only a single fast (or instantaneous) reaction is involved, relatively slow mixing and state of segregation may cause a change in the apparent reaction rate (reduction in plant capacity), but no



Mixing on molecular level (micro-mixing); hence reaction occurs

Only aggregates intermix (macro-mixing); hence no reaction occurs

FIGURE 9.20 Differences in behavior of micro-fluids in the reaction of A and B.

effect on product quality (no side reactions). However, this is rarely the case in reality; multiple series and parallel reactions are always involved. Effects not observed on a small scale may appear on large scale, that is, color, yield loss, lower quality, and so forth.

Consider the series-parallel reaction scheme, also referred to as the competitive consecutive reaction scheme, discussed earlier. The desired product R continues to react with the initial reactant B to produce the undesired product *S*. Usually the reaction conditions (temperature or catalyst) are arranged such that k_1 is much faster than k_2. The selectivity, X_S, is defined as

$$X_S = \frac{2S}{R + 2S} \tag{9.20}$$

For optimum performance, X_S should be kept as low as possible.

If we let equimolar quantities of A and B react, the following diagram clarifies how mixing can control selectivity under two limiting cases:

Initial State
(Completely Segregated)

A	A	A	A
A	A	A	A
B	B	B	B
B	B	B	B

Poor Mixing:
$\tau_M >> \tau_R$
First reacts, then mixes

↓

A	A	A	A
R	R	R	R
B	B	B	B

↓

A	A	A	A
S	S	S	S

(Undesirable)

Ideal **Mixing:**
$\tau_M << \tau_R$
First mixes, then reacts

↓

A	B	A	B
B	A	B	A
A	B	A	B
B	A	B	A

↓

R	R	R	R
R	R	R	R

(Desirable)

Considering the agglomerate size to be on the order of the Kolmogoroff scale (or some other appropriate length scale), the micro-mixing time for molecular diffusion is given by

$$T_m = \lambda_\kappa^2/D \tag{9.21}$$

where D is the molecular diffusivity. For typical waterlike fluid, the micro-mixing time falls in the range of 1 to 20 ms.

Equation (9.22) can be used to determine the reaction time for the second reaction, forming an undesirable product:

$$T_r = \frac{1}{\left(k_2^* B_o\right)} \tag{9.22}$$

where B_o is the initial or local concentration of B. It is important to remember that the local reaction rate is not given by the bulk concentration, but by the feed or local concentration.

The ratio of time constants for mixing and reaction defines the Dämköhler number or the micro-mixing modulus, a dimensionless number shown in

$$Da = \frac{k_2 \lambda_k^2 B_o}{D} \tag{9.23}$$

The dependence of X_S on the micro-mixing modulus is given in Figure 9.21 at various ratios of the two kinetics constants. The S-shaped curve for high ratio of k_1/k_2 (practically relevant for reasons stated earlier) shows that the selectivity is sensitive to micro-mixing, especially if the Dämköhler number is around 1 or greater.

Bourne and coworkers [21–23] have developed the mathematics and applied their model to predict the effects of stoichiometric ratio, startup of a semi-batch reactor, effect of volumetric feed ratio, batch vs. continuous operation, etc. They have also experimentally demonstrated the use of reaction systems with well-characterized kinetics to determine the level of micro-mixing. Thus chemical reactions can be considered as molecular probes to be used to study segregation. Other

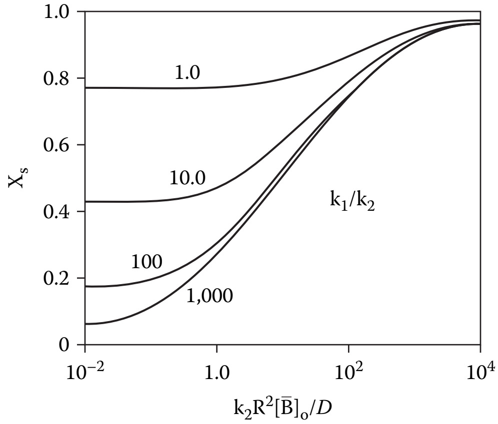


FIGURE 9.21 Influence of k_1/k_2 on product distribution from CSTR; parameter: k_1/k_2 (a = 1; $N_{AO} = N_{BO}$; τ = 100 τ_E). (From Baldyga et al., 1984.)

techniques such as optical or conductivity probes have limited spatial resolution and cannot give information down to the smallest scales of turbulence.

There are other more advanced micro-mixing models such as the engulfment, deformation, and diffusion (EDD) model [24–26] and the interaction by exchange with the mean (IEM) model [27]. The reader should consult the original papers for details.

9.5.7 Micro-Mixing: Practical Implications

Always suspect micro-mixing to be important when reactions are fast and lab-scale studies show minimal side reactions. If possible, make the quantitative comparison using the appropriate reaction scheme and micro-mixing modulus. Laboratory reactors tend to run at much higher turbulence levels than plant reactors.

When micro-mixing is important, the point of addition of ingredients makes a large difference on selectivity [28]. In such cases, ingredients should be added at the point of highest energy dissipation and highest turbulence. Note that the local energy dissipation rate is not uniform in an agitated vessel (see Figure 9.10) and can vary by more than an order of magnitude in both directions from the average energy dissipation rate calculated from the power per unit volume. X_S is a strong function of the local power dissipation rate, ε_T. In a stirred vessel, a high ε_T region is within and downstream of the impeller tip region. The best addition point is just before the bulk of the flow enters a region with a high local energy dissipation rate, such as the suction of an impeller.

High local energy dissipation is very advantageous for fast competitive and consecutive reactions. In such cases, improvements in micro-mixing will result in reduction of unwanted materials, in improvement of quality, and possibly in increased production capacity.

9.5.8 Reactive Mixing in Multiphase Systems

The physical aspects of gas-liquid, liquid-liquid, solid-liquid, and gas-liquid-solid systems are discussed in the subsequent sections of this chapter. Using the guidelines given there, it is possible to get an estimate of local and average mass-transfer coefficients, interfacial areas, and contacting patterns. This section briefly considers the effect of reactions on mass transfer, a subject treated elsewhere in this handbook and in advanced texts [29, 30]. Note that while we will refer mostly to gas-liquid systems, the same treatment would more or less apply to liquid-liquid and liquid-solid systems. In the case of gas-liquid-solid systems, it may be possible to determine the controlling resistance and simplify the analysis to a two-phase system, as far as the reaction part is concerned.

In gas-liquid reactions carried out in agitated tanks, generally the gas-side resistance is small compared with the liquid-side resistance, and hence the following discussion is limited to only processes where the liquid-side resistance controls. If a pure gas is used, there is no gas-side resistance.

In reactions involving gas-liquid mixing, one of the first things to determine is the controlling process: (bulk) chemical reaction or mass transfer. Experimentally, this is done by checking the effect of agitator speed on rate of reaction, as shown in Figure 9.22.

If the process is mass-transfer controlled, there are three possible regimes:

Film diffusion (regime 2)
Film kinetics (regime 3)
Instantaneous reaction (regime 4)

The volumetric mass-transfer coefficient, k_La, increases as the stirrer speed increases. (Refer to correlations given in Section 9.7 later in this chapter.) If the process is bulk-reaction controlled, then the stirrer speed increases and the volumetric mass-transfer coefficient, k_La, increases (refer to correlations given in Section 9.7). If the process is mass-transfer controlled (regimes 2, 3, 4),

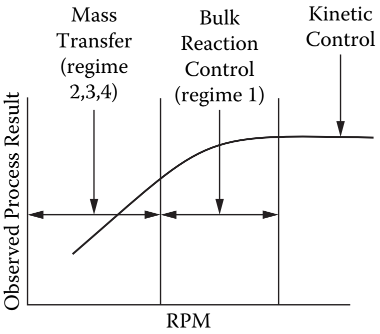

FIGURE 9.22 Effect of agitation speed on observed process rate.

the observed rate of reaction increases. However, a condition may be reached when the observed rate does not increase with increasing the rpm or mixing intensity, indicating the overall process is bulk-reaction controlled (regime 1). For the exact mathematical conditions for the various regimes, please refer to the illustrative example and the reference book [29]. Design speed should be at the minimum required to keep reaction conditions in regime 1.

Certain fast or instantaneous reactions (for example, proton transfer reactions) are always mass-transfer controlled. The enhancement factor, *I*, accounts for the effect of chemical reactions on mass transfer and is defined as the ratio of the process rate over the mass-transfer rate in absence of a chemical reaction.

- In regime 2, the reaction is fast enough to keep the bulk liquid phase concentration of the gaseous reactant essentially zero but not fast enough to occur substantially in the liquid film. There is no enhancement of mass transfer due to reaction. Diffusion and reaction take place in series fashion.
- In regime 3, the reaction is sufficiently fast to completely consume the gaseous reactant in the liquid film. Diffusion and reaction are occurring simultaneously in a parallel fashion in the liquid film. The true liquid-side mass-transfer coefficient has no effect on the overall process rate.
- In regime 4, the reaction is so fast (virtually instantaneous) that the gaseous reactant (A) and the liquid-phase reactant (B) cannot coexist. Diffusion of A from the interface and diffusion of B from the bulk liquid toward the reaction plane control the overall process.

There are systems that could fall between these regimes, and the division between them is not always clear-cut.

It is important to determine the regime of a particular reaction system, since the equipment choice and the effect of design and operating variables on the process performance depend on the regime. A lack of this fundamental understanding leads to many apparent discrepancies between different scales of operations and sometimes to scale-up failures. For instance, in the lab, the process may be operating in regime 1, while in production scale it could operate in regime 2. In this specific case, on the lab scale, the increasing concentration of the liquid-phase reactant increases the process rate, while on the production scale, there would be a essentially no effect. Alternatively, one may design equipment for minimal mass-transfer requirements based on the confirmation of regime 1 on lab scale only to find much lower process rates. There would be a negligible effect of partial pressure of A if the process operates in regime 4. The effect of temperature is minimal if the system is in regimes 2 and 4. It is substantial in regime 3 (apparent activation energy is half of the true activation energy) and maximum in regime 1 (apparent activation energy is equal to the true activation energy).

9.5.9 Equipment Types and Design Guidelines

For typical reactive mixing systems in a stirred tank, a dual impeller system, Figure 9.23, with a radial-flow impeller at the bottom and an axial flow on the top is recommended [31–33]. We recommend the following ratios as initial starting points for a typical batch with liquid height equal to tank diameter:

- Lower impeller diameter/vessel diameter, $D_l/T = 0.25$
- Upper impeller diameter/vessel diameter, $D_u/T = 0.33$
- Distance between impellers/lower impeller diameter = 1.75
- Clearance of lower impeller from bottom = $0.75 \times D_l$

If a single impeller is desired, we recommend a 45° four-blade PBT with a diameter equal to one-third of the tank diameter located at a clearance of 0.75 times the impeller diameter from the bottom as the starting point.

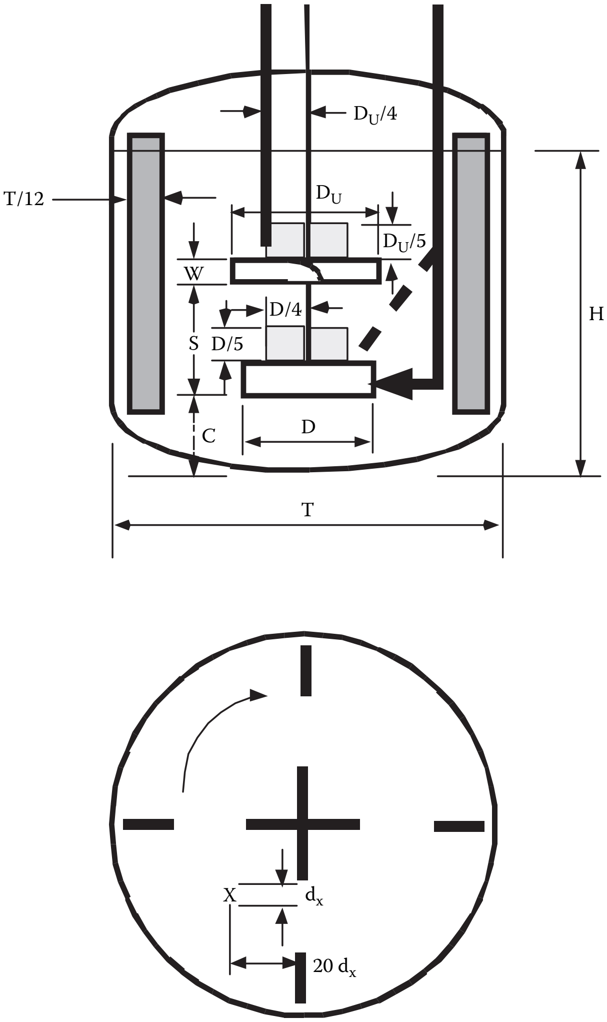

FIGURE 9.23 Feed point preferences for reactive mixing. (From Fasano, J. B., and W. R. Penney, *Chem. Eng. Prog.* 87: 46 (1991). With permission.)

The feed should be introduced to the suction of the impeller, as shown in Figure 9.23 [31], to take full advantage of maximum energy dissipation to promote rapid blending of the feed. Unfortunately, it is the worst possible location for getting back-mixing into the feed pipe with potential subsequent reactions under milder turbulent conditions leading to plugging problems.

To minimize back-mixing into feed pipe and to prevent the feed jet from penetrating through the impeller zone, Fasano and Penney [31] recommend:

- For feed location above impeller: $0.09\ V_t < V_f < 0.12\ V_t$
- For feeding in the plane of impeller: $V_t < V_f < 40$ ft/s

where V_t = impeller tip speed, and V_f = feed jet velocity.

Other devices are used to conduct reactive mixing. Reaction injection-molding systems (RIM) use high-energy opposing jets, each delivering a reactive component such as for polyurethane parts. Reaction rates are fast relative to diffusion. High-velocity impinging jets ensure intensive mixing for RIM applications. A typical micro-mixing Kolmogoroff scale (referred to as striation thickness in reaction injection mixing, RIM, literature) is 10 to 50 µm. Reactive mixing can also be carried out in other types of equipment, such as static mixers, coaxial pipes, tee-mixers, dynamic propeller driven in-line mixers, and rotor-stator mixers.

Static mixers (see Section 9.9) can be used for fast and instantaneous reactions involving low-viscosity fluids when high turbulence intensity and short residence time are needed. The turbulence encountered by the fluid is more uniform in static mixers than in an agitated tank. Static mixers give very good radial mixing, and the flow pattern is close to plug flow. All the fluid elements leaving the static mixer have similar residence times and have encountered essentially the identical environment (neighbor elements). The absence of back-mixing is very advantageous for consecutive competitive reaction schemes. Hence a small, well-designed static mixer can replace a large agitated tank with improved yield, lower capital costs, and lower operating costs.

The turbulent energy dissipation rate in static mixers typically varies between 100 to 1000 kW/m^3 (20 to 200 hp/1000 gal) for waterlike fluids at room temperature. Values of volumetric mass-transfer coefficients (k_La) for gas-liquid systems obtained in static mixers are 10 to 100 times higher than those obtained in agitated tanks [32, 33]. In the design of static mixers as reactors, the main variables are (a) standard mixer diameter, (b) element lengths, (c) mixer voidage, and (d) pressure drop. Turbulence intensity and hence mixer performance are strongly dependent on diameter for a fixed throughput. For example, a 25% increase in diameter decreases the energy dissipation rate by a factor of five.

If plugging is apt to be a potential problem, a static mixer with more open area (higher voidage) should be selected. The absence of back-mixing requires very precise, controlled metering of feed streams into static mixers. Any variations in the feed flows and concentrations could lead to uncorrectable and wrong stoichiometric ratios of reactants, eliminating the selectivity and yield improvements that static mixers have over agitated tanks.

In stirred vessels, with some reaction systems such as nitrations and sulfonations, unmixed zones can form in the reactor either due to density differences in the case of homogeneous systems or phase separation in the case of heterogeneous systems. Unmixed zones can result from poor design, agitator failure, low-impact initial addition, or feed interruption in a continuous reactor. If unmixed fluids are suddenly mixed, violent exothermic reactions can occur, leading to a major disaster. This possibility should be carefully considered in the design of equipment and operating procedures involving fast exothermic reactions.

For highly exothermic reactions, consider semi-batch operation instead of a batch operation. The semi-batch operation allows for a better control of temperature and heat removal by limiting the feed rate of the reactants.

If the reaction intermediates are potentially hazardous, their concentration levels should be kept minimal in the reactors. For continuous processes, consider a plug-flow operation instead of a

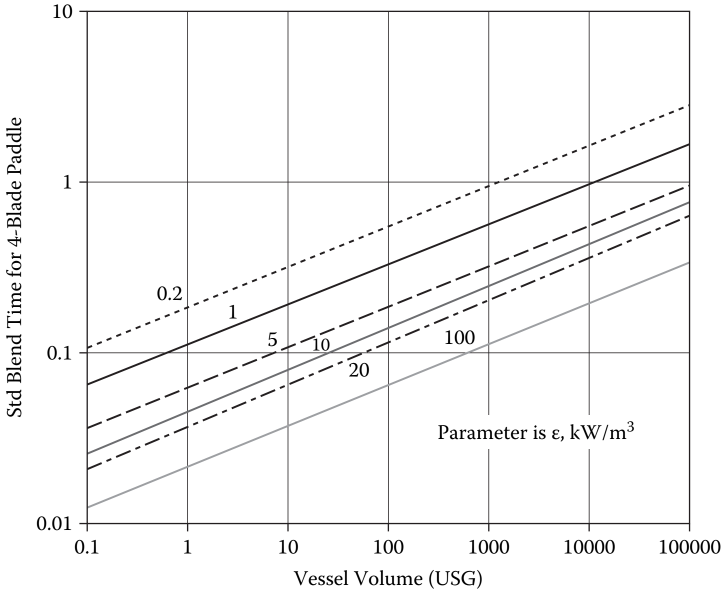

FIGURE 9.24 Blend time comparisons at constant *P*/*V* for different scales. (From Fasano et al., 1991.)

CSTR to minimize the inventory of intermediates. A plug-flow reactor would also typically have smaller volumes, hence a smaller inventory of reactants, intermediates, and products than a CSTR for the same throughput. This can be a big safety advantage.

9.5.10 Scale-Up

The intrinsic kinetics of a reaction system is independent of scale. The fundamental chemistry is the same whether on a lab scale or plant scale. What changes with scale is the environment. In the case of multiphase systems, the mass-transfer characteristics change drastically with scale. It is virtually impossible to keep all aspects of the fluid environment equal upon scale-up, as reported by Leng [35]. Specifically, mixing parameters such as mixing time, power per unit volume, turbulence intensity and its distribution, average shear and maximum shear, tip-speed, Reynolds number, and flow distribution, etc., cannot all be kept constant. This necessitates choosing the most essential mixing scale-up variable for the system and compromising and understanding the impact other variables will have on the process.

For example, typical ranges of blend times with scale for a standard four-blade 45° PBT are given in Figure 8 from Fasano and Penney [31].

Figure 9.24 shows that for a typical 1-hp/1000-gal (0.2 kW/m^3) power input, the blend time would go up from about 0.1 min in a 1-gal reactor to 0.8 min in a 10,000-gal reactor. Would this type of increase have any detrimental effect on the reaction system? Of course the answer depends on the specific chemistry. Comparative mixing times are given for different impellers. These are shown in the following equation for the correction factor, CF. If the mix time is known for a given impeller system, multiplying this time by the CF gives the mix time for a different system:

$$CF = \alpha \cdot (sg)^{1/3} \left[-\ln(1-U)/4.605\right] \cdot \left[T/Z\right]^{0.056} \left[\beta / D/T\right]^{X} \tag{9.24}$$

where sg = specific gravity, U = extent of complete mixing, T = vessel diameter, Z = height of straight side, and D = impeller diameter. Constants are given in Table 9.5.

TABLE 9.5
Constants for Use with Equation (9.24)

Impeller	α	β	X
HE-3	0.77	1.0	0.0
Square-pitch marine propeller	0.83	0.442	0.06
45° PBT-4	1.00	0.327	0.52
FBT-4	1.035	0.270	0.63
Disc: R-100, D-6	1.06	0.250	0.50

As discussed earlier, micro-mixing depends upon how the local energy dissipation affects the glob size at the feed point, and how long it takes for the glob (position of feed in the circulation loop) to reach the impeller zone (where the glob size could be reduced to its ultimate size). If the ingredients are added at the point of maximum energy dissipation, as suggested earlier, the scale-up could be based on the local power per unit volume as long as the reactions are extremely fast, i.e., virtually instantaneously. If reactions are not completed by the time the "fresh reactants" leave the region of high turbulence intensity, the constant local power per unit volume may not be adequate. To complete the reaction, macro-mixing becomes important, and the blend time could become the limiting scale-up criterion.

The chemical kinetics are usually not known for many industrial reactions and are often quite difficult to determine. While CFD holds the most promising approach for homogeneous systems when the kinetics are fully known, some experimental work with verification of CFD predictions is required for a successful scale-up. Most frequently, there is no luxury of determining detailed kinetics and doing CFD computations and verification. Hence, the following procedure (modified from Fasano [31]) is recommended:

- Conduct experiments to determine yield, (X_S), varying N, D/T, feed location, and feed time or feed rate. If possible, this should be done at two scales (for example, 1-gal and 25-gal reactors).
- Plot the yield data vs. mixing time, power per unit volume, local power per unit volume, etc., and determine the appropriate scale-up criterion.
- If blend time is the appropriate criterion, use Figure 9.24 to determine the feasibility of using an agitated vessel without a pump-around loop.
- If blend time is excessive on a large scale without requiring impractical power input, use a circulation loop containing static mixers.
- If local power per unit volume (micro-mixing) is the criterion, generally there should be no scale-up difficulty in terms of design. Make sure that macro-mixing does not become limiting upon scale-up.

9.5.11 Some Practical Guidelines for Small-Scale (Lab) Experimentation

To set process conditions successfully in industrial design, it is useful to first determine the optimal conditions and design on a model scale. When applied properly, upscaling and downscaling have immense advantages. One of the important, but often ignored, functions of small-scale research is to learn from "blunders."

The lab reactor should be geometrically similar to a full-scale reactor, with the proper impeller and baffles as appropriate, not round-bottom flasks with magnetic stirrers. The latter ones are not useful to gather scale-up data.

Create a similar environment to that of the large scale. This means using the same concentrations and purity of reactants as on the industrial scale. In some reaction systems, it may be possible to reduce mixing sensitivity by changing temperature.

Run the lab reactor at the same blend time as the large scale and determine/compare the product quality. If you are told "mixing is not important," ask the researcher to run the reaction without any agitation. Mixing often appears to be noncritical at the bench scale because it is not rate limiting and turnover is fast. This usually changes with scale-up. One method to determine the effect of micro-mixing on product quality is to measure purity, color, presence of by-products, etc., as a function of agitator speed. Care must be taken to select very slow speeds capable of simulating conditions in the intended large reactor. For example, the effect of rate of addition of reactants on quality needs to be explored for batch and semi-batch reactions. Fast addition rates can lead to poor quality. This critical "addition time" usually depends on impeller speed (energy dissipation), the number and location of injection points, and reactant concentration for a given system.

The minimum recommended scale ratio for experimentation must not be less than 1/100 to 1/500 of full-scale equipment. If critical mass-transfer-dependent multiphase reactions are involved, the scale-up ratio should be reduced to 1/10 to 1/50.

9.6 SOLID-LIQUID MIXING

9.6.1 Introduction

Solid-liquid mixing involves the suspension, distribution, and the drawing down of solids by agitation. In addition to vessel geometry, impeller variables include type, diameter, number, speed, and location. Process results include the desired level (quality) of suspension, such as just off-the-bottom, complete uniformity, or any intermediate condition. The slurry properties, density difference (solid/liquid), viscosity, and solids concentration all determine how difficult the task may be. As alternatives to stirred vessels, jets (see Section 9.10) can be used for light-duty suspension. Literature references deal mainly with settling solids as opposed to floating solids. We will try to address both conditions.

Solid-liquid mixing is used extensively throughout the chemical process industries. Examples include the suspension of solid catalysts in a reactor, the dissolution of solids to form a solution, the suspension of solids in crystallization, suspension polymerization, and fermentation. Crystallizers are usually designed to maximize flow, hence solids suspension, and to minimize shear to avoid crystal attrition. A common application is to provide solids-liquid mixing to feed a solids separator such as a centrifuge. Here the task is to provide a uniform solids feed as levels recede in the feed vessel.

Solids concentrations can vary from a few percent to well over 50% in a typical stirred tank. Solids concentration, particle shape, and the viscosity of the suspending phase are the main factors affecting the rheology and settling characteristics of the slurry. Cubic- and spherical-shaped solids tend to form Newtonian slurries, while needle-, oblong-, and plate-shaped solids form thixotropic slurries. Such slurries exhibit yield stresses even at quite low solids concentrations. This can lead to the development of caverns, as shown in Section 9.4. Proper design can usually overcome these stagnation problems.

9.6.2 Settling Solids

The settling rate of a solid in a liquid is determined by its drag, a force defined by many parameters, including the shape-dependent drag coefficient. The motion of particle settling is described by the particle Reynolds number, as seen in

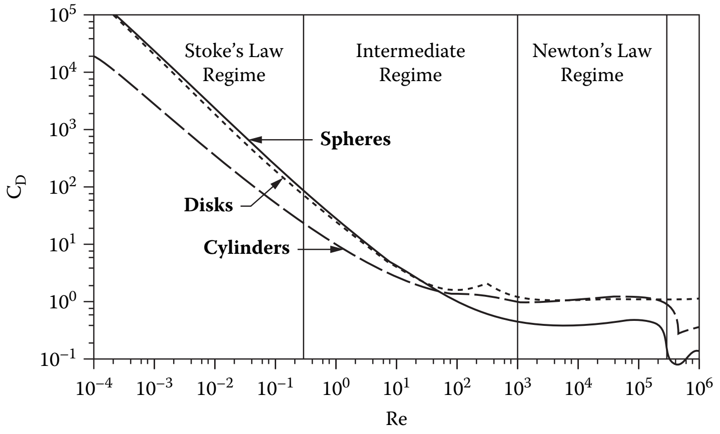

FIGURE 9.25 Dependence of drag coefficient on Reynolds number for spheres, cylinders, and discs.

TABLE 9.6
Expressions for C_D for Spheres in Different Flow Regimes

Region	Reynolds Number	Expression for C_D
Stokes law regime	Re ≤ 0.3	$C_D = 24/Re_p$
Intermediate regime	$0.3 \le Re_p \le 1000$	$C_D = 18.5/Re_p^{3/5}$
Newton's law regime	$1000 \le Re_p \le 3.5\ 10^5$	$C_D = 0.445$

$$Re_{particle} = \frac{d_p V_t \rho_l}{\mu_l} \tag{9.25}$$

where d_p is the particle diameter, V_t is the terminal settling velocity, and ρ_l and μ_l are the density and viscosity of the suspending phase. Stokes's law applies when the particle Reynolds number is less than 0.3.

Figure 9.25 shows the effect of particle shape on the drag coefficient over a range of Reynolds numbers.

The following equation enables one to calculate the free settling velocity of a particle:

$$V_t = \left(\frac{4 g_c d_p \left(\rho_s - \rho_l \right)}{3 C_D \rho_l} \right)^{1/2} \tag{9.26}$$

The drag coefficient C_D is a variable depending on the flow conditions represented by the particle Reynolds number and is given in Table 9.6 or Figure 9.25.

Equation (9.27) is the corresponding terminal settling velocity expression for the laminar regime or Stokes's law given in Table 9.6:

$$V_t = \frac{g_c d_p \left(\rho_s - \rho_l \right)}{18\ \mu} \tag{9.27}$$

Equation (9.28) gives the settling velocity for the turbulent regime:

$$V_t = 1.73\sqrt{\frac{g_c d_p\left(\rho_s - \rho_l\right)}{\rho_l}} \tag{9.28}$$

When slurry concentrations reach 15–20% solids, a phenomenon known as hindered settling occurs, which reduces settling velocities over those predicted by Equations (9.27 and 9.28). Equation (9.29) is proposed by Maude [36] in an attempt to correct for hindered settling.

$$V_{hs} = V_t\left(1-\bar{C}\right)^m \tag{9.29}$$

where m = 4.65 for Stokes's law regime, and 2.33 for Newton's law regime.

The settling velocity correction factor $(1-\bar{C})^m$ is 0.98 at 1% and 0.89 at 5%, for Newton law regime.

9.6.3 Particle Suspension in Stirred Vessels

The just-suspended state is defined as the condition where no particle remains on the bottom of the vessel (or upper surface of the liquid) for longer than 1 to 2 s. At just-suspended conditions, all solids are in motion, but their concentration in the vessel is not uniform. There is no solid buildup in corners or behind baffles. This condition is ideal for many mass- and heat-transfer operations, including chemical reactions and dissolution of solids. At just-suspended conditions, the slip velocity is high, and this leads to good mass/heat-transfer rates. The precise definition of the just-suspended condition coupled with the ability to observe movement using glass or transparent tank bottoms has enabled consistent data to be collected. These data have helped with the development of reliable, semi-empirical models for predicting the just-suspended speed. Complete suspension refers to nearly complete uniformity. Power requirement for the just-suspended condition is much lower than for complete suspension.

Many agitated waste-treatment ponds operate at conditions shown in Figure 9.26(a). Power is low and solids build up in the corners of the vessel, and that buildup is acceptable. Figure 9.26(b) represents the just-suspended state, an excellent situation for establishing good mass and heat transfer around a particle. Energy levels are low to moderate, and this condition is the most common in industry. Figure 9.26(c) represents uniform solids suspension. This is desirable for certain reactions and feeding separation equipment such as filters, centrifuges, or continuous processing equipment. Particles are fully entrained by the flows, and slip velocities are lower than for the just-suspended case, illustrated in Figure 9.26(b). The relative standard deviation or RSD has become a quantitative tool to describe the degree of uniformity, as is shown later in this section.

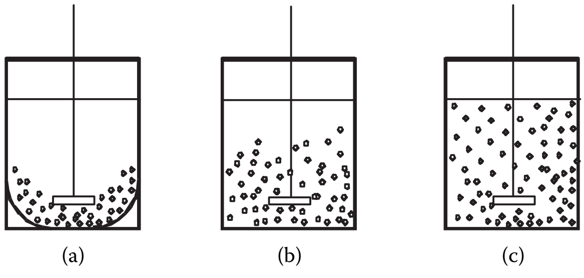

FIGURE 9.26 (a–c). Typical solids suspension conditions.

TABLE 9.7
Power Numbers and *s* Values (Zwietering Equation) for Different Impellers, Clearances (*C*/*T*), and Impeller Sizes (*D*/*T*)

6–45°-PBT, upflow	1/4	1/2	1.6	6.9

9.6.4 Just-Suspended Conditions

The determination of the just-suspended speed, N_{JS}, for off-the-bottom suspension has been extensively studied [37, 38], most recently by the British Hydrodynamics Group (BHRG). All studies support the Zwietering equation given by

$$N_{js} = s\upsilon^{0.1}\left[\frac{g\Delta\rho}{\rho_l}\right]^{0.45} X^{0.13} d_p^{\ 0.20} D^{-0.85} \tag{9.30}$$

where N_{js} = speed in rps to just-suspended particles, $\Delta\rho$ = difference in density between the solid and liquid phases, ρ_l the density of the liquid phase in kg/m^3, X = mass ratio of solids to liquid, ν = kinematic liquid viscosity in m^2/s, g = 9.8 m/s^2, d_p = average particle size in m, D = impeller diameter in m, and s is the geometry factor given below in Table 9.7.

The speed for just suspension can be calculated by means of Equation (9.30) using *s* values given in Table 9.7. Note that *s* varies with impeller type, clearance, and *D*/*T*. Additional values for *s* may be found in the *Handbook of Industrial Mixing* (chapter 10, 560) [1].

For purposes of scale-up, the Zweitering equation predicts for equal systems that

$$ND^{0.85} = \text{const} \tag{9.31}$$

Equation (9.31) would represent scale-up conditions for off-the-bottom suspension. Lacking precise process information, vendors sometimes recommend the value of 0.75 for the scale-up exponent for conditions where Re > 10^4 and vessels are geometrically similar. This is an intermediate value between 0.85, the Zwietering value, and 0.67, the value required for scaling solids uniformity.

These relationships are for a single impeller installation. The use of a second impeller has little effect on N_{JS}, but does provide for better solids uniformity.

9.6.5 Floating Solids

The formation of slurries of nonwetting, floating solids occurs in two stages. First, clumps of dry solids are engulfed by surface eddies. Once entrained, gas is separated from the solids as the clumps pass through the impeller. Successful engulfment depends on a locally high velocity interacting with the settled solids. While such flows are easy to create at the bottom of the vessel, they are hard to form at the top. The task is made quite difficult by (a) the flat, deformable upper surface in contrast to a smooth dish-shaped bottom that helps suspend solids assisted by a directed impeller flow; (b) the poor ability of the impeller to direct a discharge stream to engage the solids; and (c) the poor solids wetting that resists engulfment. Floating wetted solids are much easier to form into slurries.

If a surface vortex can be formed, it helps to incorporate floating solids. This can be a central vortex created by full-body swirl, or a localized one such as those formed behind a baffle. In both cases, the tip of the vortex helps feed solids to a region beneath the surface, where stronger flows exist. An impeller submerged a distance T/4 can do a good job of forming a slurry. Here care must be taken not to engulf gas. If gas bubbles attach to the floating solids, it makes suspension forming much more difficult.

Rigid, thixotropic floating solids can be broken up by shear using rakelike arms extending down into the slurry from horizontal arms located above the surface. This design breaks up tendencies to stagnate. The drag produced by the fingers requires little power yet creates the necessary shear stress to break up caking solids.

More power is needed to create suspensions of floating than for settling solids. A 45° PBT placed at a depth of T/4 from the surface in combination with a second impeller placed lower down in the vessel usually works well and should avoid gas entrainment. The placement of baffles is critical. If a central vortex is to be used to incorporate solids, the vessel should be baffle-free in the upper half of the tank. Short, wide baffles suspended from the top of the tank extending to a depth of T/3 are an alternative for initiation of engulfment [39]. A large $D/T = 0.6$, four-blade 45° PBT placed near the bottom of the tank was used in Joosten's work. The minimum speed N_{DF} for just-suspending conditions is given by Equation (9.32):

$$\frac{N_{DF}^2 D}{g} = 3.6 \cdot 10^{-2} \cdot \left(\frac{D}{T}\right)^{-3.65} \left(\frac{\Delta\rho}{\rho_l}\right)^{0.42} \tag{9.32}$$

It takes more energy to reach the critical speed for suspending floating solids than that for settling solids. Scale-up is $ND^{0.5}$ = constant (similar geometry and $Re > 10^4$). The 0.5 value for the exponent suggests that more power is needed for scale-up than for constant P/V.

9.6.6 Uniform Solids Concentrations

Occasionally, processes require solids uniformity in the vessel. Uniformity is more difficult to measure than off-the-bottom suspension. The best acceptable parameter is the relative standard deviation, or RSD. This involves multiple depth sampling and analysis under steady conditions at known positions in the vessel. The following equation gives a definition of the RSD. Examples of this measure of uniformity are given by Mak [40].

$$RSD_j = \frac{1}{C_m}\left[\frac{1}{n-1}\sum_{i=1}^{n}\left(C_{ij} - C_m\right)^2\right]^{1/2} \tag{9.33}$$

where C_m is the overall mean concentration, n is the number of sample points, and C_{ij} is the concentration of the ith position, jth speed.

Low values of the RSD mean better uniformity. Dual impellers help establish better uniformity by effectively distributing flow, hence solids, throughout the vessel. Recent CFD studies have shown reasonably good agreement between measured and calculated solids concentration profiles.

Design recommendations for obtaining good solids uniformity include using:

- Dish-shaped bottom heads
- Four baffles T/12 wide, placed T/72 away from the wall, and extending from the lower tangent line to the surface of the liquid
- Impellers: 45° PBT, hydrofoil (HE-3, A-310), or a bottom-located RCI
- A second impeller, if solids uniformity is essential, and $H/T > 1.2$

Mak [41] has shown that at three different scales, the RSD scales up using constant P/V. This is shown in Figure 9.27. Increasing the power (increasing N^3D^2) reduces the relative standard deviation (RSD). The data for three widely different scales were originally plotted against various different scaling criteria; the one shown in Figure 9.27 is for constant P/V. The close agreement for the three scales validates the P/V scaling assumption. This agreement for large-scale vessels is important. It implies that model suspension experiments can safely be conducted in fairly small equipment. At the Dow Chemical Company, the author determined the power needed to form completely uniform suspension of fast-settling solids. Studies were done in three bench-scale vessels of 0.3 m, 0.457 m, and 0.61 m in diameter using process materials. Equivalent solids suspension at different sizes was found at P/V = constant. This result was applied to a (20-ft diameter) 50,000-gal slurry reactor. Sampling at different positions showed solids uniformity had been reached.

A useful rule of thumb for solids suspension is to relate the solids settling velocity to the calculated suspension velocity created by the impeller. When the flow velocity exceeds the solids settling velocity by a factor of 1.5 to 2.0, usually good performance can be expected. As an example, we calculate the speed to completely suspend solids in a 3.05-m (10-ft) vessel equipped with a 1.22-m (4-ft) HE-3 impeller. The solids settling velocity is 3.05 m/min (10 ft/min). Furthermore, it is assumed that downflow occurs in an area of 1.2 D and that the circulation pattern is single loop. The annular upflow area becomes $(\pi/4)(3.048^2 - 1.52^2) = 5.48\ m^2$. The velocity in this region must

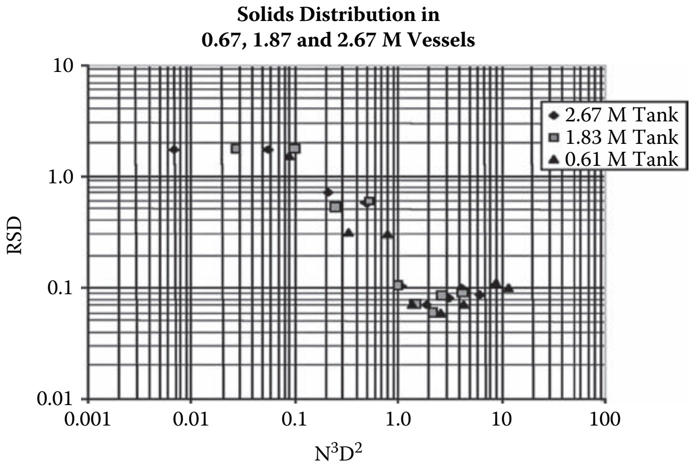

FIGURE 9.27 Power per unit volume as the scale-up criterion for solids distribution. (From Mak et al., 1990.)

TABLE 9.8
Relative Power and Speed Required for Solids Suspension with Solids-Settling Velocities of 5–18.3 m/min

Criterion	Speed Ratio	Power Ratio
On-bottom suspension	1.0	1.0
Off-bottom suspension	1.7	5.0
Complete uniformity	2.9	25.0

be ≥2(3.05) or 6.1 m/min or a volume flow of 33.4 m^3/min. This must match the pumping rate of the impeller. Nq for the HE-3 (Table 9.1) is 0.54. Solving $Q = \mathrm{Nq}ND^3$ for N gives 136 rpm as the speed required to deliver twice the settling velocity, and 102 rpm for 1.5 times the settling velocity.

9.6.7 Power Requirements

There is a heavy penalty for specifying uniform slurry conditions if that is not really required. Oldshue [42] points out, as is shown in Table 9.8, the differences (right-hand column) in power between conditions of complete uniformity and just suspended.

The calculation of power follows methods described previously, using the estimated weight average density, ρ, in the expression for Reynolds number and power. The viscosity for a Newtonian system is best measured by using a paddle-type rotating bob viscometer. The Metzner-Otto method is commonly used to determine the Re for a non-Newtonian system, where viscosity is a function of shear rate. This method consists of determining the mean shear rate from $\bar{\gamma} = KN$, where N is the stirring speed in rps, K is 10 for a propeller, and $\bar{\gamma}$ is the mean shear rate is in s^{-1}. Viscosity will not influence the calculation of power when Re ≥ 200.

As stated previously, complete solids uniformity requires scale-up by P/V = constant, Re ≥ 10^4, and geometric similarity, including baffles. Scale-up is given by Equation (9.34) for constant power per unit volume:

$$ND^{2/3} = const \tag{9.34}$$

9.6.8 Equipment

A variety of impellers can be used for just-suspension purposes. Generally, for settling solids where $\rho_s \geq \rho_l$, a down-pumping axial or mixed-flow impeller is better than radially discharging impellers. One exception is the low-shear retreat-curve impeller (RCI), normally located at the bottom of the vessel. It does a good job of suspension and minimizes crystal breakage. Clearances of C = T/4 to T/6 are a common practice. A good choice for impeller diameter is D/T = 1/3 to 1/2. Overly large impellers produce complex flows at the bottom of the vessel, with often undesirable results. Multiple impellers are not needed for off-bottom suspension applications [43], since only solid movement at the bottom is required. Any additional impellers add to the power consumption, and improve uniformity, but do not affect bottom movement. With the exception of viscous and non-Newtonian slurries, vessels need to be baffled. Four baffles, T/10 to T/12 wide, are desirable and are set away from the wall a distance ≈T/72. When vessel proportions exceed H/T = 1.2, multiple impellers are recommended. A good design might include an upper hydrofoil and a lower PBT.

Example 9.4

Calculate the minimum suspension speed and the power requirement for the following:

Solids $X = 0.30$
$D = 0.51$ m
$dp = 10^{-4}$ m
$\nu = 10^{-6}$ m^2/s
$(g\,\Delta\rho/\rho) = 9.81 \times 2.34$ m/s^2
$s = 3.9$ (for flat-blade turbines, taken to be equivalent to the glassed impeller)

Solution

The basis for the calculation is the Zwietering Equation (Equation (9.29)). Substituting, we get

$$N_{JS} = 3.9 \cdot \left(10^{-6}\right)^{0.1} \left[9.81 \cdot 2.34\right]^{0.45} 0.30^{0.13} \left(10^{-4}\right)^{0.2} 0.51^{-0.85} = 1.92 rps$$

Given that the impeller is a glass-coated retreat-curve type, the approximate calculation for the minimum suspension speed is 115 rpm. A recommended design speed would be 130–150 rpm. This would guarantee more than minimum suspension conditions. The power at 150 rpm based on a power number of 0.6 would be 0.323 kW (≈0.5 hp).

9.6.9 Solids Suspension by Jet Mixing

Liquid jets can be used to suspend solids. There are both simple nozzle designs and proprietary designs such as the Aerocleve-Pentech. In the latter, multiple jets radiate outward from the central feeder. Jets function in a similar fashion to impeller streams, so that many of the terms used in the Zwietering equation apply to solids suspended by jets. Effective suspension is created when the jet is centrally placed at a height of about T/6 to T/10 above the bottom of the floor of the tank. Jet solid suspension is designed on the basis of the V_{JS}, the jet velocity required to just suspend particles. Particle movement is the same as defined for the case of the agitated vessel. Research at BHRG for the FMP consortium has developed extensive technology on jet solid suspension for its members. For more information on jet mixing, see Section 9.10.

9.7 GAS-LIQUID MIXING

9.7.1 Introduction and Scope

Gas-liquid mixing is one of the most frequently used operations in the process industries, being involved with waste treatment, fermentation, hydrogenation, oxidation, chlorination, and gas stripping. Throughout this section, liquid is the continuous phase and gas is the dispersed phase. The purpose of gas-liquid mixing is to introduce soluble gases into the liquid phase, where reactions can take place. Mixing affects how quickly this process occurs by creating an interfacial bubble surface area and a suitable bubble distribution throughout the vessel. If the interfacial area controls the rate of a reaction, reactions are referred to as being mass-transfer-controlled. If chemistry is slow and mass transfer is not limiting, reactions are referred to as being kinetically limiting.

Energy provided by agitation creates an interfacial area by dispersing bubbles. High-shear impellers (four- or six-blade flat-blade disc designs) are often used, since they can deliver more power (at a given speed and diameter) to the fluid than other impeller designs. The disc, shown in Figure 9.3, helps collect gas and direct it to the blades, where dispersion occurs. While disc turbines are most commonly used for gas dispersion, any impeller capable of delivering energy to the liquid can be used to disperse gas. This includes the 45° or 60° PBT, the FBT, hydrofoils, and even retreat-curve impellers.

Cavitation commonly occurs in g-l mixing operations, and this reduces the impeller function. Cavitation, shown in Figure 9.28, is a condition where large pockets of gas collect and cling to the

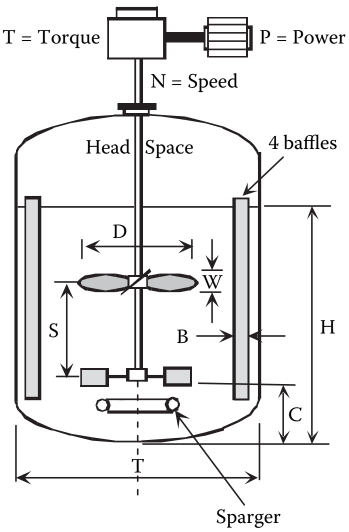

FIGURE 9.28 General design for g-l mixing.

back side of impeller blades. It is associated with high gas flow rates and low impeller speeds. All impellers cavitate, some more easily than others. A seriously cavitating impeller is incapable of dispersing gas or providing good mixing, since adequate power can no longer be transferred to the fluid. It is important to predict the onset of cavitation and its effect on the process. The tendency for an impeller to cavitate is design dependent.

Impellers used for gas-liquid mixing have three tasks:

1. Creation of bubble surface area for mass transfer
2. Attainment of gas holdup
3. Avoidance of impeller flooding

9.7.2 Mass Transfer—General

Equation (9.35) describes the rate of mass transfer, N_i, of species (i) from the gas bubble to the continuous liquid phase. It depends on (a) the total surface area, a, at the gas-liquid interface; (b) the driving force, ($C^*_{Li} - C_{Li}$); and (c) the mass-transfer coefficient, k_L. C^*_{Li} represents the concentration of component (i) in the liquid phase in equilibrium with gas in the bubble, and C_{Li} represents the concentration of component (i) in the bulk of the liquid. Normally, a and k_L are combined into a lumped parameter, k_La, since determination of separate values of a and k_L is difficult. The units of k_La are in min^{-1} or s^{-1}.

$$N_i = k_L a\left(C^*_{Li} - C_{Li}\right) \tag{9.35}$$

At a given fraction gas holdup, Φ, and bubble diameter, d_{32}, the total surface area of the gas, a, is related as shown by

$$a = 6 \cdot \Phi / d_{32} \tag{9.36}$$

where d_{32} is the Sauter mean bubble diameter (also written as d_{SM}). Note that a in Equations (9.35) and (9.36) is the same variable, the interfacial bubble area per unit volume, and has units of m^2/m^3.

The mass-transfer coefficient $k_L a$ is often correlated by equations such as

$$k_L a = c \cdot \left(\frac{P_g}{V} \right)^{\alpha} \cdot v_{sg}{}^{\beta} \cdot \left(\frac{\mu^*}{\mu_{ref}} \right)^{\gamma} \tag{9.37}$$

where V_{sg} is the superficial gas velocity, P_g/V is the gassed power per unit volume, C is a constant, and μ^* is the viscosity at process conditions relative to μ_{ref} at reference conditions.

9.7.3 Equipment and Its Function

A conventional stirred vessel used for gas-liquid mixing is shown in Figure 9.29. A very common configuration for gas-liquid mixing includes a drive unit, four sidewall baffles, a sparger, a lower gas-dispersing impeller, and an upper axial-flow-type impeller. Some operations place the gas-dispersing turbine as the upper one and the axial-flow turbine as the lower one. In this case, the axial-flow turbine is up-pumping. Advantages for this configuration are that it greatly reduces fluctuating loading on the drive, and it reduces cavitation. On the negative side, gas holdup is more difficult to achieve. Various vessel shapes can be used for gas-liquid mixing. Tall vessels, e.g., H/T = 4/1 containing multiple impellers, have the advantage of providing longer gas residence times, but it is more difficult for these to provide good turnover. The minimum *H*/*T* should be at least 1:1. A common impeller-to-tank diameter ratio for gas dispersion is *D*/*T* = 0.4, but this can vary from 0.33 to 0.50. The energy input for gas dispersion is high and can vary from 0.5 to 6.0 kW/m^3 (2.5 to 30 hp/1000 gal). Many applications fall into 1–2 kW/m^3 (5–10 hp/1000 gal) based on gassed conditions. Because of this high energy, other aspects such as uniformity are usually met with ease.

Effective gas dispersion occurs in stages. First, large bubbles form from a sparger or inlet pipe. These are entrained by flow to the impeller blades, where the second stage of dispersion takes place. Smaller bubbles form here. Ring spargers, shown in Figure 9.29, are commonly used for introducing gas to the impeller. They are described more fully later in this section. Pipes can also be used to introduce gas. These can be single or multiple dip-pipe arrangements. Because of their large openings, pipes deliver larger bubbles than ring spargers. These bubbles can bypass the impeller. In pipe sparging, entering gas is sheared away from the tip, creating bubbles by a shedding mechanism.

Direct loading is a term used to describe gas bubbles passing directly from the point of entry to the impeller. *Indirect loading* refers to the condition where bubbles first pass up the tank, then get redirected by entrainment to the impeller for dispersion.

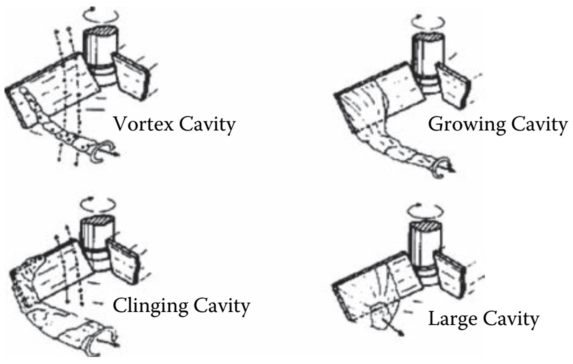

FIGURE 9.29 Development of cavity formation on a 45° PBT.

At constant speed, the impeller power demand decreases with increasing gas flow. This is because (a) the average mixed density decreases and (b) blades cavitate as shown in Figure 9.28. A cavitating Rushton impeller loses up to 60% of its ungassed power draw. Both impeller blade shape and the number of impeller blades affect cavitation. The CD-6, BT-6, and Scaba designs are examples of low-cavitating impellers (see Figure 9.3). Their curved “trailing surfaces” delay the onset of cavitation, allowing more gas to be dispersed.

Baffles must always be used for low-viscosity fluids for gas-liquid mixing. They help convert tangential to axial momentum, producing shear for dispersion and axial flow for good mixing. In the absence of baffles, the tangential swirl forces all bubbles to leave the liquid because of centrifugal forces.

Curved-blade disc turbines are good choices for gas dispersion (see Figure 9.3(a), second row, right). Note that the open cup advances into the liquid. A second impeller, like an axial-flow hydrofoil, helps improve circulation and gas holdup. Multiple disc turbines should be avoided, since they lead to compartmentalization and poorer overall mixing.

Ring spargers are an excellent means for good initial distribution of gas and this avoids an unbalanced loading of the impeller. The relatively small bubbles are easily entrained to the impeller blades. A good design practice is to make the cross-sectional area of the ring two to three times larger than the sum of the area of the holes. The sparger ring diameter ought to be ≈80% of the diameter of the dispersing turbine. Larger ring diameters run the risk of gas bypassing the turbine blades. The ring is located concentrically below the dispersing turbine at a clearance (C) of $0.3 \leq (C/D) \leq 0.5$.

It is often not feasible or easy to use a ring sparger. An alternative is to use single or multiple pipes as spargers. These can be roughly 80% as effective as ring spargers.

Lightnin proposed a four-pipe sparger design to be used with their A-315 four-blade hydrofoil impeller for G-L mixing. (See Figure 9.3(a), fourth row, left.) Gas was introduced through four equally placed pipes spaced 90° apart and discharged close to the bottom of the vessel. There gas was sheared away by tangential liquid flow from the impeller. This design resulted in an indirect loading condition but virtually avoided flooding. The design could create high gas holdup, avoiding cavitation and providing excellent circulation and bubble distribution. The chief drawback was that it was more difficult to create very small bubbles, because of the low power number of the A-315.

Static mixers are also used for continuous gas-liquid operations (see Section 9.9). The orientation of the mixer is important. A vertical orientation with both gas and liquids passing cocurrently downward is desirable. Considerable vendor information is available on gas-liquid dispersion in static mixers.

9.7.4 Impeller Characteristics in Gas-Liquid Mixing

When gas passes through the impeller, several things happen, and their extent depends on the gas flow rate:

- The impeller discharge flow rate is lower.
- The power delivered to the agitator decreases by as much as 60%, depending on the impeller selected.
- Vessel flow patterns become dominated by gas flow rather than impeller flow.
- Regions below the bottom impeller are often void of bubbles.
- Cavitation and finally flooding effects can totally dominate the vessel, leading to very poor gas dispersion and mixing.

Figure 9.28 shows typical cavity formation at the blade tips of a 45° PBT. It is easy to see how these cavities affect dispersion and mixing conditions in the vessel. Cavities reach a steady-state

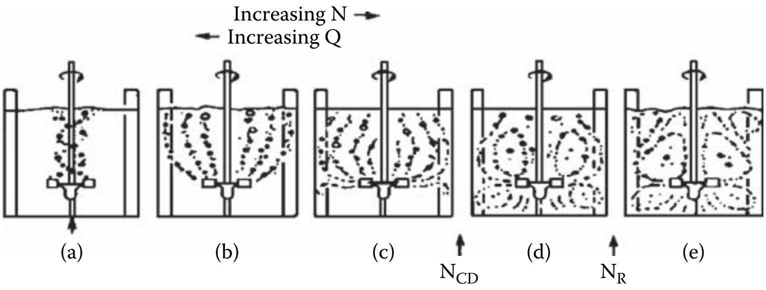

FIGURE 9.30 Changing vessel performance with agitation and gassing rates. (From Nienow et al., 1977.)

size at constant conditions. The sweeping motion of the blades first collects gas bubbles. There they impinge on the blades, creating large cavities (bottom right) because of coalescence. Gas leaves the cavities by shedding from the vortex tip. (See upper right picture in Figure 9.28.)

Figure 9.30 shows the changing bubble distribution patterns in the vessel as gassing and agitation rates change. Figure 9.30(a) shows a flooded impeller. Gas, instead of being dispersed by the impeller, passes centrally up the middle of the tank to the surface. As the agitation rate increases, N_{CD} is reached (shown by Figure 9.30(d)), and a condition known as "complete" dispersion is reached. At still higher speeds, N_R, gas bubbles are entrained back to the impeller. This condition (Figure 9.30(e)) represents excellent circulation and bubble distribution throughout the vessel. Figures 9.30(a–e) show the effects of decreased gas flow at a given rate of agitation. At Figure 9.30(a), while agitation is strong, the gas flow is high, and the impeller cavitates, resulting in gas bypassing the impeller.

The conditions shown by Figure 9.30(a–e) are represented schematically in a regime map, Figure 9.31, where the Froude number is shown as a function of the gas flow number. The Froude number, Fr, is N^2D/g, and the gas flow number, Fl_g, is Q/ND^3. These numbers are calculated for a design and its operation; the values are then placed on the regime map to determine if the design is workable. Such a procedure can help avoid costly scale-up mistakes.

The following are design guidelines for good gas-liquid mixing. Conditions shown by Figure 9.30(a, b) exist for Fr < 0.05. This condition must be avoided. Regime I represents conditions shown by Figure 9.30(e). While dispersion and mixing are excellent, power may be excessive for most applications. Regime II is a practical compromise between performance and energy cost. Most industrial gas-liquid applications will fall into regime II. Regime III is reached by high gassing rates or by low-speed conditions. Regime III is equivalent to conditions shown by Figure 9.30(c). The bubble distribution is not uniform, and holdup is decreased. In some cases, operation in regime III is acceptable, provided that liquid circulation below the impeller is good. The actual location of all lines is a function of the impeller selection. It is essential to determine into which region the system falls, both from a standpoint of design and for troubleshooting. Some suppliers provide charts similar to Figure 9.31 with their literature and proposals.

The following applies to Rushton (D-6) turbines having $(D/T) = 0.40$ [44]:

- Flooding occurs when $Fl_g > \approx 1.2$ Fr (Figure 9.30(a) and the lower-sloped line in Figure 9.31).
- Gas recirculation begins when Fr $> \approx 2.75\ Fl_g^{1/2}$ (Figure 9.30(e) and the upper line in Figure 9.31).
- Vortex and large cavities on upper impellers (multiple impeller systems) develop when $Fl_g Fr \times 0.2$ (Figure 9.30(c))

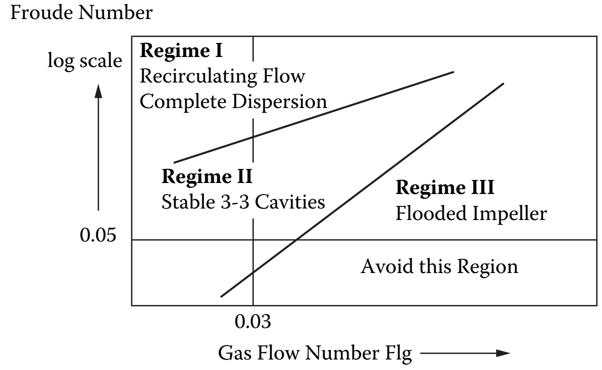

FIGURE 9.31 Flow regimes in gas-liquid systems.

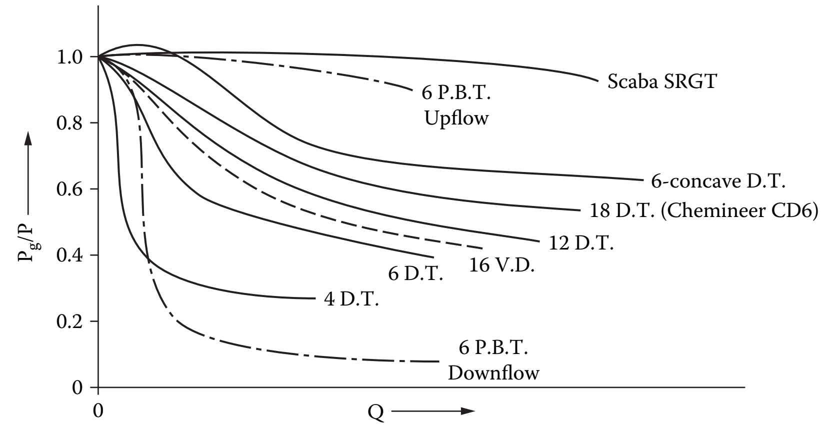

FIGURE 9.32 Impellers used for gassing: the effect of gas on power. (From Middleton, 1995.)

- Vortex and large cavities will begin to develop when $Fl_g \geq 0.03$
- Stable cavities develop when $Fr > 0.05$

Mass transfer and gas holdup depend on gassed power input. It is therefore important to know the power delivered under gassed conditions. Experimental curves such as those shown in Figure 9.32 relate the ratio of gassed to ungassed power, P_G/P_{UG}, to either gas flow rate or the gas flow number, Fl_g. Data in Figure 9.32 show how nine different impellers compare. Note that:

1. All impellers show a decrease in power with increasing gas flow.
2. The Scaba and A-200 or PBT-6 up-pumping turbines are least affected by gas flow.
3. The power ratio for the CD-6 drops to only 0.7, but the Rushton (R-100, DT-6) falls to 0.4.
4. More power is retained when impellers with more blades are used.

Actual power ratios can be calculated using Equation (9.38) (developed by Chemineer) with constants given in Table 9.9. The viscosity μ is in centipoise.

$$P_G/P = 1 - (a \cdot \mu + b) \cdot \tanh(c \cdot Fl_g) \cdot Fr^d \tag{9.38}$$

9.7.5 Mass Transfer and Gas Holdup

The general features of mass transfer were previously given in Section 9.7.1. The mass-transfer coefficient, k_La, and gas fraction holdup, Φ, are closely related and depend on the same variables. Equation (9.36) relates area, holdup, and mean bubble size, and the main variables affected by agitation is d_{32} and a. Bubble rise time and thus escaping tendency are a function of the bubble size, and this affects holdup. The fundamental expression for mass transport includes the k_La, and the driving force and is given by

$$N_i = k_L a\left(C_{Li}^* - C_{Li}\right) \tag{9.35}$$

Agitation mainly affects the a in k_La, since it represents the total interfacial area per unit volume of gas plus liquid. It therefore has units of length^{-1}. The units of k_La are usually expressed in s^{-1} or min^{-1}. Typical k_La values for agitated vessels lie between 0.05 to 0.4 s^{-1}. The mass-transfer coefficient k_L, is one of the resistances to transport of species (i) from the gas phase inside the bubble to the bulk fluid outside the bubble. The overall resistance $1/K_L$ is the sum of the inside and outside resistances shown in Equation (9.39), where E is the equilibrium constant. In the great majority of cases, $k_L \approx K_L$. This implies that k_G is small compared with k_L and means that the liquid film resistance outside the bubble is controlling:

$$\frac{1}{K_L} = \frac{1}{Ek_G} + \frac{1}{k_L} \tag{9.39}$$

The gas film resistance, k_G, for small bubbles is controlled by diffusion, D_G, as shown by

$$k_G = \frac{2\pi^2 D_G}{3d_{32}} = 6.6\frac{D_G}{d_{32}} \tag{9.40}$$

The liquid-side mass-transfer coefficient, k_La (s^{-1}), is related to the superficial gas velocity, V_{SG} (m/s), and the gassed power per unit volume of liquid, P_G/V, (kW/m^3). The viscosity term μ*/μ accounts for the effect of process viscosity on the mass-transfer coefficient relative to standard conditions, typically water at 20°C:

$$k_L a = C \cdot \left({P_g}/{V}\right)^{\alpha} \cdot \left(V_{SG}\right)^{\beta} \cdot \left({m^*}/{m_{ref}}\right)^{\gamma} \tag{9.37}$$

TABLE 9.10

Table 9.10 gives values of the constants in Equation (9.37). Values of $\alpha = 0.7$ and $\beta = 0.3$ for scale-up are suggested by Middleton [45].

Smith [48] obtained Equation (9.41) for the correlation of $k_L a$ by grouping terms of Equation (9.37) and setting $\alpha = 1$, $\beta = 0.45$, and $\gamma = -0.7$

$$k_L a = 1.25 \cdot 10^{-4} \left(\frac{D}{T}\right)^{2.8} Fr^{0.6} \cdot \mathrm{Re}^{0.7} \cdot Fl_g^{\,0.45} \left(\frac{D}{g}\right)^{-0.5} \tag{9.41}$$

The most important physical property affecting k_L is the liquid viscosity, since it is directly related to the film resistance around bubbles as well as their rise velocity. The Weber number used extensively for immiscible liquid-liquid dispersion (see Section 9.8) is seldom used for gas-liquid systems. The surface tension for many gases and liquids is more constant than the interfacial tension used for liquid-liquid systems.

Gas holdup, Φ, is expressed as a volume fraction and is represented by $V_G/(V_G + V_L)$, where V_G and V_L are the volumes of gas and liquid, respectively, in the vessel. Gas holdup values can vary from 0.01 (1%) to as high as 0.50 (50%) for industrial applications. Holdup depends on bubble size, bubble rise velocity, and bubble coalescence. Gas holdup can be easily measured by observing liquid heights under gassing and nongassing conditions (Figure 9.29):

$$\Phi = \frac{H_{aerated} - H_{unaerated}}{H_{aerated}} \tag{9.42}$$

An expression commonly used for gas holdup is

$$\Phi = K \left({}^{Pg}\!/_{V} \right)^{\alpha} V_{SG}^{\ \beta} \tag{9.43}$$

The mean values from a review [49] are $\alpha = 0.45$ and $\beta = 0.48$. Values listed in Table 9.11 were found by Kar [46] using a ring-type sparger and $C/D = 0.5$, $D/T = 0.4$–0.51.Gas holdup has also been correlated using dimensionless groups. For example, Smith [48] proposes:

$$\Phi = 0.85 \cdot \left(\mathrm{Re} \cdot Fr \cdot Fl_g\right)^{0.35} \cdot \left(\frac{D}{T}\right)^{1.35} \tag{9.44}$$

Source: Pinelli, D., M. Nocentini, and F. Magelli, "Hold-Up in Low Viscosity Gas-Liquid Systems Stirred with Multiple Impellers: Comparison of Different Agitators Types and Sets," I. C. Engrs., Eighth European Conference on Mixing, University of Cambridge (*I. Chem. E.* 136, 81–88 [1994]).

Gas holdup studies in tall vessels including three impeller configurations were reported by Pinelli [51] for (a) three equally spaced Rushton turbines, (b) three A-315 turbines, and (c) one Rushton (bottom) and two A-315 turbines. Holdup was correlated using Equation (9.43), with constants shown in Table 9.12. The units for P_G/V are in W/m^3, V in m/s, and holdup in volume fraction gas.

For the case of equally spaced Rushton turbines in deionized water (fast coalescence), all constants are virtually the same. Power was additive, suggesting that the turbines functioned independently. While there is some variation in K for other configurations, values of α and β are nearly constant. The gas flow constant dominates over power. This is not the case for noncoalescing polyvinylpyrolidone (PVP) and salt-containing solutions. Experiments included one impeller with H/T = 1.0, two impellers with H/T = 2.0, and three impellers with H/T = 3. All impellers were equally spaced.

Holdup and bubble size can be rough indications of the quality and intensity of mixing, but less information is revealed than for k_La.

9.7.6 Gas Residence Time

The gas residence time becomes important for sparingly soluble gases and cases where a high gas conversion is desired. The gas residence time depends on viscosity, flow rate, bubble size, and the height of liquid in the vessel. In Figures 9.30(a–c), bubble rise time and liquid height are dominant factors, but in Figures 9.30(d–e), entrained flow is also important. Actually, very little has been

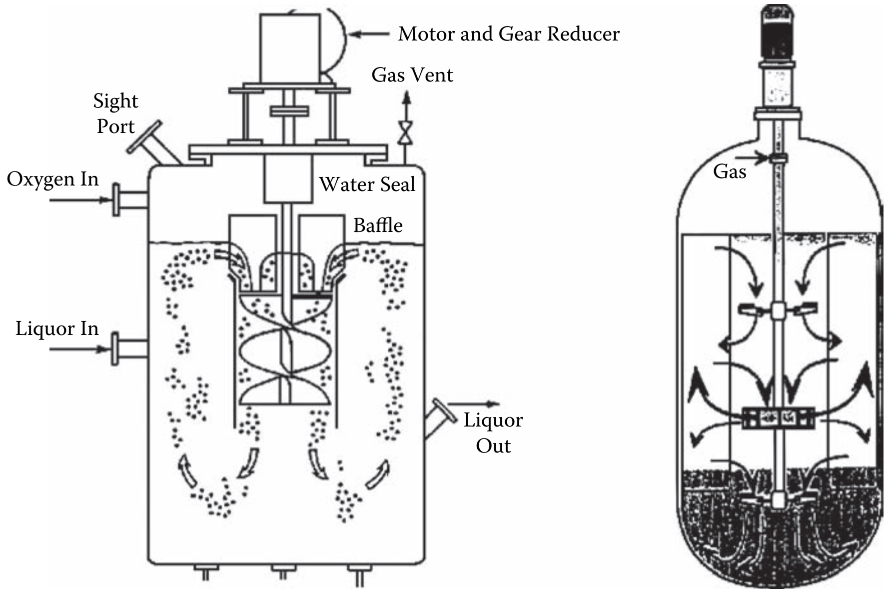

FIGURE 9.33 Circulate headspace reactors: Biazzi/Ekato hydrogenation reactor (right) and Praxair's AGR reactor (left).

published on the residence-time distribution for gas (RTD_G) as a function of design and operating conditions. Still, RTD is important when carrying out chemical reactions, particularly in cases where the gas is sparingly soluble in the liquid phase. The residence time will be a distribution, with larger bubbles having a shorter residence time than smaller bubbles. If visual inspection is possible, a rough order of magnitude is to stop agitation and measure the time it takes for all bubbles to reach the surface.

The gas residence time can be increased by (a) returning the headspace gases back to the gas feed by means of an external compressor; (b) using a self-inducing hollow tube impeller [52, 53]; or (c) using a propriety design configuration, such as Praxair's AGR reactor or Biazzi/Ekato's reactor, both shown in Figure 9.33. These designs are intended to recycle headspace gasses, thereby increasing the gas residence time.

In the Biazzi/Ekato reactor, gas enters the hollow shaft through holes located above the liquid. It is ejected in holes around the eight-blade turbine, where dispersion occurs. The flat-blade turbine has an upper and lower disc to improve suction pressure. Two axial-flow turbines—one above and one below the disperser—provide circulation in the vessel. Closely spaced vertical baffles double as heat exchangers. In the Praxair AGR design (advanced gas reactor), headspace gases are engulfed by a close-fitting high-speed screw operating in a draft tube. A flat-blade dispersing impeller at the bottom of the screw helps disperse the gas. Several design variations are available. The design is reported to give good flow and bubble distribution. It can be retrofitted to existing vessels.

9.7.7 Scale-Up

A scale-up problem that needs to be recognized is that, at small scale, a large quantity of gas enters through the liquid surface. This is not the case at the industrial scale. Humphrey [54] outlines a method for dealing with this scaling problem, and a method to correct for surface aeration.

It is recommended that well-gassed conditions such as those shown in Figures 9.30(d, e) be used for scaling. It is recommended that k_La and holdup be scaled using Equations (9.37) and (9.43).

Two criteria are often used for gas-liquid scale-up:

1. Keep the vvm (volume of gas per volume of liquid per minute) constant. This leads to an increase in V_g and results in higher gas holdup and k_La values. If the gas is a reagent, constant vvm maintains reaction stoichiometry.
2. Maintain both V_{SG} and $[P_G/V]$ constant. This preserves both k_La and holdup, but leads to reduced rates of reaction.

Example 9.5

Batch fermentation is being used to produce an antibiotic. The broth is assumed to be Newtonian. Examination of the operating data suggests that insufficient oxygen is available at certain times. The viscosity reaches a maximum of 300 cP during fermentation.

Examine the design and make recommendations for improvements. The volume of the fermenter is 80 m^3. Its critical vessel and impeller dimensions are $T = 3.66$ m, $H = 5.1$ m, $D_L = 1.4$ m, and $D_U = 1.65$ m. The vessel has four conventional baffles, and a 1.3-m ring sparger is located below the lower impeller. The lower impeller is a Rushton (R-100, D-6) type, and the upper impeller is a hydrofoil of A-310, HE-3 type. The speed is 60 rpm. The air flow rate is 1.0 vvm.

Solution

At the maximum viscosity, the impeller Reynolds number for the lower impeller is 6500, which indicates that the flow is in the transitional regime, but close to fully developed turbulent flow. At ungassed conditions, the Rushton impeller ($D = 1.4$ m, Np = 5.75) consumes 30.5 kW (40.98 hp). The upper impeller ($D = 1.65$ m, Np = 0.3) consumes 3.68 kW (4.93 hp). The combined power is 34.2 kW (45.91 hp). The quiescent volume at a height of 5.1 m (200 in.), including the dished head, is 50.5 m^3 (13,333 gal). This makes the P/V for the lower R-100 impeller = 0.61 kW/m^3 (3.1 hp/1000 gal). The gas flow at 1.0 vvm is 50.5 m^3/min (13,333 gal/min), 0.841 m^3/s (46.5 ft^3/s). The superficial gas velocity, V_{SG}, is 0.125 m/s (0.41 ft/s). The Froude number, N^2D/g, is 0.1423 and the gas flow number, Fl_g, (i.e., Q_g/ND^3), is 0.482.

1. Determine the gassed power input using Equation (9.38). Substituting values, P_G/P_{UG} is 0.688. So $P_G/V = 0.419$ kW/m^3 (2.13 hp/1000) gal.
2. Determine bubble dynamics in the vessel. Flooding occurs when $Fl_g > 1.2$ Fr. In this case, 1.2 Fr = 0.171. From this, we conclude that the impeller is flooded. The Froude number is greater than 0.05, so operations (with reference to Figure 9.31) are in regime III, and gas will not reach the lower portions of the vessel. Conditions represented by Figure 9.30(a) or 9.30(b) probably exist. The best option is to increase the speed and then consider increasing the gas flow rate (first the speed).
3. Solving $Fl_g > 1.2$ Fr for N, at $Q = 1.317$ m^3/s (46.5 ft^3/s), using $D = 1.397$ m (55 in), gives $N > 85$ rpm. This speed would result in a 41% increase in shear rate, which might be unacceptable to the microorganisms. Maintaining the same impellers operating at 85 rpm results in a power draw of 91.44 kW or a P/V of 1.69 kW/m^3 (10 hp/1000 gal).
4. If a CD-6 having an Np = 3.67 were selected, the combined impeller power draw at ungassed conditions would be 60.0 kW (80.44 hp). The corresponding Froude number = 0.28, and the gas flow number is 0.341. Thus 1.2 Fr = 0.342, so conditions are just at the onset of flooding. Increasing the gas flow by 20% results in $Q = 1.58$ m^3/s (55.8 ft^3/s), which would make $Fl_g = 0.409$. This condition would place operations solidly in region II, a more desirable condition.
5. Calculate gassed power, k_La, and holdup at these new conditions. $P_G/P_{UG} = 0.745$, and $P_G = 55.47(0.745) = 41.32 + 4.55 = 45.87$ kW. (For k_La, use only the power draw for the lower turbine.) Use Kar's constants found in Table 9.10, $A = 0.78$, $\alpha = 0.48$, $\beta = 0.57$, and $\gamma = -0.77$. The input variables are $P_G/V = 0.756$ kW/m^3 and $V_{SG} = 0.15$ m/s. The calculation for k_La using Equation (9.37) is 0.00286 s^{-1}. The high viscosity causes this value to be low. At 1 cP, the k_La would be 0.231 s^{-1}, an acceptable value. Calculations

for gas holdup using Pinelli's correlation give 43.8% for noncoalescing and 23.1% for air-water or coalescing systems. These numbers are very high. Note that the P_G/V is in units of W/m^3 in Pinelli's correlation.

9.8 IMMISCIBLE LIQUID-LIQUID MIXING

9.8.1 Introduction

Immiscible liquid-liquid mixing involves dispersion, suspension, and coalescence of liquid drops in a second liquid phase. Effects of mixing are complex, often poorly understood, and lack industrially usable measuring tools. Scale-up is particularly difficult, since coalescence dispersion and suspension are affected to different degrees by scale. For a more in-depth treatment of this subject, see Chapter 12 by Leng and Calabrese in the *Handbook of Industrial Mixing* [1].

Industrial applications of liquid-liquid mixing include emulsion, suspension polymerization, alkylation, nitration, phase transfer catalysis, solvent extraction, decantation, centrifugation, and electrostatic precipitation. The dynamic behavior of drops is important to the understanding of liquid-liquid mixing. This includes flow direction and intensity as well as the velocity gradients, commonly known as shear. Shear, whether turbulent or laminar, causes drops to deform, disperse, collide, and coalesce. On the other hand, drop suspension depends on bulk flow movement. Whether a drop breaks, or remains intact, depends on stress variation and magnitude. When a drop breaks, there can be few or many daughter drops formed. Higher energies during dispersion lead to the formation of many more daughter drops. Coalescence probability depends on collision, contact time, and film drainage time. Coalescence, dispersion, and suspension processes occur simultaneously but often to different degrees, depending on local flow.

Coalescence is also controlled by the condition of drop surfaces. Surfactants reduce the interfacial tension and help preserve drop stability, therefore affecting drop sizes. Surface-active materials are important in suspension/emulsion polymerization processes.

9.8.2 Characterization of Immiscible Liquid-Liquid Systems

Characterization of immiscible liquid-liquid systems into broad groups based on coalescence rates can sometimes help reduce the complexity that must be considered. Noncoalescing systems can be treated as dispersions only. Examples include dilute dispersions, typically <5% dispersed phase, and stabilized, more-concentrated systems. Many industrial systems are either noncoalescing or very slowly coalescing.

A simple test to characterize relative drop stability is to measure the time it takes to separate a given dispersion into two distinct clear layers. Table 9.13 gives rough guidelines for such a characterization.

TABLE 9.13
System Characterization by Coalescence Rates

Time for Phase Separation	Characterization	Process Implication
< 10 s	Very rapid coalescence	Expect severe scale-up problems
<1 min	Fast coalescence	Scale-up problems exist, but can be managed by the proper selection of equipment; process is apt to operate differently at different scales
2–5 min	Moderate coalescence	Design for coalescence; use broad-blade impellers producing high flow
>5 min	Slow coalescence	Problem can be considered as dispersion only

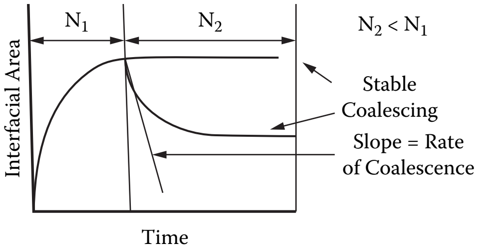

FIGURE 9.34 Dynamic test for coalescence.

TABLE 9.14
Dispersions Classified by Drop Size

Drop Size	Comments	Equipment, Agents Used
<0.5 µm	Stabilized by Brownian motion	Emulsifiers, ultrasonic devices, rotor-stator mixers, impingement mixers, etc.
$0.5 \geq d \geq 3.0$ µm	Marginally stable, can cream and separate	Rotor-stator, impingement mixers, static mixers, emulsifiers
>3.0 µm	Often unstable	Static mixers, in-line mixers, stirred vessels

A more accurate dynamic test for relative drop stability uses agitation and an optical transmission probe. First, a dispersion is created using vigorous mixing, N_1. Agitation is then decreased to N_2. If the interfacial area (indicated by a decrease in optical transmission) decreases, it is due to either coalescence or settling. If settling is the cause, choose a higher value for N_2. If the transmission remains constant after speed change, it suggests that the system is noncoalescing. The probe reading is constant under dynamic equilibrium between dispersion and coalescence. If the system coalesces, the optical transmission will increase, indicating a loss of interfacial area. The probe used is similar to that described by Rodger [55]. The output is schematically illustrated in Figure 9.34. If the optical transmission is recorded and the probe calibrated (e.g., with glass beads), the initial slope of the curve gives the coalescence rate. Another way to classify liquid-liquid systems is by drop size, as shown by Table 9.14. This section focuses on drops larger than ≈5.0 µm.

Initially, dispersion occurs throughout the vessel, but with time, the dispersion region shrinks to that close to the impeller. Experimental data and computational fluid dynamics (CFD) have confirmed that energy dissipation close to the impeller can be ≈40 times greater than the mean for the vessel. Coalescence rates are fastest in regions of gentle flow, where drop contact/rest times are longer. Under stagnant conditions, drops settle, touch each other, and can coalesce to form a condensed layer. Under gentle dynamic conditions, drops collide and remain in contact so that, if sufficient film thinning takes place, coalescence occurs. If the contact time is brief, so that insufficient drainage occurs, drops will separate and no coalescence occurs. Coalescence also results from drop collisions with impeller blades, baffles, and vessel walls.

9.8.3 Drop Sizes

The Sauter mean drop diameter, d_{SM} or d_{32}, defined by Equation (9.45), is most commonly used to characterize drop size because it relates to the volume fraction of the dispersed phase, Φ, and the interfacial area, a. The Sauter mean drop diameter is also known as the volume-to-surface average drop diameter. The interfacial area, a, in Equation (9.45) is also used to deal with mass transfer, such as $k_L a$. Other commonly used terms are d_{50}, d_{90}, and $d_{max.}$ They represent the midsize, the 90th percentile, and the largest size in the drop size distribution, respectively, on a volume basis. The

dispersed-phase fraction, Φ, the Sauter mean drop diameter, d_{SM}, and the interfacial area, a, are related as shown by Equation (9.45).

$$d_{SM} = d_{32} = \frac{6\Phi}{a} = \frac{\sum_{i=1}^{i=n} n_i d_i^3}{\sum_{i=1}^{i=n} n_i d_i^2} \tag{9.45}$$

The maximum surviving drop diameter, d_{max}, is approximately 1.6 times d_{SM}. The Sauter mean drop diameter can be calculated using Equation (9.45) from a population of n drops of different sizes, d_i, $d_{i+1, \ldots,}$ d_n. The drop size distribution often becomes self-preserving (similar shape distribution) after ≈30 passes through the impeller region.

9.8.4 Dispersion of Drops, Laminar Flow, and Low Viscosity

Single-drop studies have shown that a drop in a rotational shear field will both elongate and undergo internal rotation with increasing shear, until the critical deformation D_{crit} is reached. Beyond this point, breakage occurs. Taylor [56] established the relationship between drop deformation, D, and the magnitude of the rotational shear field. This is shown by Equation (9.46), where $P = \mu_D/\mu_C$:

$$D_{crit} = \frac{L-B}{L+B} = \left(\frac{\bar{G} \cdot d_D \mu_C}{2\gamma}\right) \cdot \left(\frac{1.1875 \cdot P + 1}{P+1}\right) = We \cdot f(P) \tag{9.46}$$

Figure 9.35 [57] and similar curves from Karam and Bellinger [58] show regions for drop breakage. Conditions must be above the curve for dispersion to occur. The burst energy E_B is a function of the variables shown in Figure 9.35.

Leng and Quarderer [59] modified Equation (9.46) by substituting impeller variables (N, D, etc.) for G_B. The resulting equation for dispersion under laminar conditions (boundary layer flow)

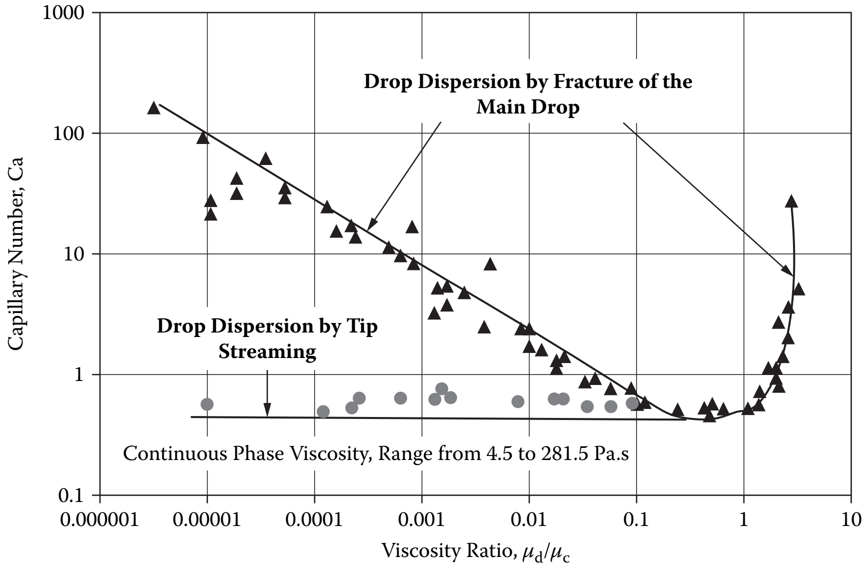

FIGURE 9.35 Critical bursting conditions as a function of the viscosity ratio. (From Grace, 1982.)

for a loop impeller of diameter D and a circular cross-sectional diameter D_C is given by Equation (9.47). A loop impeller consists of rectangular-shaped arms made from pipe. The diameter is usually $D/T = 0.67$, and the height is nearly equal to the depth of liquid in the vessel. The number of arms is commonly two, but four arms have been used successfully. The ratio of V_{tan}/V_{tip} at the tip of the impeller determines the value of k, where V_{tan} is the tangential velocity component at the impeller tip.

$$d_{max} = Const \cdot \gamma \cdot \left(\frac{D_C}{\mu_C \rho_C} \right)^{0.5} \cdot \left[ND(1-k) \right]^{-1.5} \left(\frac{P+1}{1.19P+1} \right) f(P) \tag{9.47}$$

Equation (9.48) gives the expression for a flat paddle:

$$d_{max} = Const \cdot \gamma \cdot \left(\frac{1}{\mu_C \rho_C} \right)^{0.5} \left[N^{-1.5} D^{-1} \left(1-k^2\right)^{-0.75} \right] \cdot \left(\frac{P+1}{1.19P+1} \right) \cdot f(P) \tag{9.48}$$

Equation (9.48) was tested commercially for scale-up using geometrically similar vessels and for drop sizes ranging from 300 to 1200 μm. Noncoalescing suspension polymerization experiments enabled sizes to be determined for finished beads using screen-analysis measurements. Equation (9.48) was confirmed for dimensionally similar vessels from 8.2 to 15,000 liters. Long dispersion times were used to ensure that complete dispersion had occurred.

9.8.5 Dispersion of Low-Viscosity (Inviscid) Drops (μ < 0.020 Pa·s) Turbulent Flow

The maximum drop size is determined by equating the surface energy, E_S, associated with a drop of diameter d with the equivalent turbulent energy, E_T, associated with a spherical volume of fluid of diameter d shown by Equation (9.49).

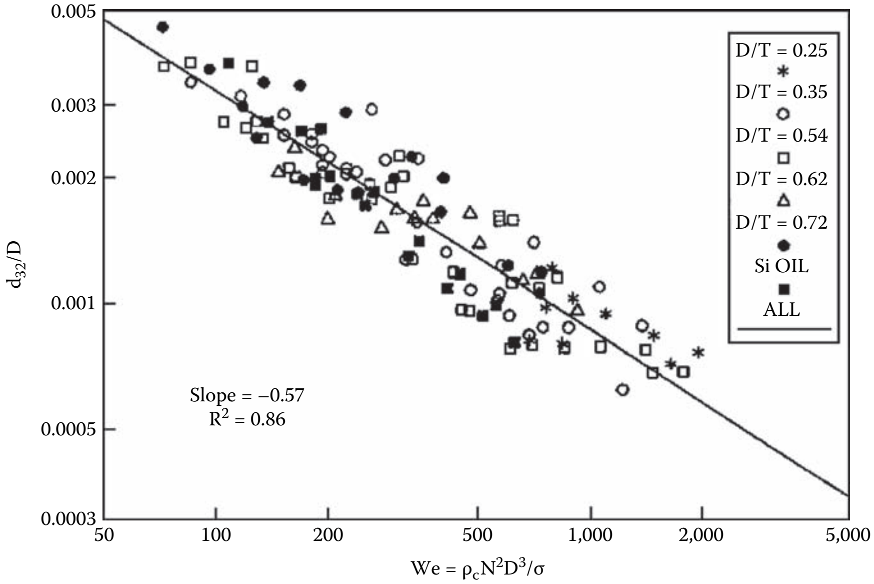
$$E_T \geq E_s \tag{9.49}$$

The turbulent energy is determined by integrating the energy spectrum over wave numbers from $1/d$ to ∞. Assuming isotropic turbulence, the function can be integrated upon substitution of the Kolmogoroff hypothesis relationship for $E(k)$. This procedure leads to Equation (9.50) [60].

$$\frac{d_{max}}{D} = Const \cdot We^{-0.6} = Const \cdot \left(\frac{D^3 N^2 \rho}{\gamma} \right)^{-0.6} \tag{9.50}$$

Chen [60], using data for 14 inviscid organic/water systems, determined the proportionality constant to be 0.053–0.057. Different-size disc turbines were used, and the L-L systems had interfacial tensions from 0.0047 to 0.048 N/m (4.7 to 48 dyne/cm). Figure 9.36 shows the data. The slope of the statistical correlation of the data is –0.57, which is in close agreement with the –0.6 indicated by Equation (9.50).

Ample literature data show that drop diameters depend on the Weber number. However, much early data were erroneous due to unreported effects of coalescence, the presence of contaminants, and nonsteady-state operating conditions.



$$\frac{d_{max}}{d} = \text{Const} \cdot We^{-0.6} = \text{Const} \cdot \left(\frac{D^3N^2\rho}{\gamma}\right)^{-0.6}$$

FIGURE 9.36 Data of Chen and Middleman for 14 L-L systems ratios. (From Chen et al., 1967.)

Chen's equation applies to low-viscosity fluids and Rushton impellers. It is shown by

$$\frac{d_{32}}{D} = 0.053 \cdot \left(\frac{D^3N^2\rho}{\gamma}\right)^{-0.6} \tag{9.51}$$

When impellers other than the Rushton (D-6 or R-100) are being used, McManamey [61] recommends using Equation (9.52):

$$\frac{d_{32}}{D} = C_1 Np^{-0.4} We^{-0.6} \tag{9.52}$$

where Np is the power number of the impeller used for dispersion and C_1 is a system constant. It is recommended to first use Equation (9.51) to calculate the drop size, and then ratio the power numbers to arrive at the predicted size for the different impeller types.

Within the equilibrium range (also referred to as the inertia subrange) in turbulent flow, eddy size is related to the kinematic viscosity, and local energy dissipation by the Kolmogoroff hypothesis is given in

$$\lambda_k = \left(\frac{\upsilon^3}{\varepsilon}\right)^{1/4} \tag{9.53}$$

For example, a stirred vessel containing water having a power input of 1.0 kW/m^3 (5 hp/1000 USG) has a Kolmogoroff length scale, η, of 30 μm. Drops smaller than this scale are entrained and not further dispersed. Larger drops are broken up by eddy interactions.

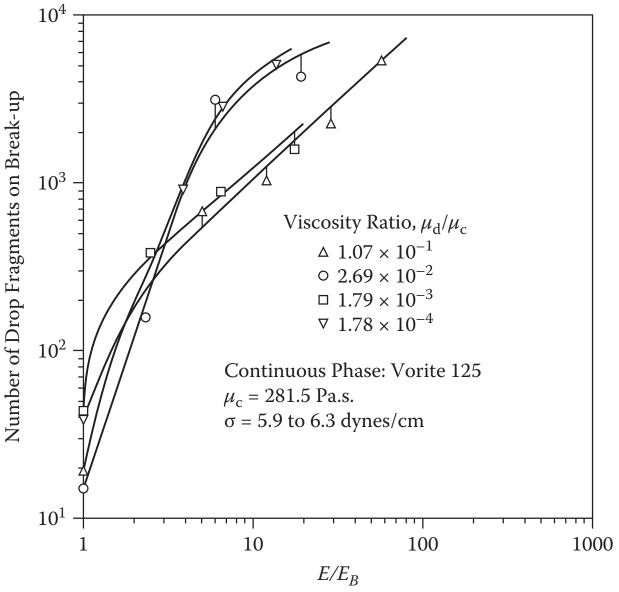


FIGURE 9.37 Drop fragmentation as a function of excess energy ratio E/E_B. (From Grace, 1982.)

Drop size distribution will be addressed briefly. When a drop breaks, there can be few or many fragments. The breadth of the distribution of daughter drops depends on the level of energy intensity at the time of breakage. Figure 9.37 shows that a large number of drops can form from a single drop at high energy. E/E_B is the ratio of local energy E to minimum bursting energy E_B for the drop. The viscosity ratio also affects drop breakage. More fragments form when μ_d/μ_c is small. In applications where the breadth of the size distribution must be minimized, such as in suspension polymerization, it is essential to provide uniform energy distribution.

9.8.6 Dispersion of Higher-Viscosity Drops (μ > 0.02 Pa·s) Turbulent Flow

Calabrese et al. [60] and Wang et al. [63] show that the breakage condition in Equation (9.49) should include a term E_v for dealing with drop viscosity. Equations (9.54) and (9.55) show the result:

$$E_T \geq E_S + E_V \tag{9.54}$$

Equation (9.55) by Calabrese et al. [62] includes viscous terms:

$$\frac{\rho_c \varepsilon^{-2/3} d_{max}^{5/3}}{\gamma} = C_5 \left[1 + C_6 \left(\frac{\rho_c}{\rho_d} \right)^{1/2} \frac{\mu_d \varepsilon^{-1/3} D_{max}^{1/3}}{\gamma} \right] \tag{9.55}$$

When interfacial tension is the main resistance ($E_s \geq E_v$), Equation (9.52) reduces to Equation (9.56), which is equivalent to Equation (9.50):

$$d_{max} = const \cdot \left(\frac{\gamma^{0.6}}{\rho_C^{0.6} \varepsilon^{0.4}} \right) \tag{9.56}$$

When the disperse-phase viscosity provides the main resistance ($E_v \geq E_s$), Equation (9.56) becomes

$$d_{\max} = C_8 \left(\rho_c \cdot \rho_d\right)^{-3/8} \cdot \mu_d^{3/4} \cdot \bar{\varepsilon}^{-1/4} \tag{9.57}$$

9.8.7 Time for Dispersion

The time for equivalent dispersion is scale dependent. A large vessel takes much longer to disperse drops to an equivalent degree of dispersion than a small vessel. If scale-up demands equal dispersion time, the larger vessel will be less completely dispersed than the smaller one. If the desired result is equal drop size, one solution is to increase the speed for the larger vessel and acknowledge that drop sizes will continue to be dispersion-time dependent.

9.8.8 Coalescence of Suspended Drops

Coalescence is the combining of drops either by collision or at a surface. It is desirable in some applications, while undesirable in others. It aids mass transfer and separation processes, but it is harmful to suspension and emulsion polymerization. Coalescence can occur when drops collide with one another or come to rest on surfaces and interfaces. Collisions between drops can result in either coalescence or rebounding. The impact creates transient forces that act on the colliding drops to thin the film separating them. As this film gets thinner, rupture (coalescence) occurs when the thickness reaches a critical value. If the film thickness does not reach this critical thickness during contact, the drops will depart without coalescing.

The coalescence rate is the product of the collision rate and the coalescence efficiency. The collision rate depends on the drop population and the velocity gradient. The coalescence efficiency depends on film thinning during contact and the time of contact.

Figure 9.38 shows two liquid drops approaching one another. The net force due to the change in momentum caused by the collision is *F*. Drops are separated from each other by a film of continuous-phase liquid of thickness *h*.

The leading edges are flattened, since drops are deformable. This deformation creates a parallel disclike geometry representing the thinning liquid acting under *F*. When a critical thickness is reached, rupture occurs. Equation (9.58) shows the rate of thinning. The reasoning is similar for drops resting at a flat liquid-liquid interface.

$$\frac{dh}{dt} = -\left(\frac{2F}{3\pi\eta R^4}\right) h^3 \tag{9.58}$$

The rate of thinning, *dh*/*dt*, depends on the force *F*, the fourth power of *R*, the thickness of the film *h*, and the viscosity η of the continuous phase.

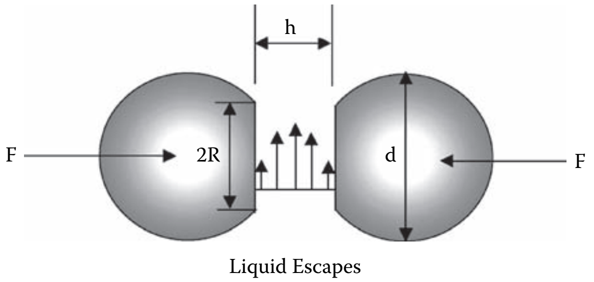

FIGURE 9.38 Film drainage between two colliding drops.

Upon integration and substitution of the initial and final conditions, $h = h_0$ at $t = 0$, and $h = h$ at time t, Equation (9.58) becomes

$$\Delta t = t - t_0 = \frac{3\pi\eta R^4}{4F}\left(\frac{1}{h^2} - \frac{1}{h_o^2}\right) \tag{9.59}$$

The initial distance h_0 is large compared with h, the thickness of the film at time t. The change in time, Δt, is the time it takes to reach a critical thickness for film rupture. Several versions of this equation exist that include internal circulation within the drop, rigid yet deformable interfaces, and complete interface mobility [64, 65].

This relationship has practical implications:

- If Δt, the total drainage, is sufficient such that the critical separation thickness is reached during the contact interval, the drops will coalesce.
- If insufficient drainage occurs during the contact interval, Δt, the drops will not coalesce.
- A low interfacial tension leads to greater flattening of the approaching drop surfaces. This produces a larger disc and makes the thinning process slower. Surfactants lower the interfacial tension, γ, and reduce the likelihood of coalescence. The surfactant may also reduce interfacial mobility, leading to further retardation of drainage rates.
- A higher impact force, F might increase the likelihood of coalescence, but it also creates larger discs, trapping more liquid and making drainage more difficult. Centrifuges and electrostatic coalescers are examples of force-amplification devices; decanters, on the other hand, depend on gravitational force.
- A higher continuous-phase viscosity reduces drainage rates and coalescence probability. For this reason, if two similar volumes of immiscible liquids are dispersed, the fluid with the higher viscosity will normally become the continuous phase.

The presence of solids at the interface usually retards film drainage rates, thereby reducing the probability of coalescence. A few suspension-polymerization processes use solid particles as suspending agents.

9.8.9 Population-Balance Methods

Population-balance analysis has been adapted to both coalescence and dispersion of drops in numerous papers by Calabrese, Ramkrishna, and Tavlarides. The analyses with these tools have led to a considerably better understanding of breakage kernels, breakage rates, coalescence efficiency, and collision rates. However, the description and use of these tools goes beyond the scope of this chapter. For a detailed understanding, see Ramkrishna [66].

9.8.10 Creating a Dispersion—Maintaining Drop Suspension

This subsection deals with creating a dispersion from two settled phases of different density, obtaining uniformity, and then determining the minimum speed to accomplish a dispersion.

The minimum speed, N_m, to form dispersions from two settled phases of different densities is expressed in terms of dimensionless variables. Differences in constant C reflect the effect of impeller clearance. Similarities can be seen between N_{JS} for solids suspension and N_{min} for

TABLE 9.15
Constants for Use in Equation (9.45)

Impeller Type	Clearance	C_1	α_1
1 propeller	H/4	15.32	0.28
1 propeller	3H/4	9.97	0.55
1 propeller	H/2	15.31	0.39

1 flat-blade turbine	3H/4	…	…
1 flat-blade turbine	H/2	3.99	0.88
2 flat-blade turbines	H/4 + 3H/4	…	…
1 curved-blade turbine	H/4	3.61	1.46
1 curved-blade turbine	3H/4	…	…
1 curved-blade turbine	H/2	4.71	0.80
2 curved-blade turbines	H/4 + 3H/4	4.29	0.54

drop suspension. Both are functions of density differences, viscosity, and impeller diameter. Skelland et al. [67] showed suspension speeds for equal phase volumes of two immiscible liquids. They also studied the effect of impeller location by placing a single impeller midway in the dense phase (C = H/4), at the phase interface (C = H/2), and midway in the light phase (C = 3H/4). For studies involving dual impellers, the impellers were placed midway in both phases to determine the minimum speed to form a suspension. Table 9.15 gives values for the constants in

$$N_m D^{o.5} / g^{0.5} = C_1 \left(\frac{T}{D}\right)^{\alpha 1} \left(\frac{\mu_c}{\mu_d}\right)^{1/9} \left(\frac{\Delta\rho}{\rho_c}\right)^{0.25} \left(\frac{\sigma}{D^2 \rho_c g}\right)^{0.3} \tag{9.60}$$

N_m is the stirrer speed in rps required to form a complete suspension. The C constants indicate the importance of impeller location. Single propellers have large constants, thus requiring higher speed. Impellers placed at the L-L interface use a minimum power to form dispersions. Flat-blade, radial discharge impellers do not work efficiently when placed in the light phase. More recent work by Armenante et al. [68] deal with the just-dispersed conditions in vessels equipped with multiple impellers.

Several methods can be used to form L-L dispersions. Placing the impeller in the lower phase will draw the upper phase in by interfacial vortex feeding. If placed in the upper layer, the impeller would normally disperse the lower phase into the light phase. However, the initially formed dispersion can be unstable. As mentioned earlier, the more viscous phase normally becomes the continuous phase. If the less viscous phase is initially the continuous phase, phase inversion is apt to happen. Another method commonly used to form dispersions is to continuously add a second phase while agitating the first phase. This method forces the added fluid to be dispersed. If phase volumes or viscosities are different, phase inversions can occur regardless of how the dispersion was first formed.

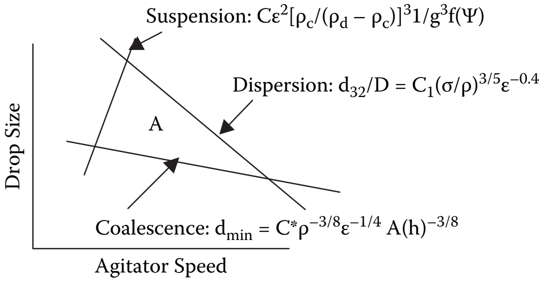

FIGURE 9.39 Dispersion, coalescence, and suspension. (From Church et al., 1961.)

9.8.11 Simultaneous Suspension, Dispersion, and Coalescence

Church [69] describes the simultaneous processes taking place in a stirred vessel. Figure 9.39 shows the result of three processes that form a bounded region. Within this region, equilibrium stability exists. For example, a drop within the region bounded by the three lines can grow by coalescence until it reaches the upper dispersion line. At this point it is dispersed by the local energy. Smaller drops below the coalescence line grow by coalescence until they reach the coalescence line. A drop located to the left of the suspension line will separate. The expressions that describe the lines in Figure 9.39 are given as Equations (9.61 to 9.63).

Dispersion:

$$d_{32}/D = C_1 \cdot \left(We\right)^{-0.6} = \left(\frac{\sigma^{3/5}}{\rho_c^{3/5} \cdot \bar{\varepsilon}^{2/5}}\right) \tag{9.61}$$

Coalescence:

$$d_{32} = C_2 N^{-0.75} D^{-0.5} \rho^{-0.375} A\left(h\right)^{0.375} \tag{9.62}$$

where $A(h)$ is the adhesive or attractive force and is a function of the separation distance, h.

Suspension:

$$d_{\max} = C_3 D^4 N^6 \left({}^{\Delta\rho}\!/\!{}_{\rho_c}\right)^3 \left({}^{1}\!/\!{}_{g}\right)^3 f\left(\Psi\right) \tag{9.63}$$

Regions around the impeller are usually dominated by high turbulence that causes dispersion. Elsewhere in the vessel, turbulence is much lower, and this promotes coalescence. Church [69] refers to this ongoing process as an agitation-stabilized system. This is fine, but the problem comes when one is scaling up a coalescing system. In a small vessel, circulation times are short and the turbulence zones dominate. The reverse is true for a large vessel. Simply keeping P/V constant and the geometry similar does not guarantee comparable drop size with scale-up. As mentioned earlier, an added complication for noncoalescing systems is the time to reach comparable stages of dispersion in different scales. Strongly coalescing systems reach steady state much more quickly than noncoalescing systems.

TABLE 9.16
Common Types of Equipment Used in Immiscible L-L Mixing

Description	Impeller Types	Batch/ Continuous	Desired Result	Comments
Stirred tanks, baffles	flat, pitch, and disc type	either	$30 \le d_{32} \le 300$ μm	general; mass-transfer operations
Stirred tanks, baffles	retreat curve	either	$30 \le d_{32} \le 500$ μm	general; emulsion polymerization
Stirred tanks, no baffles	paddle, loop, special types	batch	$100 \le d_{32} \le 1000$ μm	suspension polymerization; suspending agent required
Static/in-line mixers	none	continuous	$10 \le d_{32} \le 200$ μm	dispersant or protective colloid needed
Rotor-stator mixers	slotted ring + slotted stator	usually continuous	$1 \le d_{32} \le 50$ μm	sparse data for scale-up; need extensive testing
Impingement mixers	none	continuous	$1 \le d_{32} \le 50$ μm	sparse data; work with vendors
Homogenizers	valve homogenizers, ultrasonic mixers	continuous	$0.1 \le d_{32} \le 10$ μ	sparse data; work with vendors

9.8.12 Equipment Used for Liquid-Liquid Mixing

Liquid-liquid dispersion similar to gas-liquid dispersion depends on power being delivered to the dispersed phase. Many different power sources have been studied, including static mixers, stirred vessels, colloid mills, liquid whistles, ultrasonic devices, and valve homogenizers. At equivalent conditions, Davies [70] found that the maximum surviving drop size correlated with energy supplied and was to a degree independent of the device. A straight-line (log-log) plot represented all drop sizes with energy very well. This does not mean the drop size distribution is independent of the device. Indeed, devices producing very high local energy are likely to produce a much finer drop size distribution (dsd), because of how the drops fracture.

Process requirements, such as particle/drop size or distribution, determine the selection of equipment to be used in immiscible liquid mixing, as shown in Table 9.16. Energy is required for drop dispersion. Commonly used are agitated, baffled, and jacketed vessels, typically with impellers where D/T varies from 0.25 to 0.7. Large, high-flow impellers are used to help deal with strong drop-coalescence tendencies. Particular attention must be paid to mixing in the top and bottom regions of the vessel when significant density differences exist, for example, >200 kg/m^3. A second impeller should be used to cope with settling problems.

9.8.13 Processes

A common goal of suspension polymerization is to make uniform-sized drops that polymerize to form uniform size beads. Suspending agents prevent coalescence, thus preserving drops created by agitation. They also reduce the interfacial tension and drop size. Excessively high stirring leads to the creation of unduly small drops/beads. Slow agitation leads to large beads of broad size distribution and can lead to settling of the dispersed phase. Low, uniform shear rates are desirable. Baffling, if used, should be minimal. Impellers include retreat-curve turbines, two- and four-blade paddles, and rectangular-shaped open pipe loops. Impellers having large blade widths promote better circulation while maintaining low shear. Jacketed vessels are used to remove the heat of polymerization.

Dispersion, suspension, and heat removal must be simultaneously controlled in dealing with suspension polymerization. In Figure 9.39, the intersection of suspension and dispersion lines represents the largest maximum drop size that can be produced under existing conditions. Selection of different impellers can affect the position of this intersection. In continuous extraction applications, the goal is to create a large interfacial area, yet not make the drops so small that they are difficult to coalesce.

Other types of equipment such as static (motionless) mixers, rotor-stator mixers, and impingement mixers are used to create dispersions (see Section 9.9).

Example 6

In this example, solvent extraction is to be used to recover a product from a fermentation process. Processing information includes: broth viscosity $\mu = 0.3$ Pa·s (300 cP), interfacial tension $\sigma = 0.003$ N/m (3.0 dynes/cm), bulk density $\rho_C = 1000$ kg/m^3 (1.0 g/cm^3), vessel volume = 3.54 m^3 (750 gal), vessel diameter = 1.524 m (5.0 ft), and $D/T = 0.4$. Laboratory studies showed that acceptable extraction efficiency was obtained with mean drop sizes of 50 μm. Determine the power and speed required to produce 50-μm drops in the 750-gal extractor.

Solution

The solvent will disperse in the broth phase and will be slow to coalesce, since the broth has high viscosity. Equation (9.51) from Chen [60], $d_{max}/D = 0.053(D^3N^2\rho/\sigma)^{-0.6}$, will be used. Substituting $d_{32} = 0.005$ cm, $D = 61$ cm, $\sigma = 3.0$ dyne/cm, and $\rho = 1.0$ g/cm^3, then solving for N gives $N = 48$ rpm (0.8 rps).

The Reynolds number, Re = $D^2N\bar{\rho}/\mu$, is 7700 using a volume average viscosity of 38.6 cP. Flow is transitional but nearly turbulent. The power requirement using Np = 5.0, a mean density of 1.0, and impeller speed of 48 rpm, gives

$$\text{hp} = N\text{p}\,\bar{\rho}N^3D^5/17{,}719 = 0.3$$

9.9 STATIC IN-LINE MIXERS

9.9.1 Introduction to In-Line Static Mixers

A static mixer, also known as a motionless mixer, is a mixing device without any moving parts. It is also known as a pipeline mixer. It creates mixing as fluids pass through stationary geometric elements located inside the pipe. Static mixing elements vary in geometry from ordinary pipe internals such as orifices and baffles to specially designed complex structures. Turbulent pipe flow will ordinarily achieve a reasonably high degree of radial mixing in a length of roughly 100 pipe diameters. Static mixers achieve the same mixing in lengths of three to five pipe diameters.

There are over 30 different designs of static mixer elements. The more popular commercial ones and their suppliers include:

- Chemineer Kenics: KM series and HEV, Figure 9.40(a)
- Sulzer Chemtech: (or Koch) SMX, SMXL, SMV, SMVL, Figure 9.40(b)
- Ross: LPD, LLPD, Figure 9.40(c); ISG, Figure 9.40(d)
- Komax mixer

Static mixers are readily available in a wide variety of materials, including metals, alloys, and plastics in sizes from 1/2 to 24 inches in diameter.

Static mixers are widely used in situations where continuous in-line or pipeline mixing is required. Table 9.17 shows that applications span the entire spectrum from laminar to turbulent flow regimes, and they cover a wide variety of mixing processes involving the blending of gas-gas

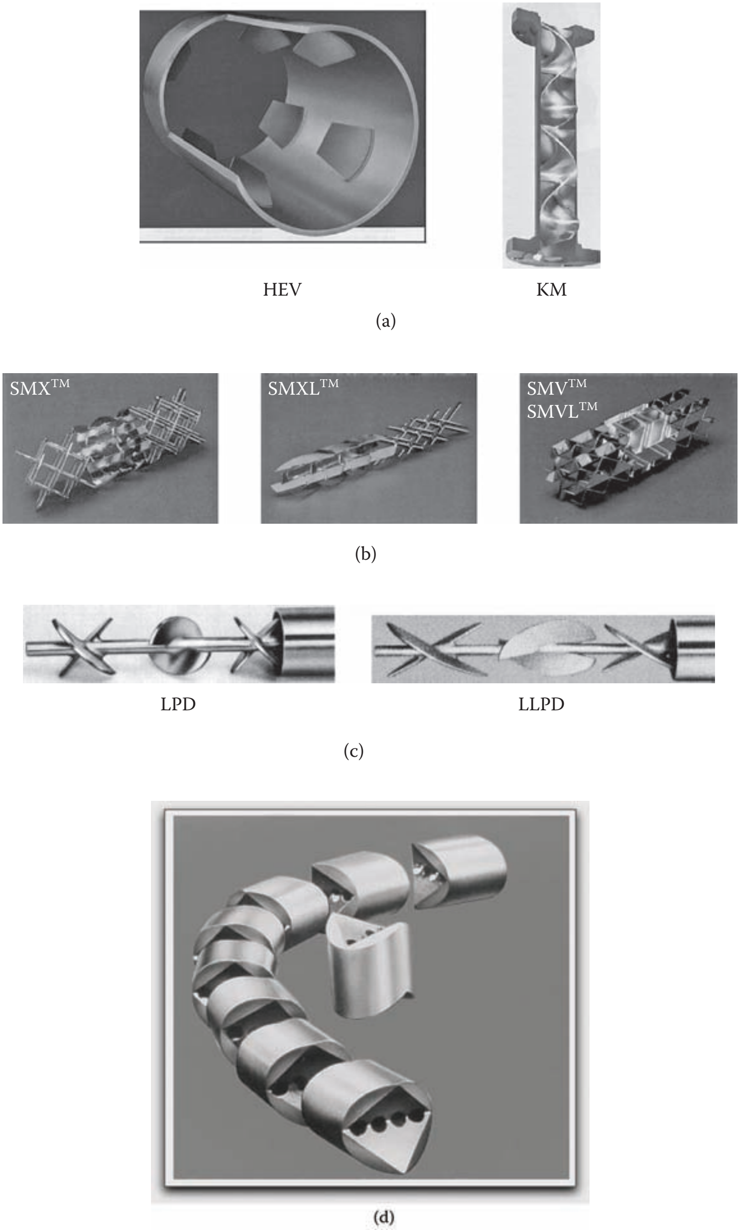

FIGURE 9.40 (a) Chemineer Kenics static mixers. (b) Sulzer or Koch static mixers. (c) Ross static mixers. (d) Ross ISG static mixer. (From Ross Systems and Controls.)

(G-G) or miscible liquid-liquid (L-L) streams as well as dispersions of solid-liquid (S-L), gas-liquid (G-L), and immiscible liquid-liquid (L-L) systems. Static mixers are also used in heat-exchanger tubes to enhance heat transfer under laminar flow conditions.

9.9.2 Hydrodynamics and Other Characteristics of Mixing in Static Mixers

Mixing by static mixing elements results from the hydrodynamic environment created by the fixed elements. These elements cause the fluids to divide and recombine, rotate clockwise and then

TABLE 9.17

anticlockwise, induce jets or turbulence eddies that interact with one another, etc., as the fluids move down the pipe. The specific hydrodynamic environment depends on the flow regime, laminar or turbulent. It is also different for different mixer designs, but the end result is good transverse or radial mixing with little or no axial back-mixing. The energy for mixing is the additional pressure drop due to the elements. Energy for mixing is supplied by feed pumps.

The manufacturer provides scale-up rules and correlations. These include the estimation of pressure drop and the number of elements required for a desired process result. These are reliable and may be used with confidence.

Static mixers offer certain advantages over dynamic in-line mixers and continuous stirred tanks. Table 9.18 is a summary of the characteristics of a static mixer compared with a conventional mechanically stirred vessel.

The hydrodynamic environment in a static mixer is characterized by a more uniform distribution of energy and shear rates than in a conventional agitated tank. Thus, for dispersion processes, a static mixer can produce a narrower drop or bubble size distribution. Also, the narrower residence-time distribution in a static mixer makes it the preferred mixing device for processes involving fast reactions or polymerizations requiring no back-mixing.

The static mixer produces an outlet concentration profile nearly as sharp as a step-change input in a plug-flow device.

Limitations of static mixers include the following:

- Provide little or no axial mixing (but excellent radial mixing)
- Cannot compensate for temporal variations in concentration or flow
- Pressure drop increases with the number of elements
- Certain slurries are prone to plug
- Low residence time and holdup are limitations for many reactions
- Performance is flow sensitive in turbulent applications
- Not easy to adapt to unexpected performance requirements

9.9.3 Static Mixer Selection and Design Issues

The proper selection or design of a static mixer starts with a clear understanding of process objectives and limitations. Table 9.19 gives design information for blending and dispersion applications. The following steps are recommended:

TABLE 9.18
Comparative Characteristics of the Static Mixer and the Continuous Stirred-Tank Mixer

Item	Static Mixer	Continuous Stirred Tank
Capital cost	lower	higher
Operating cost	lower because of lower power	higher
Maintenance cost	lower—no rotating component to wear out	higher—bearings, seals, gears, gearbox oil changes, etc.
Space requirements	smaller	larger
Hazard	volume small, contained, less hazard	large volume, potential for uncontrolled events
Environmental aspects	low leak potential	greater potential for leakage from seals
Hydrodynamic environment	(a) approaches plug-flow radial mixing with minimal back-mixing (b) narrower residence-time distribution (c) more-uniform distribution of energy dissipation and shear rates	(a) totally back-mixed (b) broader residence-time distribution (c) broader distribution of energy dissipation and shear rates
Residence time for reaction	short	long
Applicability	(a) continuous-flow applications (b) all fluid-mixing processes, but mostly used for blending and heat transfer (c) all flow regimes—laminar, transitional, and turbulent (d) wider ranges of temperature, pressure, and chemical environments (e) not suitable for slower reactions	(a) batch, semi-batch, or continuous (b) all fluid-mixing applications (c) more suited to transitional and turbulent flow regimes (d) narrower ranges of temperature, pressure, and chemical environments (e) suitable for slower reactions

1. *Specify the desired process result*: This is the first step to consider. The process listed results listed in Table 9.19 quantify the objective of the mixing process as described below.
2. *Assemble the process information pertinent to the application*: The lists in Table 9.19 are necessary for a complete process definition. They provide insights into the nature of the mixing process. For example, the component fluid phases and their miscibility establish whether one has a blending or dispersion application.
3. *Calculate static mixing process parameters*: The pertinent process parameters, along with the process information, help establish how difficult the mixing is for the process, as discussed below.
4. *Select and design mixer to give the desired process result*: In the selection and design, the pertinent items listed in Table 9.19 are specified. Suppliers of static mixers can do this final step reliably, provided that they have all pertinent information from the process definition steps. It often involves the iterative evaluation of several mixer designs and sizes for the one that best matches the specified process result. The mixer selection is best based on the mixing efficiency. But in retrofit cases, it is often selected on the basis of the design with the lowest pressure drop or shortest length to fit the retrofit design constraints.

9.9.4 Reynolds Number and Flow Regime

The value of the Reynolds number, computed using Equation (9.64), determines whether the flow is turbulent or laminar:

TABLE 9.19

$$Re' = \frac{\rho V D_h}{\mu} \tag{9.64}$$

where Re′ is a dimensionless correlating parameter for static mixer design, and D_h is the hydraulic diameter. The transition from laminar to turbulent flow for pipes occurs at Re = 2100, but in static mixers, the transition point may be as low as 100. Blending under turbulent flow usually requires fewer than five elements. Laminar blending requires many more, depending on the desired uniformity.

9.9.5 Component Flow and Viscosity Ratios

These determine the difficulty of the mixing application, as illustrated in Figure 9.41. The wider the viscosity difference between the component streams, the more difficult is the blending application. The most difficult application is the addition of a small, low-viscosity stream into a large, high-viscosity stream in laminar flow. For example, Tables 9.20(a) and 9.20(b) show effects

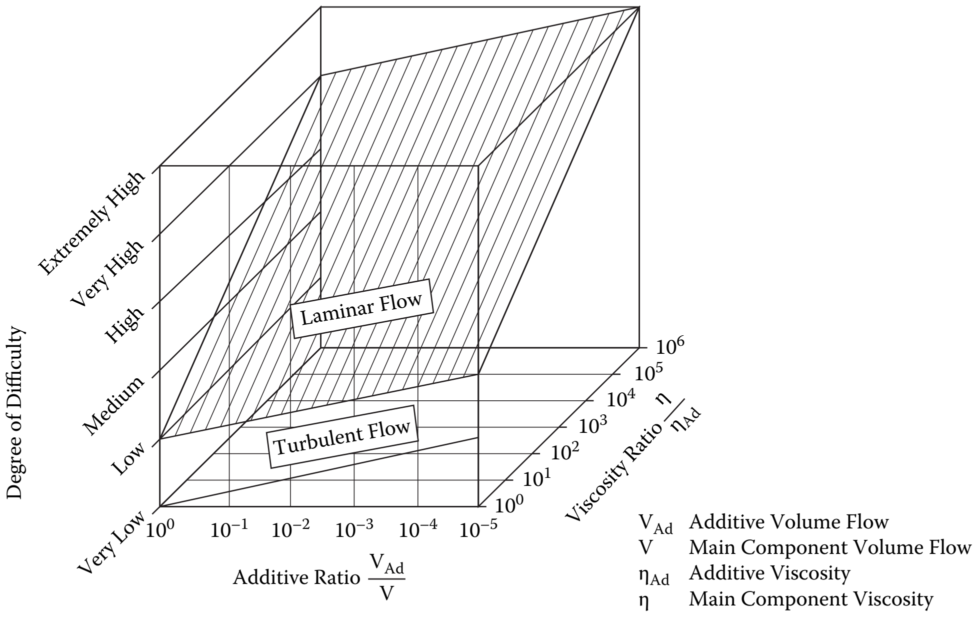

FIGURE 9.41 Additive and flow ratio effects.

TABLE 9.20(A)
Laminar Blending: Effect of Viscosity Ratio on Required Number of Elements

Viscosity Ratio: Primary to Minor Stream	Number of Ross LPD Modules	Number of Ross ISG elements
10^{-1} to 10^{3}	4–6 elements	10
10^{3} to 10^{4}	6–6 elements	14
10^{4} to 10^{5}	6–8 elements	20

TABLE 9.20(B)
Laminar Blending: Effect of Viscosity Ratio on Required Number of SMX Elements

10^{-3}	17	20
10^{-2}	15	18
10^{-1}	5	5

on the required number of elements for higher values of the viscosity ratio for Ross and Sulzer SMX, respectively.

9.9.6 Variation Coefficient in Blending Applications

The variation coefficient, $\sigma/\bar{x}$, is used in blending applications to characterize the homogeneity in a static mixer. Equation (9.65) defines $\sigma/\bar{x}$:

$$\frac{\sigma}{\bar{x}} = \frac{\sigma}{\sigma_o}\sqrt{\frac{1-\bar{x}}{\bar{x}}} \tag{9.65}$$

where σ is the standard deviation of point concentration values, x_i, at a given cross section of the mixer; σ_0 is the standard deviation at the mixer inlet; and $\bar{x}$ is the arithmetic mean of x_i values.

Figure 9.42 is a characteristic plot of $\sigma/\bar{x}$ as a function of the length-to-diameter ratio, *L*/*D*, for Sulzer SMX and SMXL mixers. It represents what happens when an additive is introduced at

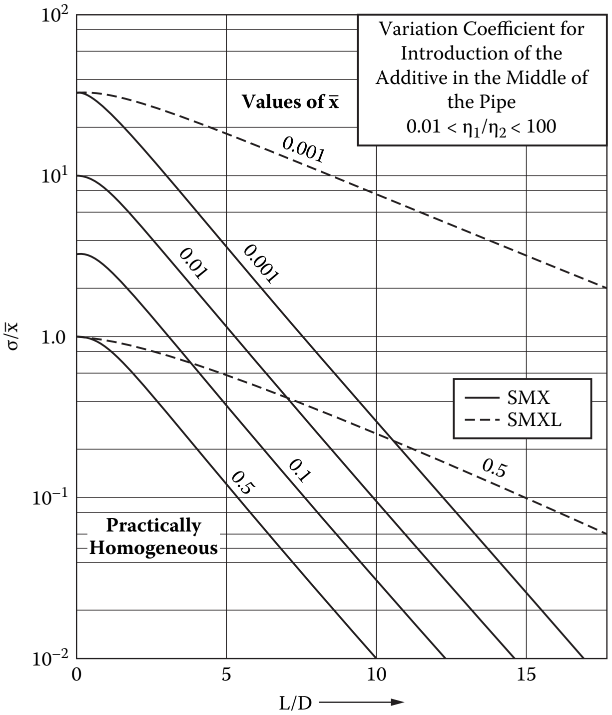

FIGURE 9.42 Variation coefficient as a function of mixer length for Koch SMX and SMXL mixers.

the center of the main flow under laminar conditions in the static mixers. The parameter, the arithmetic mean value, $\bar{x}$, represents the fraction of the additive in the total flow.

Key points in Figure 9.42 are

- Longer mixer lengths are required to reduce the variation coefficient.
- Shorter lengths are required for the SMX than for the SMXL.
- Longer mixers are required as the ratio of the additive decreases; it is easier to blend 50/50 than 99/1.
- The length required is insensitive to the viscosity ratio over a range of $0.01 < \mu_1/\mu_2 < 100$.

Key points in Figure 9.43 are

- In laminar flow, there are big differences in performance between different mixers.
- The top line represents an open pipe.
- Mixing efficiency does not necessarily follow Figure 9.44. Pressure drop needs to be considered.

A coefficient of variation, $\sigma/\bar{x}$, of 0.05 is considered to be a normal level of homogeneity. Less homogeneity may be acceptable if further processing will be done. More homogeneity may be required for critical reactions, particularly when dealing with fast competing chemical reactions.

9.9.7 Dispersed-Phase Size Distribution in Liquid-Liquid and Gas-Liquid Systems

The static mixer creates a hydrodynamic environment where critical viscous shear stresses deform drops, causing them to break. The dispersion process decreases the drop sizes and increases the

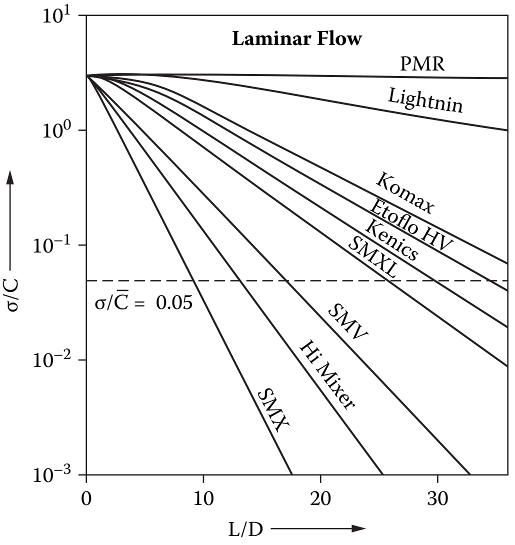

FIGURE 9.43 Comparative mixing performance of various static mixers in laminar flow.

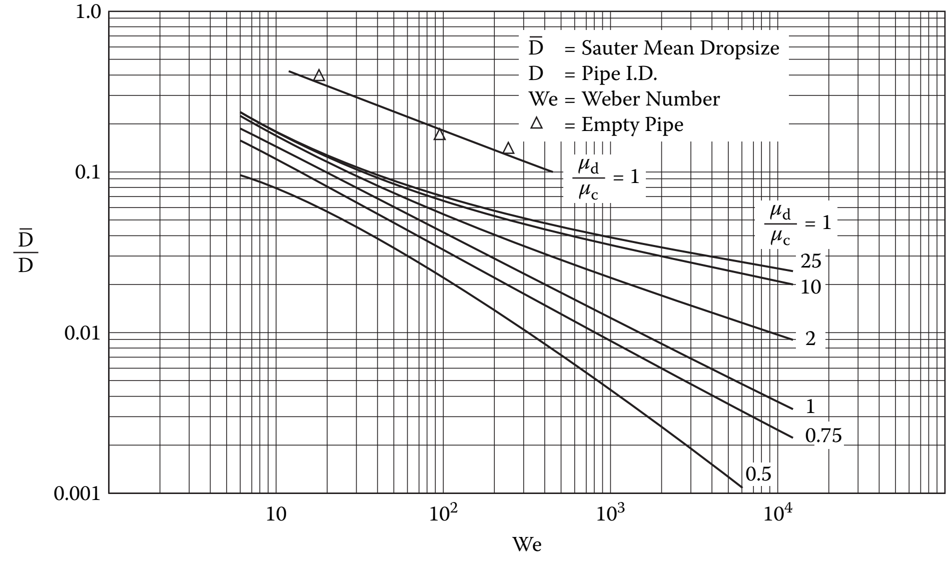

FIGURE 9.44 Sauter mean drop diameter versus Weber number for Kenics KM mixers.

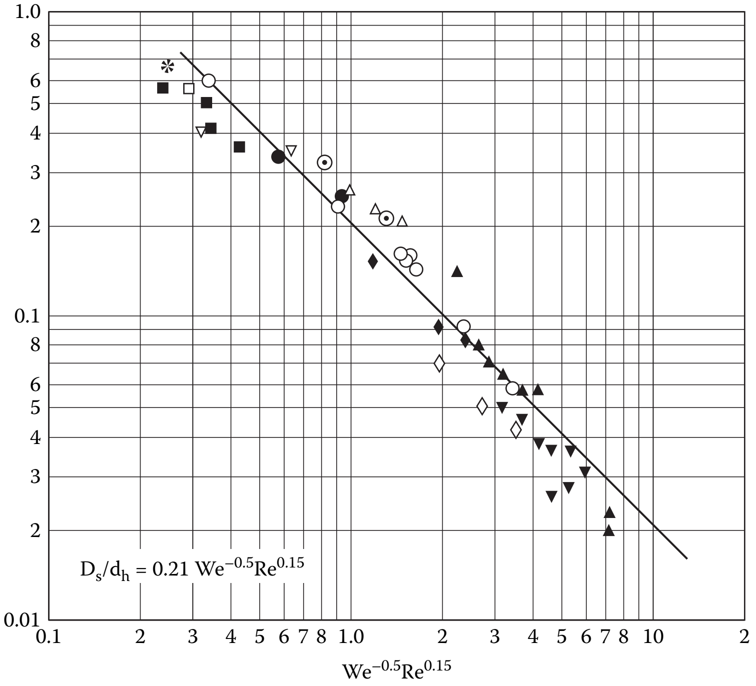
interfacial area between the phases as fluids pass through the mixer until the minimum drop size is attained. The drop size distribution for a noncoalescing system is narrower in a static mixer than in a stirred tank because the distribution of shear forces is more uniform. Typically, 70 to 80% of the volume of droplets will lie within ±20 to 30% of the mean drop diameter, and roughly 12 elements are required to reach the minimum drop diameter [72]. The Sauter mean drop size, d_{32}, is correlated by the Weber and Reynolds numbers, as shown by Figures 9.44 and 9.45, which present drop size d_{32} data for Kenics KM and Sulzer SMV mixers, respectively. It is clear from both figures that d_{32} decreases with increasing Weber number and, from Figure 9.44, d_{32} decreases as the ratio of the dispersed to the continuous liquid phase viscosity decreases.



Continuous Phase	Dispersed Phase	$\sigma (10^{-3}$ N/m)	d_h (mm)

FIGURE 9.45 Sauter mean drop diameter as a function of Weber and Reynolds numbers for Sulzer SMV mixer.

9.9.8 Interfacial Areas for Gas-Liquid Systems

The interfacial mass transfer area, a, is related to the superficial gas velocity, V_G, and gas holdup, Φ_G, for a Sulzer SMV [73], as shown in Figure 9.46. The plot shows that

$$a \propto V_G^{0.85} \phi_G^{0.15} \tag{9.66}$$

where the proportionality constant varies with the mixer geometry.

9.9.9 Mass-Transfer Coefficients for Gas-Liquid Dispersions

In the same study of gas-liquid mixing in SMV [73], the mass-transfer coefficient, k_L, was found to increase with the average liquid velocity, V_L, as

$$k_L \propto V_L^{1.22} \tag{9.67}$$

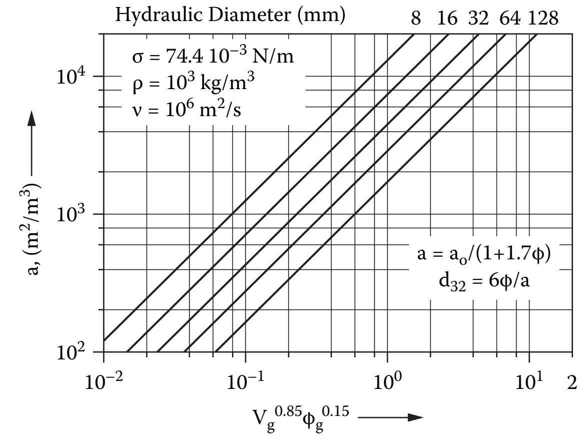

FIGURE 9.46 Interfacial area vs. product of gas velocity and dispersed-phase volume fraction.

TABLE 9.21
Constants for Heat-Transfer Equation (9.69)

Type	α	β
SMX	2.6	0.35
SMXL	0.98	0.38

The Sherwood number in terms of the Schmidt and Reynolds numbers is

$$Sh = 0.0062\,\mathrm{Re}^{1.22}\,Sc^{1/3} \tag{9.68}$$

9.9.10 Heat-Transfer Enhancement in Laminar Flow Applications

The heat-transfer coefficient, h, for laminar flow in tubes can be enhanced by a factor of two- to sixfold using static mixer elements in the heat-exchanger tubes. The heat-transfer coefficient is correlated using the Nusselt, Prandtl, and Reynolds numbers. Table 9.21 gives constants for Koch SMX and SMXL mixers for

$$Nu = \alpha \cdot \left(\mathrm{Re} \cdot \mathrm{Pr}\right)^{\beta} \tag{9.69}$$

9.9.11 Pressure Drop and Power Requirements

The pressure drop in a static mixer, ΔP_{SM}, is proportional to the pressure drop in an empty tube of the same length, ΔP, and its accurate prediction is vital to pump sizing:

$$\Delta P_{SM} = K \Delta P_{EP} \tag{9.70}$$

K depends on the mixer design and the Reynolds number. The exact values of K can be obtained from supplier literature. Typical values given in terms of the Darcy friction factor are presented in Tables 9.22–9.24. The power required for mixing in static mixers is

TABLE 9.22

$$Power = Q\Delta P_{SM} \tag{9.71}$$

where Q is the total flow rate through the static mixer.

9.9.12 Mixing Efficiency

The mixing efficiency, ε, of a static mixer has been defined as a normalized product of the pressure drop and the mixing length required to achieve a specified variation coefficient of 0.05:

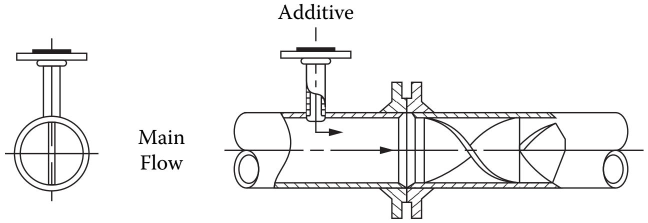

FIGURE 9.47 Simple T-connection.

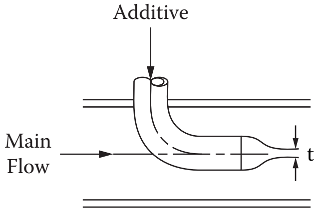

FIGURE 9.48 Coaxial injector design.

$$\varepsilon = \frac{\Delta P_{SM}}{\Delta P}\left(\frac{L}{D}\right) \tag{9.72}$$

Measured values of ε for several static mixers are ranked in Table 9.24. The corresponding *a*, for comparison, is shown in Figure 9.46.

9.9.13 Injection Considerations and Designs

A well-designed feed entry system can reduce the number of elements required to achieve a given task. The optimum design depends on the volumetric ratios of flow, component viscosity and density, and the type of operation to be carried out. A simple T-type connection as in Figure 9.47 is normally adequate for two component streams, where both the flow ratio and viscosity ratio (larger to smaller) are ≤10. In these applications, the low-viscosity side stream should be injected at about twice the velocity of the main stream and injected just short of the centerline of the pipe. The same type of T-connection is used to feed high-viscosity side streams (as in a side-arm extruder feeding a main polymer stream), since most other types of injectors have a tendency to plug.

The injector shown in Figure 9.48 is recommended for immiscible liquid-liquid or gas-liquid dispersion or blending in cases where the flow and properties of the component streams vary widely. The additive or minor stream must be introduced at twice the velocity of the main stream and as close to the leading mixer element as practical, but definitely within one pipe diameter upstream of the first element. The injector must discharge at the centerline of the primary stream. An extra element or two may be needed if the injection of the minor stream is not at the centerline.

9.9.14 Pump Selection and Flow Control

It is important to provide adequate control of the flow and concentration of the component steams because static mixers cannot compensate for variations in concentration or flow with time. Centrifugal pumps are used for low-viscosity fluids (viscosity ≤ 500 m·Pa·s). Rotary gear or screw pumps are recommended for higher-viscosity or high-pressure applications. Avoid using pulsating pumps such as reciprocating piston or air-driven diaphragm pumps. Other important criteria include potential for plugging, ease of cleaning, materials of construction, cost, and availability.

Plugging potential is related to the complexity of the design. Mixers having streamlined shape elements, such as the Kenics or the simple two-blade design of the Ross LLPD and LPD, are less apt to plug than the more complex Koch or Sulzer SMX and SMXL mixers. Removable mixer elements are preferred over welded-in-place designs for ease of cleaning or modification.

9.10 JET MIXING

9.10.1 Introduction

Liquid jets, as opposed to impellers/drives, can provide effective mixing in vessels. A typical configuration is to place a pipe/nozzle at the bottom corner of a vessel and directed upward toward the liquid surface on the opposite side. Mixing effectiveness depends on creating flow. This flow is comprised of direct pumped jet flow plus the entrained flow. The jet stream must be free in order to entrain large quantities of surrounding liquid as it moves toward the upper surface. The longer the path of the jet, the more is the liquid that becomes entrained. Jets in tanks provide effective low-viscosity blending when longer mixing times are acceptable. They can be adapted to various vessel shapes, including rail cars, highway transporters, and flat-bottomed storage tanks. Jets can also be used for light-duty solids suspension, as noted in Section 9.6. Jets should not used for dispersing immiscible liquids, blending viscous fluids, or for any application requiring rapid mixing. Frequently, a transfer pump can serve double duty as a means to provide jet mixing. Mixing times for jet mixers are given by expressions shown in Section 9.10.4. Jet mixing is similar in many ways to mixing using side-entering, wall-mounted propeller mixers.

9.10.2 Principles

A free jet moving diagonally through a vessel entrains approximately 15 to 20 times its pumped flow rate. As a first approximation, estimates of mixing times (95%) can be made assuming five turnovers and a 20:1 entrainment ratio. This gives

$$\theta_{approx} = 5V / 20 \cdot \left(pumping\ rate\right) \tag{9.73}$$

where V is the volume of liquid in the vessel.

While maximizing jet length is important for flow entrainment, applications requiring changing levels sometimes force compromises to be made. It is advisable to aim the jet at the corner representing the lowest expected operating level. This avoids the jet shooting out from the surface when lower levels are reached. At very low liquid levels, the jet must be aimed horizontally across the floor of the vessel. For this case, entrained flows are a half, due to floor effects, and mixing times will be twice that suggested by Equation (9.73).

It is important to create an efficient flow pattern in the vessel. A typical pattern is shown in Figure 9.49. When the jet is aimed diagonally across the tank, in the top view the pattern is symmetrical, and in both top and front views, two symmetrical flow patterns develop.

9.10.3 Equipment

Figure 9.49 shows the most common arrangement for a jet-stirred vessel. The jet stream expands at an angle of 15° to 25° due to entrainment and decrease in fluid velocity. The jet velocity at the centerline decreases with distance from the nozzle according to

$$V_Z = 6 \cdot \left(\frac{d_J}{z}\right) V_J \tag{9.74}$$

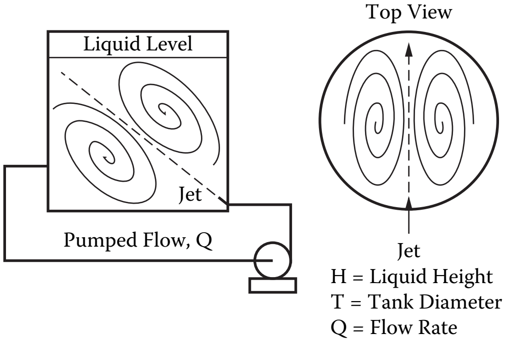

FIGURE 9.49 Typical arrangement for a jet-stirred vessel.

and

$$Q_Z = \alpha \cdot \left(\frac{z}{d_J}\right) \cdot Q_J \,, \tag{9.75}$$

where $\alpha \cong 3.0$.

9.10.4 Correlations

Researchers at DuPont (J. Gray) developed a useful, but conservative, correlation for jet mixing time, θ_M, given by

$$\theta_M = \frac{30 \cdot V_T \cdot d_J}{Q \cdot (H \cdot T)^{1/2}} \tag{9.76}$$

where d_J is the diameter of a jet required to deliver a flow, Q, the velocity of which is 25–30 ft/s; V is the volume of liquid in the vessel; H is the liquid height; and T is the vessel diameter. Any set of consistent units can be used.

Grenville [74] reported on jet mixing work done by the fluid-mixing processes (FMP) consortium, where Equation (9.77) was derived:

$$\frac{v_J \theta_M}{d_J} = 5.69 \cdot \left(\frac{T}{d_J}\right)^{3/2} \left(\frac{H}{d_J}\right)^{1/2} \tag{9.77}$$

Equation (9.77) is an empirical expression derived by correlating jet-mixing data from vessels ranging in diameter from 0.61 to 3.98 m. The correlation has an RSD of ±8.18%. For the case of $T = H$, Equation (9.77) becomes

$$\frac{v_J \theta_M}{d_J} = 5.69 \cdot \left(\frac{T}{d_J}\right)^2 \tag{9.78}$$

Equation (9.79) gives the power P (watts) required by a jet mixer:

TABLE 9.25
Fossett's Values for *K* in Equation (9.80)

Density Difference (%)	*K* in Equation (9.80)
1.0	23
2.0	18
6.0	15

$$P = \frac{\rho v_J^2}{2}\left(\frac{\pi \cdot v_J d_J^2}{4}\right) = \frac{\pi}{8}\rho v^3 d_J^2 \tag{9.79}$$

where ρ is in kg/m^3, d_J is in m, and v_J is in m/s.

An important reference for jet mixing is the work of Fossett [75]. He studied the blending of tetraethyl lead in gasoline stored in very large tanks. Fossett's work included liquids of different densities, ρ_1 and ρ_2. The jet was submerged a distance *S* from the surface and was aimed at an angle of α (measured from the horizontal). Equation (9.80) gives a relationship for *h*, the excess head needed by the jet to overcome the density differences:

$$h = \frac{KS}{\sin^2 \alpha}\left(\frac{\rho_2 - \rho_1}{\rho_2}\right) \tag{9.80}$$

Values of *K* are experimental and are given in Table 9.25.

Equation (9.81) gives Fossett's equation for mixing time for liquids of equal density:

$$\theta_M = \frac{8T^2}{\left(Qv_J\right)^{1/2}} = \frac{0.144T^2}{G^{1/3}h^{1/4}} \tag{9.81}$$

where *G* is in gallons per minute, *T* is in ft, *h* is the excess head given by Equation (9.80), and θ_M is in hours.

Example 9.7

A 3.658-m (12 ft) diameter by 4.572-m (15 ft) tall tank is to be mixed using a 0.3785-m^3/min (100 gpm) pump. The liquid level in the vessel is constant at 3.658m (12 ft), and fluids have equal densities. Determine the mixing time for 95% homogeneity.

Solution

The tank contains 38.44 m^3 (10,152 gal) of liquid.

1. As a first approximation, use Equation (9.73) to estimate the mixing time. Direct substitution in Equation (9.73) gives θ_M = 25 min.
2. Using Equation (9.76), first calculate d_J for a velocity of 9.14 m/s (30 ft/s):

$$d_J = \left(\frac{4Q}{\pi v_J}\right)^{1/2} = \left(\frac{4 \cdot 0.3875}{60 \cdot \pi \cdot 9.14}\right)^{1/2} = 0.0296 \text{ m} = 1.17 \text{ in}$$

$$\theta_M = \frac{30 \cdot V \cdot d_J}{Q\left(H \cdot T\right)^{1/2}} = \frac{30 \cdot 38.44 \cdot 0.0296}{0.3785 \cdot \left(3.658 \cdot 3.658\right)^{1/2}} = 6.74\,\text{min}$$

3. Using Equation (9.78),

$$\theta_M = 5.69\left(\frac{d_J}{v_J}\right) \cdot \left(\frac{T}{d_J}\right)^2 = 5.69\left(\frac{0.0269}{9.14}\right) \cdot \left(\frac{3.658}{0.0296}\right)^2 = 281s = 4.7\,\text{min}$$

The first estimate is very conservative and is used to consider if jet mixing is feasible. The 4.7-min figure is probably more accurate.

9.11 HEAT TRANSFER IN MIXING EQUIPMENT

9.11.1 Introduction

Heat transfer is an important consideration when the fluid motion in the vessel is in the laminar flow regime. It influences the design and operation of agitated process vessels such as reactors, evaporators, and crystallizers. For a review of working relationships, see Dream [76].

Heating and cooling of fluids in these vessels are necessary to:

- Remove the heat of reaction
- Provide uniform temperature in a vessel
- Provide accurate temperature control in a given process

It is important to recognize that agitation improves heat transfer by its effect on the process-side (inside the process vessel) heat-transfer resistance. Usually, the process-side heat-transfer resistance is the controlling resistance. The design challenge is to select and design an agitation system to minimize the process-side heat-transfer resistance while meeting other mixing requirements.

Proximity and nonproximity impellers are the two major designs used in mixing applications. Proximity relates to distance from the vessel wall. Figure 9.50(a) shows a nonproximity impeller typically used for turbulent conditions. Its blades are not close to the vessel wall. "Close proximity" agitators like anchors and helical ribbons, illustrated in Figures 9.50(b, c), are typically used for high-viscosity applications.

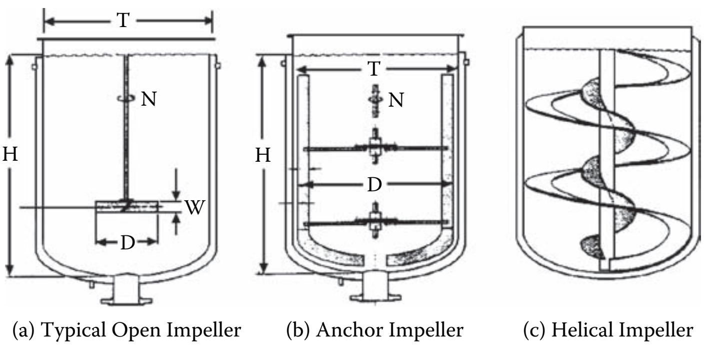

FIGURE 9.50 Types of mixing impellers for heat-transfer applications.

An agitated vessel may be operated in either a continuous, batch, or semi-batch mode. In continuous operations, the typical heat-transfer requirement is to maintain a set process temperature by either adding or removing heat, depending on the chemical reaction involved. In batch operations, the heat-transfer process can have a number of different functions at different stages of the operation. Examples include the:

- Establishment of initial reaction temperature
- Maintenance of a set temperature
- Cooling of a product to a final desired temperature

The heat-transfer coefficient on both the "process" (agitated) and "service" (jacket) side may change dramatically during the course of processing, usually as a result of physical property or chemical changes.

Heat transfer seldom dictates equipment design. Process mixing requirements dictate design for the majority of agitated tank systems. Heat transfer is then a necessary adjunct, and the design objective is to accommodate a suitable means of matching the heat-transfer requirements to other process requirements.

Surface area for process heat transfer is made available by means of jackets, coils, baffles, and plates. When these fail to adequately meet process requirements, pumps and external heat exchangers are commonly used. Under certain conditions, condensers can be designed to remove process heat through the refluxing of a solvent or reactant.

9.11.2 Important Heat-Transfer Considerations

The following are some of the key issues to consider for designing a new system or to troubleshoot an existing one:

Process characteristics:
- Is the process continuous, semi-batch, or batch?
- Is an exothermic reaction involved?
- Is the heat of reaction known? What is the magnitude of heat release?
- Is there a wall temperature limitation? (reactivity, purity, fouling)
- Are internal surface area devices acceptable?
- Is temperature control important?
- Can desirable heat-transfer rates be maintained by controlling the reaction?
- Is corrosivity a problem?
- Are gases evolved from processing? If so, can gas release rates be controlled?

Batch operations:
- What is the minimum level that will be maintained and its level relative to the agitator?
- Is heat-transfer surface area available at all stages of processing?
- How do the physical properties change during the course of processing?

Fouling:
- Can any undesirable reactions occur in the vapor space of the vessel that may deposit on the upper surface?
- Will controlling the wall temperatures prevent fouling?
- Will the process foul the surface of the vessel or any internals?
- Are solids formed upon cooling or in the course of reaction?
- Is the design suitable for cleaning?

Safety:
- Is the heat release due to mixing?

- Is there a choice of heat-transfer media?
- Can temporary power loss create a sudden heat release when power is restored?

9.11.3 Fundamentals of Heat Transfer in Agitated Vessels

Equation (9.82) is the basic heat-transfer equation for heat transfer between two fluids separated by a wall:

$$Q = U_o A \cdot \Delta T \tag{9.82}$$

where Q = heat flow, kW (Btu/h); U_O = overall heat-transfer coefficient, kW/m^2·°K (Btu/h·ft^2·°F); A = area for heat transfer, m^2 (ft^2); and *ÆT* = temperature driving force, °K (°F).

The discussion now turns to the individual resistances comprising U_O and how it is affected by impeller selection and surface area. The overall heat-transfer coefficient for a jacketed vessel can be obtained from the individual resistances by use of Equation (9.83):

$$\frac{1}{U_i} = \frac{1}{h_i} + \frac{x}{k} + \frac{A_i}{h_j A_j} + r_j + r_i \tag{9.83}$$

where h_i = heat-transfer film coefficient, kW/m^2·°K (Btu/h·ft^2·°F); x = wall thickness, m (ft); k = thermal conductivity of wall W/m·°K (Btu·ft/h·ft^2·°F); A_i = reference area, m^2 (ft^2); A_j = area inside of jacket; r_i = fouling resistance, reference side (inside surface of vessel); r_j = fouling resistance, inside jacket; and U_i = overall heat-transfer coefficient, W/m^2·°K (Btu/h·ft^2·°F).

These resistances are illustrated in Figure 9.51. The subscript "i" in Equation (9.83) refers to the coefficient at the inside wall of the mixing vessel; the subscript "j" refers to the jacket side. The other terms are the wall resistance and the fouling resistances for either side. A similar equation can be written for an internal coil or other device. In situations where both a jacket and an internal device are used, the overall coefficients for each type of surface should be calculated separately, and the two Q's should be added to obtain the overall heat-transfer capability.

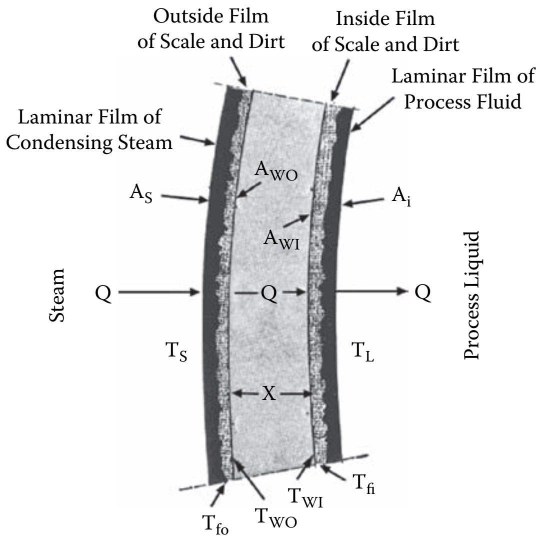

FIGURE 9.51 Heat-transfer resistances.

9.11.4 Heat-Transfer Surfaces and Effective Area

Jackets, internal helical pipe coils, tube baffles, and plate coil baffles are used to provide heat-transfer surface area. The only surface area effective for heat transfer is that portion that is wetted by both service and process fluids. The effective heat-transfer area for some items may be determined as follows:

- Use the total wetted area for plain or spirally baffled jackets.
- The area between the half-pipes is not totally effective for heat transfer when using half-pipe coil jackets, usually fabricated from 2-, 3-, or 4-in. pipes with typical 3/4-in. spacing.
- The total outside wetted area is effective for internal helical coils:

$$A_{co} = \pi\, d_{co} H_c n \left(\pi\, d_c^{\,2} + n^{-2}\right)^{0.6} \tag{9.84}$$

where n = number of coil turns per foot of coil height = 1/p; H_C = total height of coil, ft; and d_C = centerline diameter of coil helix, ft.

9.11.5 Jackets and Other Applied Devices

Jackets form what amounts to a double wall on the mixing vessel. Several varieties are possible, as illustrated in Figure 9.52. The plain jacket is the simplest construction and therefore the lowest initial cost. It is suitable for condensing heating fluids such as steam, but results in very poor performance using sensible heat-transfer fluids. Large passage areas limit the ability to create good wall velocities.

Installation of "agitating" nozzles is recommended if sensible liquid heating or cooling is to be used with plain jackets. Nozzles produce liquid jets directing the inlet jacket fluid in a spiral fashion into the jacket. This increases the effective velocity and turbulence level. Vendors have information dealing with their performance and installation.

Spiral-baffled jacket: The spiral-plate baffle consists of a spiral strip welded edgewise to the shell. This forms a channel that raises the velocity next to the wall. The largest drawback to this baffle is that there will inherently be some clearance between the edge of the baffle and the tank wall, allowing fluids to bypass the spiral passageway.

Half-pipe jacket: This type of jacket consists of a half-pipe section welded to the vessel wall. This construction is quite good if high jacket pressures are required, but it is also an expensive method, because each course requires two long welds along each edge of the cut pipe. It is suitable for sensible heating/cooling but not for condensing/vaporizing fluids. Heat-transfer predictability is well defined, since the geometry is known and no bypassing is possible.

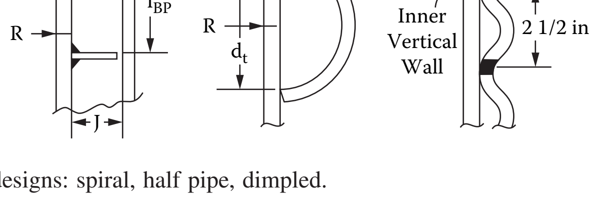

FIGURE 9.52 Jacket designs: spiral, half pipe, dimpled.

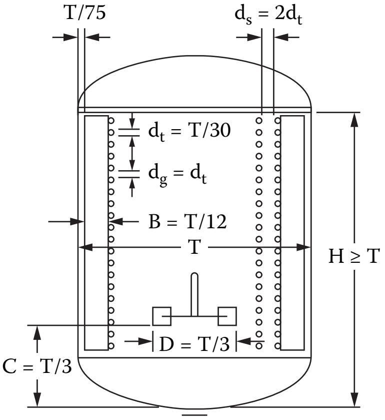

FIGURE 9.53 Recommended geometry for internal pipe coils.

Dimpled jacket: A dimpled jacket consists of an outer shell having regular indentations of the shell material. These "dimples" are intended to promote turbulence by creating high local velocities at the dimple. Heat-transfer information concerning dimple-jacketed vessels are proprietary to the fabricators; there is a little information in the open literature [77].

Other devices: There are other special devices such as clamp-on plate coils, weld-on plate coils, etc., that are often used when an unjacketed vessel needs limited heat-transfer capability.

Internal devices: Internal devices comprise coiled pipe (or tubing), baffles of various types that are also heat-transfer devices, and sometimes even the agitator. All internals interfere with the flow patterns within the vessel and likely lead to the formation of stagnant regions. Consequently, the use of internal devices needs to be carefully considered from the standpoint of harm to good mixing. If fouling is a problem (known or suspected), any internals should be avoided. Internal devices, of any type, increase mechanical complexity and maintenance. It is recommended that internal connections be welded, not flanged, to minimize maintenance.

9.11.6 Internal Pipe Coils

Internal pipe coils consist of one to three helical (concentric) coils of pipe located inside the mixing vessel for sensible heating/cooling. The effectiveness of these coils is directly related to the flow patterns generated by the agitator. Considerable area can be added in this manner, and if all the heat-transfer capability must be provided within the mixing vessel itself, this is an effective means of doing so. Potential difficulties include cleaning, mechanical integrity (the coil must be supported), and installation (both weight and access). The presence of coils and their support structures *always detracts* from mixing performance. The recommended geometry for the use of coils is shown in Figure 9.53.

9.11.7 Other Internal Devices

Tubes and flat hollow plates can be formed into assemblies that act as baffles for the mixing application. Various designs include linking surface areas by "U" bends, often outside the vessel.

9.11.8 External Auxiliary Devices

An external auxiliary heat-transfer device is usually one of the following:

- A standard condenser
- A reflux (or knock-back) condenser
- A sensible heat exchanger through which the vessel contents are circulated

These external auxiliary devices are only required when the heat-transfer requirements cannot be met by use of jackets or internal devices.

9.11.9 Process-Side Heat-Transfer Correlations

Heat-transfer coefficients on the agitated side are determined by the same principles as for any other heat-transfer process. Correlations have been developed for each of the major impeller types. These are all basically of the same form, but differ only in the pre-proportionality constant and values of the exponents.

The general form of the correlating equation is

$$Nu = \frac{h_o T}{k} = K \cdot \mathrm{Re}^a \cdot \mathrm{Pr}^b \cdot \left(\frac{\mu}{\mu_w}\right)^c \tag{9.85}$$

where K accounts for geometry variations.

Note that Equation (9.85) is basically the same general form as the familiar Dittus-Boelter equation for heat transfer in tubes. The basic heat-transfer mechanism is identical. It is dependent on the flow of fluid next to the heat-transfer surfaces, whether these are the vessel walls or some internals. Differences in the correlations are therefore mainly due to the differences in flow characteristics generated by the different impellers relative to the surface under consideration. This is reflected in the value of K.

These correlations are all of an overall nature and do not take variation in flow due to the flow pattern into account, nor do they consider any local variation in fluid bulk temperature in the vessel. If these things are critical to the application being considered, either experimentation, CFD modeling, or consultation with a vendor will be required.

The process-side heat-transfer coefficient (for flat-blade turbines) for heat transfer to a jacket is based on the work of Brooks [78]. The recommended correlation is

$$Nu = \frac{h_o T}{k} = 0.74 \cdot \mathrm{Re}^{0.66} \cdot \mathrm{Pr}^{0.33} \cdot \left(\frac{\mu}{\mu_w}\right)^{0.14} \tag{9.86}$$

where Re = impeller Reynolds number; h_o = heat-transfer coefficient at the vessel wall; k = thermal conductivity of the process fluid, W/m·°K (Btu/h·ft·°F); T = tank diameter, m (ft); Nu = Nusseldt number; Pr = Prandtl number; Re = Reynolds number; μ = viscosity of the process fluid, Pa·s (cP); and μ_W = viscosity of the process fluid at the vessel wall, Pa·s (cP).

Other authors have extended the basic correlations to include more details of the impeller geometry, such as blade width, pitch, and number of blades. As long as the process is in the turbulent regime, most of these geometrical variables have little impact on heat transfer, and their use is not recommended until details of an agitation system are selected or in place.

Ackley [79] suggests use of Equation (9.87) for unbaffled retreat-curve (blade) impellers typically used in glass-lined vessels:

$$Nu = \frac{h_o T}{k} = 0.68 \cdot \mathrm{Re}^{0.67} \cdot \mathrm{Pr}^{0.33} \cdot \left(\frac{\mu}{\mu_w}\right)^{0.14} \tag{9.87}$$

Equation (9.88) is to be used when the vessel is baffled [79]:

$$Nu = \frac{h_o T}{k} = 0.33 \cdot \text{Re}^{0.67} \cdot \text{Pr}^{0.33} \cdot \left(\frac{\mu}{\mu_w}\right)^{0.14} \tag{9.88}$$

For proximity impellers, such as the helical ribbon, for Re < 130, Blazinski [80] gives:

$$Nu = \frac{hD_T}{k} = 0.248 \cdot \text{Re}^{0.5} \cdot \text{Pr}^{0.33} \cdot \left(\frac{\mu}{\mu_w}\right)^{0.14} \cdot \left(\frac{e}{D}\right)^{-0.22} \left(\frac{i}{D}\right)^{-0.28} \tag{9.89}$$

where e = clearance = $(D_T - D)/2$, m (ft); i = ribbon pitch, m (ft); D = tank diameter, m (ft); D_T = vessel diameter, m (ft).

Oldshue [81] gives Equation (9.90) for the heat-transfer coefficient on the outside coils:

$$\frac{h_{coil} D}{k} = 0.17 \cdot \text{Re}^{0.67} \cdot \text{Pr}^{0.37} \left(\frac{D}{T}\right)^{0.1} \cdot \left(\frac{d}{T}\right)^{0.5} \cdot \left(\frac{\mu}{\mu_s}\right)^{m} \tag{9.90}$$

where h_O = heat-transfer coefficient for outside of coil; d = tube diameter making up helix, m (ft); and D = impeller diameter, m (ft).

This correlation is valid for tube spacing between two and four tube diameters and for all "practical" tube diameters.

9.11.10 Service-Side Heat-Transfer Correlations

A conservative estimate for the condensing-steam coefficient used in plain jackets is 5.678 kW/m^2·°K (1000 Btu/h·ft^2·°F). Any organic fluid will have a lower value due mainly to its lower thermal conductivity.

Bondi [82] proposes the following equations for sensible fluid in plain jacket with no agitating nozzles.

Turbulent flow conditions where Re > 10,000,

$$\frac{h_j D_e}{k} = 0.027 \cdot \text{Re}^{0.8} \cdot \text{Pr}^{0.33} \cdot \left(\frac{\mu}{\mu_w}\right)^{0.14} \tag{9.91}$$

In this case, the Reynolds number is defined as

$$\text{Re} = D_e V \rho / \mu$$

where all properties pertain to the jacket fluid

Laminar flow conditions where Re ≤ 10,000,

$$\frac{h_j D_e}{k} = 1.86 \cdot \left[\text{Re} \cdot \text{Pr} \cdot \frac{D_e}{L}\right]^{0.33} \cdot \left(\frac{\mu}{\mu_w}\right)^{0.14} \tag{9.92}$$

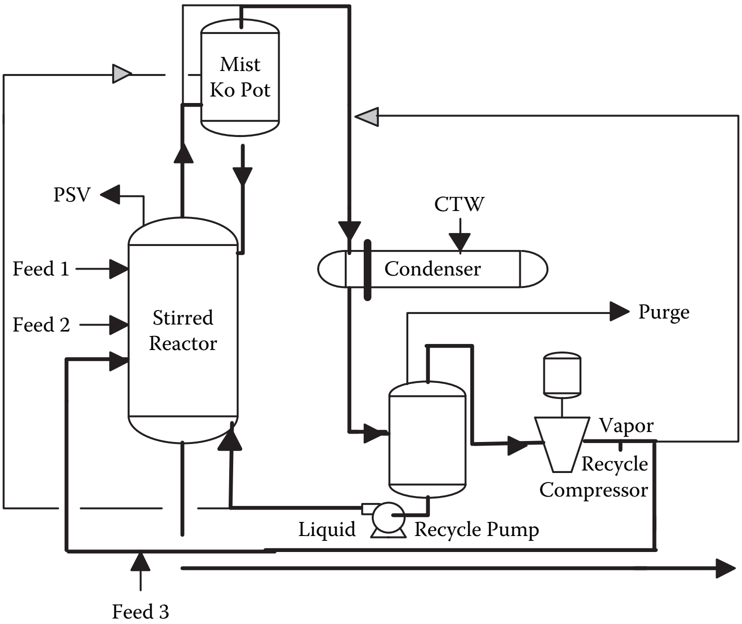

FIGURE 9.54 Reactor system schematic.

These equations require the use of the equivalent diameter, D_e, of the jacket. This is calculated by

$$D_e = \left(\frac{D_{jo}^2 - D_{ji}^2}{D_{ji}} \right)$$

and flow area A_x, by

$$A_x = \pi \cdot \left(\frac{D_{jo}^2 - D_{ji}^2}{4} \right)$$

The flow area is used to calculate the velocity, V, in the Reynolds number term.

Example 9.8

A reactor is operated according to the system schematic shown in Figure 9.54. Boiling of the carrier that is condensed out of the vapor provides most cooling, and both condensate and uncondensed gas are recycled to the reactor. This reactor has a dimpled jacket. Calculate the heat duty of the jacket under the given conditions.

The following system engineering data are provided.

Reactor: 12-ft diameter, 24-ft straight side height, 12-ft liquid level
Impeller: 5-ft diameter flat-blade turbine @ 37 rpm
Production: 10,000 lb/h
Heat of reaction: 1500 Btu/lb
Operating temp.: 85°C (176°F)

Physical properties of vessel contents:
Density: 37.58 lb/ft^3
Viscosity: 0.192 cP
Thermal conductivity: 0.0637 Btu/h·ft°F
Specific heat: 0.6197 Btu/lb°F
Coolant:
Water @ 31°C
Velocity = 2 ft/s
Density: 62.11 lb/ft^3
Viscosity: 0.78 cP
Thermal conductivity: 0.3564 Btu/h·ft·°F
Specific heat: 1.0 Btu/lb·°F

Solution

1. Calculate vessel-side Reynolds number:

$$\text{Re} = D^2N\rho/\mu = 5^2\ (37/60)\ 37.58\ (10^4)/6.72\ (0.192) = 4{,}490{,}314$$

2. Calculate the vessel-side heat-transfer coefficient using Equation (9.86):

$$h_o = (0.0637/12)0.74(4{,}490{,}314)^{0.66}(4.522)^{0.33}(1)^{0.14} = 158.8\ \text{Btu/h·ft}^2\text{·°F}$$

3. Calculate the coolant-side from Equation (9.91) using $D_e = 0.66$ in., $A_x = 1.98$ in.^{2} per foot of circumference = 1.98 πD = 0.518 ft^2:

$$F = \nu A_x = 1.037\ \text{ft}^3/\text{s} = 231{,}808\ \text{lb/h}$$

$$h_j = 579\ \text{Btu/h·ft}^2\text{·°F}$$

4. Calculate the overall coefficient:

$$1/U = 1/h_j + 1/h_i + x/(12)10.0 = 597^{-1} + 158.8^{-1} + 0.5/(12)10.0 = 0.012$$

$$U = 82\ \text{Btu/h·ft}^2\text{·°F}$$

5. Estimate the Q for the jacket: assume the temperature difference is 85 – 31°C and consider only the straight side area:

$$Q = UA\Delta T = 82\ (452)\ 97.2 = 3.6\ \text{MM Btu/h}$$

Note that this is only about 24% of the total heat to be removed of 15 MM Btu/h!

10.1 INTRODUCTION

Liquid-liquid extraction (LLE) is widely used in chemical, petroleum refinery, pharmaceutical, mining, and the nuclear industries to separate chemicals in liquid mixtures [1]. Solid-liquid extraction (SLE) is also of importance and is related in many ways. LLE involves two relatively immiscible liquids and several operational events, as summarized next.

1. The two liquids are dispersed in each other. One liquid is dispersed as liquid droplets, and the other forms a more or less continuous liquid phase. At least one of the liquids is a mixture of two or more chemical species, and the objective is to separate it.
2. While the two phases are dispersed, one or more of the chemical species (the solute) transfers across the liquid-liquid interface into the other phase. The phase into which the desired transfer occurs is designated as the *extract*; the phase from which the transfer occurs is designated as the *raffinate*. The amount and rate of mass transfer are of major importance, as discussed below.
3. Later the extract and raffinate are separated, often by gravity separation.

4. Since the amount of transfer (or separation) in a single stage (or single contact) is generally inadequate, multiple contacts are often employed in industrial processes. Generally, countercurrent flow of the two liquids is employed in the overall separation process. With multiple stages, most of the desired component often can be extracted.
5. Frequently, the extract is processed to recover the solute in a more or less pure form. This latter step is sometimes one of the following: distillation, evaporation, freeze drying, crystallization or precipitation, and filtration.

When solvent extraction is employed, two largely immiscible liquids (e.g., an aqueous feed and an organic solvent) are mixed together, allowed to settle, and then separated. During these steps, one or more species that are initially dissolved in the feed liquid transfer to the other liquid phase to form an extract. The feed liquid residual, or raffinate, is thus partly depleted of the solutes, and the original solvent becomes enriched in them. In this way, LLE can be used to separate and purify solutes.

Thermodynamic equilibrium between the two liquids determines the direction of mass transfer and the theoretical amount of compound(s) transferred in a given step. The rate of transfer depends on the level of agitation provided to the dispersion and the interfacial areas between the phases. After the extraction step is completed, separation of phases is (hopefully) rapid. As already indicated, the separated phases are often then sent countercurrent to another extraction unit [2]. Countercurrent cascades of mixers and settlers generally provide the most efficient use of solvent.

Two liquid phases may be contacted in different ways to achieve separation. In the laboratory, the simplest example of LLE involves the use of a separatory funnel where a feed mixture, perhaps an aqueous phase from a reactor, is contacted with several washes of solvent (say, diethyl ether) to extract a solute. If the same aqueous phase is contacted repeatedly with fresh amounts of extracting solvent, such a process is said to be *crosscurrent*.

Industrial applications usually are based on the most efficient methods that involve the countercurrent flow of two liquids across multiple stages. A variety of mechanical devices are available that can be used to achieve such mixing and separate the resulting extract and raffinate and so achieve the desire separation. Once the extraction is complete, almost always both the extract and raffinate need to be treated to recover solvent residuals as well as the desired products.

Liquid-liquid extraction is often advantageous if the solute is heat sensitive and can be recovered by LLE at ambient conditions. It is also advantageous whenever direct separation (e.g., distillation) is too expensive. LLE tends to be advantageous whenever the solvent has a high affinity for the solute and is highly selective for the solute, and the solute is present in very low concentrations and cannot be easily removed by direct separation techniques. Under the right conditions, it can provide high recovery and concentration factors to enable the economic purification of resource materials even when they are found in dilute forms. It is often used to reduce energy consumption by enabling preconcentration of a resource with minimal energy expenditures.

The disadvantages of solvent extraction usually revolve around the solvent cost. Since high solvent losses can easily make an extraction process uneconomical, considerable effort is usually expended to find solvents that are economical and can be easily recovered and recycled.

There are usually many candidate solvents for any particular application. Important factors to consider are (1) the affinity of the solute for the solvent (i.e., its distribution coefficient should be large); (2) the affinity of other species in the mixture for the solvent (i.e., their distribution coefficients should be small); (3) solvent safety considerations (e.g., flammability and toxicity); (4) solvent handling properties such as density, viscosity, and vapor pressure; (5) solvent solubility in the raffinate phase (high solubilities may translate into high solvent losses unless steps are taken to prevent such losses); and (6) solvent cost. In addition, liquid-liquid interfacial tension affects the interfacial area and the rate of mass transfer between the phases.

Safety and health are also often issues for extraction, particularly whenever the potential of fire from using highly flammable solvents is high. On the other hand, LLE is favored in the nuclear

industry to separate highly radioactive mixtures because of its relative simplicity and ease to operate safely under remote conditions [3].

Solvent toxicity can also be an issue, but less so as newer green* solvents are developed to replace traditional solvents that are unacceptable because of environmental concerns. There is, for example, growing interest in the use of ionic liquids in LLE, a relatively new and unexplored class of potential solvents.

On the other hand, it is often advantageous to use solvents that are already on a plant site rather than to introduce a new solvent. Such solvents are usually less expensive. Existing storage equipment can often be used in the former case, but introducing a new solvent may require additional storage and handling equipment, with additional costs. Using an existing solvent rather than a new one may avoid new cross-contamination problems that must be addressed with respect to plant safety, operability, and product quality. Solvent extraction can be very advantageous for recovering a high-quality product. On the other hand, its complexity, usually greater than separations by direct methods, is a disadvantage.

LLE may be more complicated to operate than a direct separation system (e.g., distillation), since LLE involves more processing steps (e.g., extraction, solute removal from the extract, solvent recycle, and solvent recovery from the raffinate). The solvent cost, and the additional steps that are required to recycle the solvent, increase the cost of LLE and can make it unattractive.

The complexity of the solvent recovery operation depends largely on the mutual solubility of the two liquid phases. Cleanup is generally simpler and more economical if the two liquid phases are nearly immiscible, but more expensive and complex unit operations (e.g., extractive distillation) may be required if the two phases are partly miscible. Commonly, aqueous raffinates are steam stripped to recover and recycle the solvent.

Solvent recycle from the extract is often more complex than solvent recycle from the raffinate. In the case of metal extraction, the metal solute is typically removed by stripping (washing) the extract to transfer it into a second aqueous phase for subsequent metal recovery. This aqueous phase containing the metal may then be steam stripped similarly to the raffinate from the original extraction step. In the case of organics extraction, the extract is often treated by extractive distillation to recover both the products and the solvent for recycle.

Solvent extraction is used extensively to recover chemicals from natural products. Solvents are used to extract and concentrate natural oils and products in the bioprocessing industries (nutraceutical, food, pharmaceutical, feed, cosmetic, biotechnology) in quantities from grams to metric tons. Biotechnology applications include the recovery of primary and secondary metabolites [4]. Extraction is used to recover vegetable oils and food products. It is used to process a variety of materials including groundnut, mustard seed, soybean, palm kernal, sunflower, rice bran, copra, cottonseed, and minor oil seeds like neem, mahua, watermelon seed, castor seed, and so on.

It is used in the mining industry to recover metals such as copper and nickel. Parasite plants, based on solvent extraction, are used in the phosphate industry to recover by-product uranium from crude phosphoric acid. The uranium concentration in phosphoric acid is very low but, because of the high volume of phosphoric acid that is produced to meet agricultural needs, considerable uranium can be recovered using solvent extraction. In the nuclear industry [5], solvent extraction is used to purify uranium and plutonium [using the plutonium and uranium recovery by extraction (PUREX) process], zirconium from hafnium, and for many other applications. It is also used in environmental applications to clean soil, say, to remove polychlorinated biphenyls (PCBs), dioxins, pesticides, and other hazardous pollutants.

Solvent extraction is widely used in laboratory applications on a very small scale but also on much larger industrial scale. In fact, the variety of materials, both organic and inorganic, that are processed using some form of solvent extraction is staggering. Moreover, the methods in which solvent extraction is applied to vastly different recovery and cleaning operations continues to grow

* A "green" process is one that doesn't use toxic or otherwise environmentally unfriendly chemicals.

substantially as new, environmentally acceptable techniques are developed and applied to solve separation problems.

Supercritical or near-critical fluids can be used both for extraction and chromatography. Many chemicals, primarily organic species, can be separated and analyzed using this approach [6], which is particularly useful in the food industry. Substances that are useful as supercritical fluids include carbon dioxide, water, ethane, ethene, propane, xenon, ammonia, nitrous oxide, and a fluoroform. Carbon dioxide is most commonly used, typically at a pressure near 100 bar. The required operating pressure ranges from about 43 bar for propane to 221 bar for water. Sometimes a solvent modifier is added (also called an *entrainer* or *cosolvent*), particularly when carbon dioxide is used.

On a laboratory scale, supercritical fluids may be contacted with a substrate on a once-through basis. Typically, the pressurized fluid is heated and passed through a chamber containing a solid or liquid sample. The desired solute selectively dissolves in the pressurized fluid and is transported out of the chamber and through a throttle into a container where the pressurized fluid evaporates at atmospheric pressure, leaving a solute residue in the container.

Small-scale supercritical extractions may be either dynamic or static. If the fluid is pumped through the sample chamber continuously, then the method is dynamic. If the sample container is filled batchwise with pressurized fluid, then the method is static. In the latter case, the sample container is charged, equilibrated statically, and then discharged through a throttle to collect the residue as before. In either case, the pressurized fluid or solvent is not recycled, and this feature limits the applicability to industrial use, because solvent costs, even with recycle, often determine whether or not extraction is economical.

More important solvent extraction references include the *Handbook of Solvent Extraction*, edited by Lo, Baird, and Hanson [7]. International Solvent Extraction Conferences (ISECs) have been held, and the proceedings, usually two or three volumes from each conference, provide considerable information, particularly of ongoing studies. Akell and King [8] have edited a volume of selected papers taken from ISEC '83, including papers of significant chemical engineering content and which focus on developments in solvent extraction equipment design. Schügerl [4] has written a nomograph on the use of LLE in biotechnology, primarily to recover metabolites. Kulov [9] has edited a book focusing on the kinetics of LLE. This last book also includes chapters on gas-liquid kinetics, which is appropriate since many of our kinetic models for LLE are derived from analogy with gaseous diffusion. Blumberg [10] also provides a book on LLE that may prove helpful. Marcus and Kertes [11] and Marcus, Kertes, and Yanir [12] provide extensive data on extraction systems that are based on solvation and ion exchange reactions.

10.2 DISPERSION, MASS TRANSFER, AND COALESCENCE

Quantitative and (hopefully, at least) qualitative considerations are helpful in characterizing a liquid-liquid system for a potential extraction application. Batch shakeout tests are frequently the easiest way to determine basic feasibility by simply measuring the primary and secondary break times and by analyses to measure the compositions of the equilibrated phases. Such tests are readily conducted by mixing small volumes of each phase in a vial, which is then vigorously agitated and placed on a lab bench to settle. The resulting behavior of the liquid-liquid mixture depends on physical properties and system characteristics. The greater the density difference and interfacial tension between the two liquid phases, for example, the more rapidly the phases tend to separate. More viscous systems separate more slowly.

The primary break time is that length of time required to form a clearly defined interface between the two phases, although both phases may still remain hazy. The physical properties of the liquid-liquid system and the vigor of mixing are of critical importance and usually provide qualitative information that permits rapid screening of large numbers of solvents with minimal effort. The resulting primary break time should be on the order of 1 or 2 min; Treybal [13] suggests

this time could be as great as 5 to 10 min. It is helpful if a liquid-liquid system exhibits a primary break time less than 1 min.

As a general rule, greater mass transfer between two phases tends to decrease the rate at which they separate, so longer primary break times may indicate that more mass transfer occurred between the two phases during mixing. On the other hand, liquid-liquid mixtures containing surfactants, even in very small concentrations (e.g., ppm), may form stable emulsions that do not separate at all. In some instances, the vigor of agitation, especially when surfactants are present, dramatically affects the rate of phase separation. Highly energetic mixing, resulting in very small droplets, may form stable emulsions, while less energetic mixing, resulting in larger droplet size distributions, may slowly separate into two distinct phases. The addition of ionic salts may accelerate phase separations.

A primary break time of less than about 30 sec, resulting in two clear phases, probably indicates that relatively little mass transfer has occurred. A primary break time greater than 10 min may be impractical to work with but could be interesting if significant mass transfer has occurred. In the latter case, it may be possible to accelerate the break time, for example, by adjusting the mixture temperature or by dissolving an inextractable salt in the aqueous phase.

The presence of trace concentrations of surfactant impurities (e.g., ppm concentrations of silicates) can complicate matters by yielding stable emulsions, especially if the shakeout test is based on vigorous agitation. When stable emulsions result from vigorous agitation in a bench test, then a contactor that generates a very small drop size distribution (e.g., a high-speed centrifugal contactor) may not be a good choice. On the other hand, the desired separation may occur if the agitation is more gentle and yields only a larger droplet size distribution (e.g., as results from a reciprocating or sieve-plate column). In some cases, special techniques may be required to break an emulsion, such as passing it upflow though a fiber bed that accelerates coalescence of the dispersed phase. If very vigorous agitation yields emulsions with much larger primary break times than for mixtures that are equilibrated using only gentle agitation (but still sufficient to form a liquid-liquid dispersion), then a contacting device that results in larger droplet size distributions is indicated.

The secondary break time is the time needed for the quiescent liquid-liquid mixture to achieve clarity in each of the bulk phases after rapid agitation. After initially breaking, the two liquid phases are usually hazy, especially if significant mass transfer has occurred. This haze is from very small droplets dispersed in each phase. Because of their small size, they move more slowly to the interface. After settling overnight, the two phases may appear clear when examined in normal room lighting, but examination of such liquid phases in a darkened room with a laser beam will likely reveal the continuing presence of droplets in both phases, even after many weeks of quiescent equilibration.

In some cases, the secondary haze can be removed by filtering the phase and allowing the droplets to coalesce. Centrifugation may be employed but is usually more expensive on an industrial scale. Often, some phase clarification is required.

10.3 REACTIVE SYSTEMS

Solvent extraction may be used to separate both organic and inorganic species. Since the affinity of a species for a particular phase is related to its similarity to that phase, oily species are attracted to oily phases and are said to be lipophilic (i.e., oil seeking). Species that are not oily in nature are not attracted to oily phases and are said to by lipophobic (i.e., oil avoiding). Species that are lipophobic are often hydrophilic (i.e., water seeking), and vice versa (i.e., hydrophobic species are often lipophilic).

Sometimes chemical reaction or solvation chemistry is exploited by the extraction process. Often, coordination reactions render a lipophobic species lipophilic by complexation with suitable organic ligands, which cluster around the lipophobic moiety in the complex and enable it to transfer into the solvent phase. The oily organic or solvent phase in such instances usually consists of an

inert diluent and an active extractant that reacts with the inorganic species. The extractant solvates the solutes so that they transfer into the organic layer. Chemical reactions may be characterized either as solvation reactions or those involving ion exchange. Solute mass transfer in this instance is from the aqueous to the oily solvent phase.

Similarly, chemical reactions may be used to convert a lipophilic chemical into a hydrophilic, water-seeking species. Solute mass transfer then occurs from the oily solvent phase into the aqueous phase. Pure fluids or mixtures of species that form hydrogen bonds or contain polar moieties are usually highly nonideal. In pure fluids, strong attractive interactions between like molecules may cause molecular aggregation through dipole-dipole and other interactions. In mixtures, specific interactions can occur between molecules of the same species (self-association) or between molecules of different species (solvation).

10.3.1 Lignin Extraction

Relatively large, complex lignin molecules can be extracted by complexation, solvation, and coordination with the correct solvents. The black liquor produced by the Kraft pulping process is an alkaline mixture of lignin-bearing micelles. It is essentially opaque and darkly colored, hence its name. When acidified with dilute sulfuric or hydrochloric acid, the micelles are acidified, and the oily lignin is liberated. It floats to the top of the aqueous phase to form an interfacial precipitate.

A solvent mixture can form an effective solvation system for lignin obtained from black liquor, whereas individual components in the solvent mix are ineffective. Acetone alone is miscible with black liquor, so it cannot be used as a solvent by itself, since it doesn't form a second liquid phase when mixed with water. The solvent 2-ethylhexanol is immiscible with water but does not extract lignin from acidified black liquor. On the other hand, a one-to-one by volume mixture of 2-ethylhexanol and acetone extracts much of the acidified lignin and about half of the total dissolved solids. The resulting aqueous phase is water-white after acidification and extraction by this solvent mixture. The resulting organic layer is ruby red. Presumably, acetone displaces sufficient waters of hydration around lignin to enable the resulting acetone-lignin complex to coordinate with 2-ethylhexanol and transfer into the organic layer. This system dramatically illustrates the power of extraction by solvation and coordination.

10.3.2 Simplified TBP Reaction Models

As used in the tri-*n*-butyl phosphate (TBP), or PUREX, process to recover uranium (U) and plutonium (Pu), the solvent is typically a blend of about 30 vol% TBP and 70 vol% of an aliphatic diluent, say C-12 to C-15 branched paraffins. Spent nuclear fuel[5] is dissolved in nitric acid and then contacted with this TBP solvent. Actinide elements, primarily uranium and plutonium, are coextracted into the organic layer by coordination and solvation with TBP. The extraction of uranium, for example, is thought to occur by the following reaction [14–21]:

$$
\begin{gathered}
UO_2^{2+} \cdot 6H_2O(aq) + 2(NO_3)_2(aq) + 2TBP(o) \rightleftharpoons \\
UO_2(NO_3)_2 \cdot 2TBP(o) + 6H_2O(aq)
\end{gathered}
\tag{10.1}
$$

indicating that uranyl nitrate hexahydrate in the aqueous phase coordinates with two molecules of TBP in the organic phase to form an anhydrous uranyl nitrate solvate with TBP in the organic phase and leaves six waters of hydration behind in the aqueous phase when it transfers.

The extraction of water by TBP requires a more rigorous model, but the extraction of U and HNO_3 by TBP can be modeled fairly accurately using simplified models based on equilibrium constants and the law of mass action. At least one reaction must be assumed for each species that extracts. In the case of uranium and nitric acid, the following simplified reactions [5] can be assumed:

$$UO_2^{2+}(aq) + 2NO_3^-(aq) + 2TBP(o) \rightleftharpoons UO_2(NO_3)_2 \cdot 2TBP(o) \tag{10.2}$$

$$H^+(aq) + NO_3^-(aq) + TBP(o) \rightleftharpoons HNO_3 \cdot TBP(o) \tag{10.3}$$

A simplified extraction model assumes that both liquids are ideal mixtures and neglects any changes in density. Equilibrium concentrations are then estimated by solving the equation set,

$$[UO_2^{2+}(aq)][NO_3^-(aq)]^2[TBP_f(o)]^2 = (1/K_U)[UO_2(NO_3)_2 \cdot 2TBP(o)] \tag{10.4}$$

$$[H^+(aq)][NO_3^-(aq)][TBP_f(o)] = (1/K_H)[HNO_3 \cdot TBP(o)] \tag{10.5}$$

along with the TBP material balance,

$$2[UO_2(NO_3)_2 \cdot 2TBP)_2(o)] + [HNO_3 \cdot TBP(o)] + [TBP_f(o)] = [TBP_o(o)] \tag{10.6}$$

where all quantities in brackets are molar concentrations, $[TBP_o(o)]$ is the stoichiometric TBP concentration before any reaction occurs (about 1 M in 30 vol% TBP), and $[TBP_f(o)]$ is the molar concentration of uncomplexed or "free" TBP in the organic phase. Also K_U and K_H are the approximate equilibrium constants, about 5.5 M^{-4} and 0.145 M^{-2} at 23°C, respectively.

This model is an oversimplification in that it ignores water extraction, the TBP dimer, and TBP concentrations in the aqueous phase, and it assumes ideal mixtures. Nonetheless, it is reasonably effective in predicting extraction behavior, because it correctly models this system using mass action and competition for the uncomplexed or free TBP.

Using this model, the distribution coefficients for uranium is calculated as

$$D_U = \frac{[UO_2(NO_3)_2 \cdot 2TBP(o)]}{[UO_2^{2+}(aq)]} = K_U[NO_3^-(aq)]^2[TBP_f(o)]^2 \tag{10.7}$$

and, for nitric acid extraction,

$$D_H = \frac{[HNO_3 \cdot TBP(o)]}{[H^+(aq)]} = K_H[NO_3^-(aq)][TBP_f(o)] \tag{10.8}$$

Therefore, the uranium extraction has a second-order concentration dependence on the aqueous nitrate and the organic TBP concentrations. Nitric acid extraction has a first-order dependence on the aqueous nitrate and the organic TBP concentrations. The addition of an inextractable nitrate salt (e.g., $NaNO_3$) increases the extraction of both uranium and nitric acid. This model also predicts that uranium extraction is decreased by reducing the total nitrate concentration, which is the procedure for back-extracting uranium, by washing the extract with about 0.1 M nitric acid. Also, uranium and nitric acid compete for free TBP, as indicated in Equations (10.7) and (10.8).

10.3.3 TBP Solvent Cleanup

Reactions of the solvent with species in a feed mixture may also adversely affect an extraction system. Because of the radiation field from fission products in spent nuclear fuel, TBP reacts by radiolysis and acid hydrolysis to form dibutyl and monobutyl phosphoric acids (DBP and MBP, respectively). These latter species are also highly effective in extracting U and Pu, but at conditions

that are incompatible with normal PUREX operations. While TBP strips well in the presence of dilute acid, say around 0.01 M HNO_3 or less, DBP and MBP are acidic extractants that complex actinides strongly under these same conditions. For this reason, it becomes difficult, if not impossible, to remove actinides from TBP extract using a dilute acid scrub after MBP and DBP have grown into it as radiolysis products. To maintain solvent viability, it must first be treated with aqueous sodium carbonate wash to remove the degradation products, after which it can be recycled to extract more U and Pu.

Like lignin in alkaline NaOH, DBP and MBP can be removed from TBP solvent by forming micellar structures in alkaline sodium carbonate wash solutions. Actinides that were originally complexed by DBP and MBP in the TBP organic phase prior to carbonate wash are also transferred from the solvent and are loosely incorporated into the micellar structure of the wash, the aqueous raffinate.

Reactive solvent extraction can then be used to recover the actinides from such scrub solutions, not by extracting the actinides but rather by extracting the degradation products [22] into an alcohol solvent layer. Acidification of carbonate scrub washes with nitric acid destroys the carbonate and forms an interfacial crud that floats to the top of the aqueous phase. This crud is similar in behavior to that formed by acidified lignin.

If the same acidification is performed while the scrub solution is actively mixed with 2-ethylhexanol, then a different result is achieved. In this latter case, the degradation products extract into the organic phase rather than forming an interfacial crud. When properly extracted, the resulting aqueous phase is then suitable for recycle back to the PUREX process and subsequent actinide recovery using conventional PUREX chemistry. The 2-ethylhexanol containing the degradation products can be treated using caustic wash to remove them and to enable 2-ethylhexanol solvent recycle.

10.4 DISTRIBUTION COEFFICIENTS

The initial solvent and feed concentrations, the desired final concentrations, and equilibrium behavior determine the direction of mass transfer, the minimum solvent-to-feed ratio, and the minimum theoretical tray requirements. These theoretical trays (or stages) are analogous in many respects to theoretical plates of a distillation column, and absorption (or stripping) columns discussed by Fair in another chapter. For any particular solvent-to-feed ratio, equilibrium relationships and the operating line determine theoretical stage requirements.

Experimental equilibrium data are almost always essential. While theoretical models are available to predict such data, and are very helpful in preliminary design, pilot studies and scaleup should be based on confirmed experimental measurements. Many nomographs providing data are available. Wisniak and Tamir [23–26], Sorensen and Arlt [27–29], and Macedo and Rasmussen [30] provide useful compilations of LLE data. Tiegs [31] provides activity coefficient data at infinite dilution. Although these data are generally quite good, users are advised to at least spot check them for accuracy.

10.4.1 Thermodynamic Models

Thermodynamic models predict phase equilibrium. They can be based on solubility considerations alone or on chemical reactions between the two liquid phases.

10.4.2 Nonreactive Systems

When two liquid phases are thoroughly mixed in a closed system at constant temperature and pressure,* the mixture reaches thermodynamic equilibrium. At equilibrium, the fugacities of each species in each liquid phase are equal, and

* The pressure dependence is weak except near the critical point.

$$\hat{f}_i^{\alpha} = \hat{f}_i^{\beta} \tag{10.9}$$

At low to moderate pressures, $\hat{f}_i = \gamma_i x_i P_i^{sat}$ and

$$\gamma_i^{\alpha} x_i^{\alpha} P_i^{sat} = \gamma_i^{\beta} x_i^{\beta} P_i^{sat} \tag{10.10}$$

where $\hat{f}_i^{\alpha}$ and $\hat{f}_i^{\beta}$ are the fugacities of the ith species in the α and β phases, respectively; γ_i^{α} and γ_i^{β} are the activity coefficients in the respective phase; and x_i^{α} and x_i^{β} are the respective mole fractions. The variable P_i^{sat} is the pure component vapor pressure for the ith species. Since P_i^{sat} appears on both sides of Equation (10.10), it cancels out and, consequently, the pure component vapor pressure has no effect on liquid-liquid phase equilibria. The distribution coefficient, $K_{D_i}^{\alpha/\beta}$, is thus given by

$$K_{D_i}^{\alpha/\beta} = \frac{x_i^{\alpha}}{x_i^{\beta}} = \frac{\gamma_i^{\beta}}{\gamma_i^{\alpha}} \tag{10.11}$$

and is the basis for using thermodynamic models (e.g., UNIFAC [32, 33] or UNIQUAC*, as discussed elsewhere in this book) to estimate phase equilibrium behavior.

Activity coefficients of solutes at infinite dilution, γ_i^{∞}, are nearly constant (i.e., by Henry's law). By the Lewis and Randall rule, the activity coefficients of nearly pure solutes approach unity as $x_i^{\beta} \to 1.0$. In this case, Equation (10.11) is approximately

$$K_{D_i}^{\alpha/\beta} \approx \frac{x_i^{\alpha}}{1} \approx \frac{1}{\gamma_i^{\alpha}} \tag{10.12}$$

so the solubility limits x_i^{α} and x_i^{β} can be used to estimate γ_i^{∞} in either liquid phase.

While solvent volatility at ambient conditions has little effect on liquid-liquid equilibria [because the pure component vapor pressure cancels out in Equation (10.9)], solvent volatility nonetheless can be important in solvent regeneration, particularly if simple or extractive distillation is used to recycle solvent. These techniques are commonly used in solvent regeneration when extraction is applied to the recovery of many organic chemicals (e.g., acetic acid [34] recovery, which typically involves extractive distillation to regenerate the solvent and produce glacial acetic acid). Then the latent heat of vaporization is also an important consideration. Usually, however, it is desirable to have regeneration without solvent distillation, as that approach is often inefficient and expensive.

The distribution ratio, K_{D_i}, in Equation (10.11) is defined as a mole fraction ratio of the ith solute concentration in each liquid phase. Sometimes the distribution ratio, D_i, is defined as a ratio of solute mass fractions. In either case, the distribution ratio usually refers to equilibrium concentrations (either mass or mole fractions, but sometimes molar concentrations) in either phase.

Insofar as the distribution coefficient, K_{D_i} or D_i, is constant† and not a function of composition, then Nernst's law [35] is obeyed, especially for nonreactive, simple systems. The lack of a composition dependence may be taken as an indication that a particular system is not reactive. In such cases, the distribution of solute between the two phases is primarily determined by its solubility in each phase; hence Henry's law and/or the Lewis and Randall rule apply.

* Many simulators (e.g., HYSYS or Aspen Plus) incorporate these models, and many others and generally are readily available to users.

† Empirically, D_i is often more nearly constant than K_{D_i}.

10.4.3 Reactive Systems

As mentioned above, chemical theory has been applied in many instances to explain nonideal behavior [36, 37]. Dolezalek [38] was one of the first to assume that hydrogen bonding forms new chemical species in mixtures. Since then, chemical theory has been applied to a wide range of thermodynamic problems [39–42].

Using chemical theory, one must hypothesize reactions to form specific aggregates (i.e., the "true" species) by complexation. This is a disadvantage for at least two reasons. First, there are usually many plausible aggregates. Second, each hypothesized aggregate introduces additional adjustable parameters. Thus, significant experimental data are needed to fit model parameters and to distinguish between alternative equilibria. On the other hand, chemical models can be highly effective while still relatively simple (e.g., the TBP model above), and they can give insight into the nature of the solvent extraction process and the best ways to exploit chemical behavior.

Lattice theories [37] enable one to consider nonspecific physical forces (e.g., molecular dipole moments, induction effects, and London dispersion forces) and have been applied successfully to model nonideality in a wide range of mixtures. Guggenheim [43] was the first to develop a quasichemical theory using lattice models. Wilson [44], Renon and Prausnitz [45], Abrams and Prausnitz [46], and Vera et al. [47] modified it for nonrandom mixtures. Panayiotou and Vera [48, 49] developed expressions for estimating local surfaces and compositions based on quasichemical theory. Kumar et al. [50] revised the equations for multicomponent mixtures. Martinez [51] applied lattice theory to clustering and dissociation. Sayegh and Vera [52] provide a review.

Tri-*n*-butyl phosphate (TBP) is a reactive extractant that has been widely used in the processing of heavy metal ores and spent fuel elements [53]. It is often mixed with a diluent to improve solvent properties (e.g., to reduce viscosity or to control its extraction power). Such diluents include paraffins such as Amsco 125-82 and *n*-heptane, benzene, and, to a lesser extent, chloroform and carbon tetrachloride.

Tributyl phosphate extracts metals by solvation and can be considered a reactive solvent, but experimental evidence suggests that it may also dimerize [54]. Of course, adding paraffinic diluents to TBP decreases the degree of TBP self-association by mass action, and diluents such as chloroform or 1-butanol may also form TBP solvates [55]. Phosphorus NMR shift in the system *n*-heptane and TBP suggests that diluent mass action and TBP dissociation in the dilute TBP range affect phosphorus chemical shift [54–56]. Rytting et al. [57] arrived at a similar conclusion from studying TBP and carbon tetrachloride mixtures in the dilute TBP range. Extraction studies often suggest the existence of complexes of the TBP monomer and dimer in the presence of diluents [58, 59], but virtually all of these investigators have assumed that solvation and association reactions form ideal mixtures in the TBP-diluent phase rather than attempting to evaluate activities.

A more realistic approach attempts to describe each equilibrium in terms of its thermodynamic equilibrium constant, molar volumes of specific aggregates, and a heat of reaction to estimate the chemical contribution to excess enthalpy H^E_{chem}. The first two parameters contribute to the excess Gibbs energy g^E model.

A more general reaction model considers both chemical (specific) and physical (nonspecific) contributions to excess Gibbs energy. Using TBP as an example, one first begins by assuming that the physical and chemical contributions are separable so that

$$g^E = g^E_{chem} + g^E_{phys} \tag{10.13}$$

Then the chemical contribution can be computed from the estimated "true" mole fractions. With the assumption that the mixture is ideal, chemical activities simply equal the true mole fractions of monomeric species, and Prigogine and Defay [60] have shown that, regardless of the solvation or association reactions that may occur, in an ideal true mixture with $g^E_{phys} = 0$,

$$\hat{a}_i = \gamma_{i,s} x_{i,s} = z_{i_1} \tag{10.14}$$

where $\hat{a}_i$ and $\gamma_{i,s}$ are the activity and activity coefficient based on the stoichiometric composition $x_{i,s}$, and where z_{i_1} is the true mole fraction of the ith monomer. The reference states for A and B in this case are the pure, unassociated liquids with chemical potentials, pure component Gibbs energies, fugacities, and activities related by $(\mu_i - G_i^o)/RT = \ln \hat{a}_i = \ln \hat{f}_i / f_i^o$.

The extract (or solvent) phase is seldom ideal, however, since the molecules are not uniform in size, and other, nonspecific interactions may occur; but the true mole fractions can still be used to estimate physical contributions to g^E via molecular size and shape difference terms and using regular solution theory.

The stoichiometric mole fractions of diluent and TBP or other reactive extractants (with $i = \{A,B\}$, respectively) are simply the overall mole fractions $x_{i,s}$, molar concentrations $C_{i,s}$, or volume fractions $\phi_{i,s}$.

True mole fractions z_i, molar concentrations C_i, and volume fractions ϕ_i can be computed simply from pure component properties if one assumes that the excess molar volume $V^E = 0$. This assumption can be made initially so as to satisfy component volume and material balances exactly for each mixture. So, using the pure component molar volumes V_i at a given temperature, then $V = \Sigma_{i=1}^{2} x_{i,s} V_i$, $C_{i,s} = x_{i,s}/V$, and $\phi_{i,s} = V_i C_{i,s}$.

Specific chemical interactions can be considered by assuming appropriate combinations of solvation and self-association reactions. If, for example, the true species are the diluent and TBP monomers z_{A_1} and z_{B_1}, the TBP dimer z_{B_2}, and various combinations of aggregates or complexes (e.g., AB, z_{AB}; AB_2; z_{AB_2}; and so forth), then for the jth solvation or self-association reaction in a binary mixture of diluent (A) and TBP (B):

$$n_j A_1 + m_j B_1 \rightleftharpoons A_{n_j} B_{m_j} \tag{10.15}$$

where n_j molecules of A_1 monomer and m_j molecules of B_1, the TBP monomer, are assumed to form a complex. At equilibrium, the chemical potentials of the two monomeric species and the complex are equal, and the product of their activities equals the thermodynamic equilibrium constant $K_{\hat{a}_j}$:

$$K_{\hat{a}_j} = \frac{\hat{a}_{An_jBm_j}}{\hat{a}_{A_1}^{n_j} \hat{a}_{B_1}^{m_j}} \tag{10.16}$$

Defining volume fraction-based activity coefficients for the jth species γ'_j, where $\hat{a}_j = \gamma'_j \phi_j$, leads to

$$K_{\hat{a}_j} = K_{\phi_j} K_{\gamma'_j} = K_{z_j} K_{\gamma_j} \tag{10.17}$$

Also, $\hat{a}_j = \gamma_j z_j$ for each species, γ_j is the true mole fraction-based activity coefficient for the jth species, and $K_{\hat{a}_j}$ is the thermodynamic equilibrium constant.

Physical interactions may be approximated using regular solution theory, and differences in molecular size and shape by using the estimated true species concentrations to estimate the activity coefficient products K_{γ_j} and $K_{\gamma'_j}$ in each mixture and the reference states.

Given a set of true species compositions, differences in molecular sizes, available surface areas, and cohesive energy densities still exist. The physical effects contributing to nonideality may be divided into three terms:

$$g^E_{phys} = g^E_{ms} + g^E_{sd} + g^E_{rs} \tag{10.18}$$

By equating activities for the stoichiometric species with those for the monomers, one eventually obtains an expression for the stoichiometric activity coefficient:

$$\gamma_{i,s} = \frac{\gamma_{i_1} z_{i_1}}{x_{i,s} \gamma^o_{i_1} z^o_{i_1}} \tag{10.19}$$

in terms of monomeric mole fractions in the true mixture and reference states, the stoichiometric mole fraction, and activity coefficients in the true mixture and reference states.

Additional details describing these models can be found elsewhere [61–63]. Such models describe extraction and enthalpic behavior, and measured shifts in nuclear magnetic resonance.

10.4.4 Empirical Distribution Models

In preliminary design work, it is convenient to correlate distribution coefficients on a mass-fraction basis. An empirical correlation technique that is simple to use and often highly effective is

$$\ln D_i = \beta_0 + \sum_{i=1}^{n} \beta_i X_i + \beta_{n+1} V_m + \beta_{n+2} / T \tag{10.20}$$

where the β_i are empirical parameters; X_i are mass fractions at equilibrium in the mixture; V_m is the stoichiometric volume fraction of the active extractant, which is a solvent blend; and T is the temperature in either K or R. The variable n is the number of components in the mixture. While it is true that D_i may exhibit a composition dependence on any of the species in a mixture (i.e., $\beta_i \neq 0$, $i = 1,2,\ldots n$), it is also commonly true that only a few of the β_i parameters inside the summation term on the right-hand side of Equation (10.20) are statistically nonzero. In fact, the strongest dependence may simply be on the solute mass fraction, while other species can be ignored. In any event, the appropriateness of Equation (10.20) is easily determined by fitting experimental data.

Equation (10.20) is often sufficient to model a liquid-liquid extraction system, especially in the early stages of design. Its simplicity is advantageous, but it has no theoretical basis. As a consequence, users should be careful not to extrapolate it to untested compositions. An additional limitation is the fact that Equation (10.20) does not predict the locus of the mutual solubility curve, and, for $\beta_i > 0$, one might be tempted by this equation to extrapolate to conditions that are actually outside the two-phase region (see Figure 10.1).

Many useful solvents are actually blends of a diluent and a modifier. These blends are often formulated on a volume basis (e.g., 30 vol% TBP in Isopar-M), and for such systems the V_m variable is helpful if the solvent blend can be designed and optimized.

The key feature of Equation (10.20) that makes it particularly useful is the fact that D_i often exhibits a weaker composition dependence than K_{D_i}, which is based on the ratio of mole fractions as shown in Equation (10.11).

10.5 DESIGN OF EXTRACTION SYSTEMS

Liquid-liquid extraction columns may be designed in three different ways: (1) as a collection of equilibrium stages, (2) as a continuous differential contactor with mass transfer, or (3) using purely kinetic models. The first two methods are more commonly used (particularly the first) and, when correctly and carefully performed, they give essentially the same results. The latter method, design

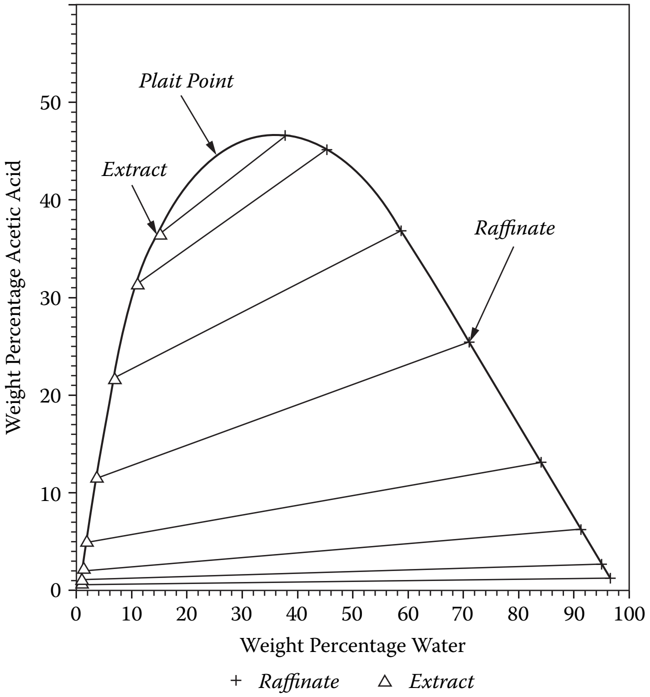

FIGURE 10.1 Liquid-liquid equilibrium data at 25°C for water, acetic acid, and isopropyl ether, showing raffinate and extract compositions at several tie lies and the plait point. At the plait point, both phases dissolve into a single phase with the same composition. The weight percentage of isopropyl ether equals 100 less the weight percentage of water less the weight percentage of acetic acid.

based on mass transfer rates and extraction kinetics, can be important, particularly in high-speed contactors with very short liquid-liquid contact times, but it is less frequently utilized. The first method requires an estimate of stage efficiency. The theoretical stages are divided by the stage efficiency to estimate the actual stages. The second method requires an estimate of the height of column that is equivalent either to a theoretical stage or a transfer unit [2].

10.5.1 Phase Diagrams

Analysis of liquid-liquid behavior and the design of an extraction cascade usually begin with the acquisition of phase equilibrium data. Example data are provided in Table 10.1 for the ternary system, acetic acid, water, and isopropyl ether. Each row in Table 10.1 corresponds to one tie line linking the organic (extract) and aqueous (raffinate) phase compositions at equilibrium. It is convenient to plot such data in an $x - y$ diagram as shown in Figure 10.1. The mutual solubility curve indicates the raffinate and extract compositions, and it defines the limits of the two-phase region. The extract and raffinate merge into a single phase at the plait point.

Any point on Figure 10.1 defines one ternary composition. Points interior to the mutual solubility diagram form two phases as shown in Figure 10.2, where a mixture with composition M in this diagram is shown to separate into two phases with extract composition E and raffinate composition R. The inverse lever rule defines the relative amounts of the two phases. So, given the line segment $\overline{EM}$ and $\overline{MR}$, relative amounts are

$$\frac{\overline{EM}}{\overline{MR}} = \frac{R}{E} = \frac{x_{wm} - x_{we}}{x_{wr} - x_{wm}} = \frac{x_{am} - x_{ae}}{x_{ar} - x_{am}} \tag{10.21}$$

TABLE 10.1
Liquid-Liquid Equilibrium Data Obtained at 25°C and 1 atm [64]

LLE Data for Acetic Acid (A), Water(W), and Isopropyl Ether (E)

Water-Rich Layer			Ether-Rich Layer		
Wt% A	Wt% W	Wt% E	Wt% A	Wt% W	Wt% E
1.41	97.1	1.49	0.37	0.73	98.9
2.89	95.5	1.61	0.79	0.81	98.4
6.42	91.7	1.88	1.93	0.97	97.1
13.30	84.4	2.3	4.82	1.88	93.3
25.50	71.1	3.4	11.4	3.9	84.7
36.70	58.9	4.4	21.6	6.9	71.5
45.30	45.1	9.6	31.1	10.8	58.1
46.40	37.1	16.5	36.2	15.1	48.7

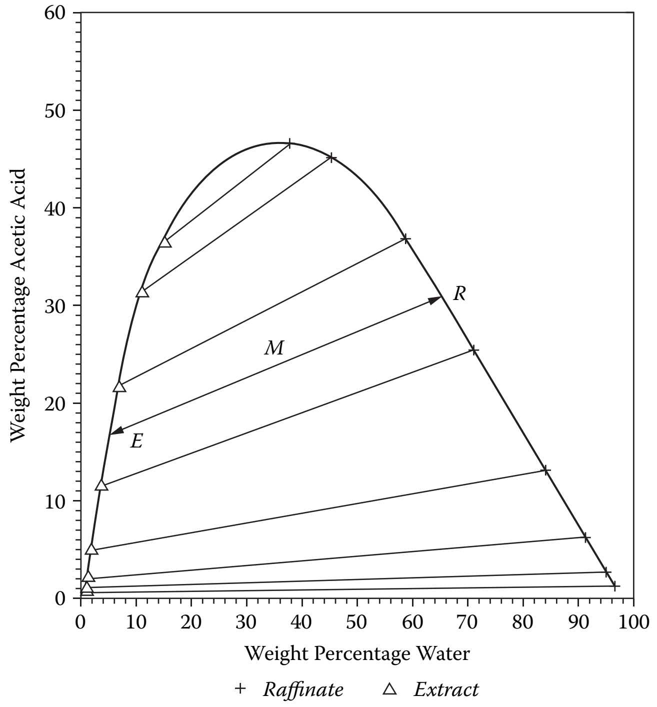

FIGURE 10.2 Liquid-liquid data for the system water, acetic acid, and isopropyl ether. Since mixture *M* falls inside the mutual solubility curve, it separates into extract and raffinate phases with compositions *E* and *R*, respectively. The equilibrium data are at 25°C and 1 atm.

where *R* and *E* are the masses of raffinate and extract, respectively, and x_{ij} are mass fractions, with $i = \{w,a\}$ referring to either with water or acetic acid mass fractions and $j = \{e,m,r\}$ referring to either point *E*, *M*, or *R*.

The point *M* is also known as the mix point, and it defines the overall stoichiometric composition of the mixture (i.e., the composition if only a single phase was formed by mixing), while the extract and raffinate compositions *E* and *R* are found from constructing a line parallel to the nearest tie lies that also intersects the mix points and the mutual solubility curve.

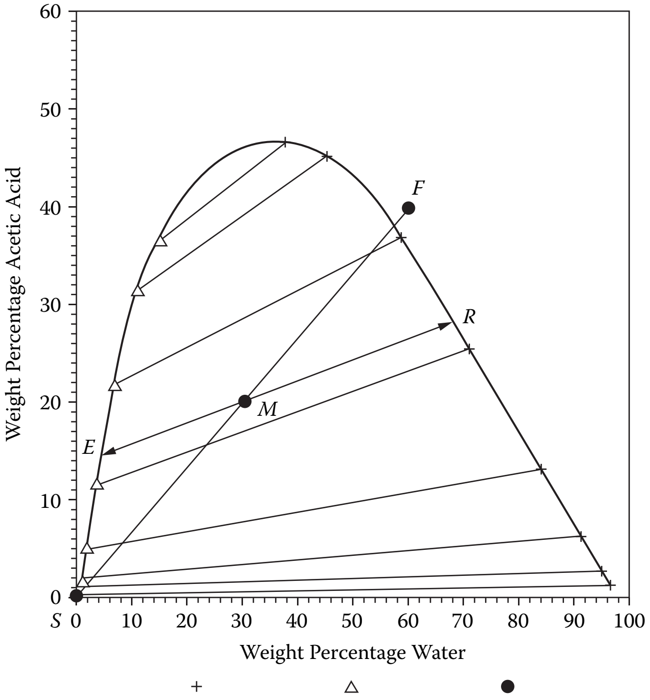

FIGURE 10.3 Liquid-liquid data at 25°C for the system water, acetic acid, and isopropyl ether. Mixing liquids with compositions *F* and *S* in equal proportions by mass results in mix point *M*, which separates into phases with compositions *E* and *R*. The equilibrium data are at 25°C and 1 atm.

The compositions of feeds and solvent mixtures may lie outside the mutual solubility curve but, if upon mixing, the overall stoichiometry is such that the *M* point falls inside the mutual solubility curve, then two liquid phases will form. Mixtures outside of the mutual solubility curve are only a single phase. Thus, Figure 10.2 indicates that the addition of acetic acid to water increases the solubility of isopropyl ether in both the extract and raffinate phases. Aqueous mixtures containing 50 mass% or more of acetic acid are miscible with isopropyl ether in all proportions.

Consider mixing equal amounts of pure isopropyl ether with an aqueous feed that is 40 mass% acetic acid in water. The mix point *M* then lies at a point equidistant between the feed composition point *F* and the solvent composition point *S*. The resulting two phases then have the compositions *E* and *R*, as illustrated in Figure 10.3.

10.5.2 Countercurrent Extractors

Cascades of countercurrent extractors, as shown in Figure 10.4, give the highest recovery of solute while requiring the least amount of solvent [65], so they are of the greatest industrial interest. The alternatives, cocurrent and crosscurrent extractions, are of less interest industrially, although the latter is sometimes used in laboratory applications. Steady-state material balances written around the *j*th stage in Figure 10.4 lead to the equation

$$R_{j-1}x_{j-1} + E_{j+1}y_{j+1} = R_j x_j + E_j y_j \qquad (10.22)$$

For a cascade consisting of n stages, R_1 is the feed and E_{n+1} is the fresh solvent added to the cascade, or column, at the opposite end. The mix point, M, can then be defined in terms of

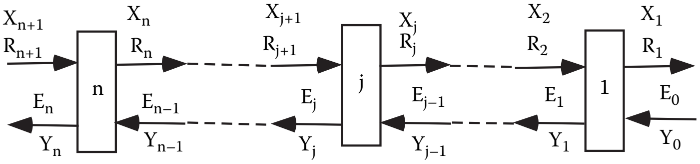

FIGURE 10.4 Stages in a countercurrent cascade. R_{n+1} is the aqueous feed. E_0 is the fresh solvent.

$$M = E_0 + R_{n+1} = E_n + R_1 \tag{10.23}$$

which can be rearranged to give the difference point D,

$$D = E_0 - R_1 = E_n - R_{n+1} \tag{10.24}$$

As shown in Figure 10.5, the line $E_0 - R_1$ intersects the line $E_n - R_{n+1}$ at the D-point. Graphically, all lines that intersect the D-point and a raffinate composition on the mutual solubility curve between R_1 and R_{n+1}, say R_{j+1}, also intersect the extract composition, E_j, on the solvent-rich side of the mutual solubility curve. So each line intersecting the D-point and a raffinate composition, R_{j+1}, also intersects the extract, E_j, which is passing that raffinate on the jth stage. If the extract E_j and raffinate R_j leaving the jth stage are assumed to be at equilibrium, then a graphical method can be used to step off theoretical stages, as shown in Figure 10.6.

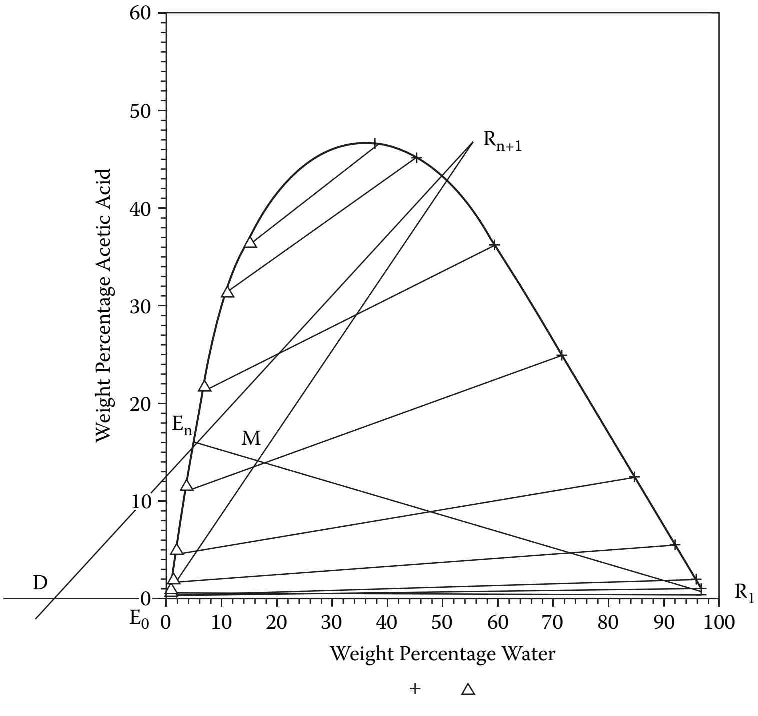

FIGURE 10.5 Liquid-liquid data at 25°C for the system water, acetic acid, and isopropyl ether. Mixing liquids with compositions R_{n+1} and E_0 results in mix point M. Specification of R_1 yields E_n, since the same line also intersects M. The equilibrium data are at 25°C and 1 atm.

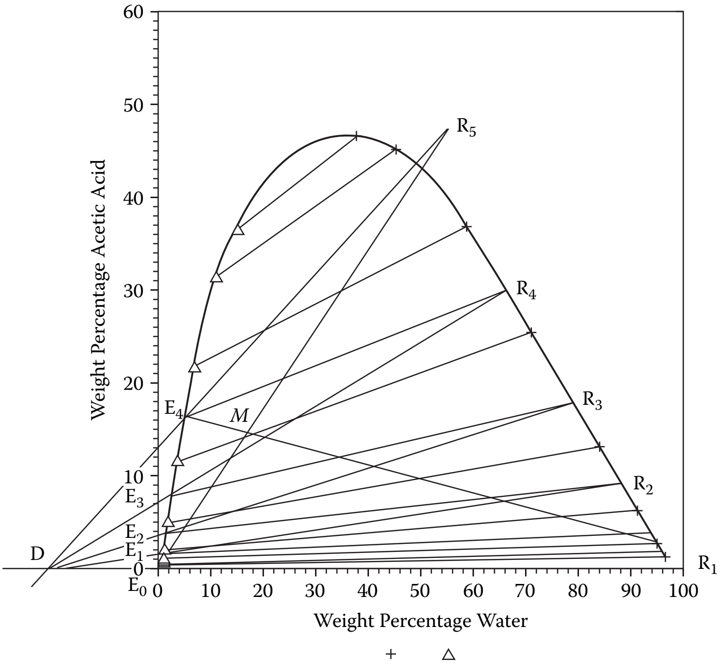

FIGURE 10.6 Liquid-liquid data at 25°C for the system water, acetic acid, and isopropyl ether. Theoretical stages are stepped off by either drawing lines through D to obtain an extract composition or interpolating between nearby tie lines to estimate the extract composition on the next stage. The equilibrium data are at 25°C and 1 atm.

Graphical methods are suitable whenever the two liquid phases are partly miscible as for the water, acetic acid, and isopropyl ether system. If the two liquid phases are nearly immiscible, and their mutual solubility is not affected by the solute concentration, then the Kremser equation discussed below may be applicable.

10.5.3 Kremser Equation

Liquid-liquid systems that obey Nernst's law can be particularly simple to analyze, since the equilibrium relationship is linear in composition. If the two liquid phases are nearly immiscible, and if the solute concentrations are low in either phase, then the operating or material balance line is also nearly linear. Writing a material balance around the jth stage and the raffinate end of the cascade in Figure 10.4 gives the operating line,

$$y_j = \frac{R_{j+1}}{E_j} x_{j+1} + \frac{E_0 y_0 - R_1 x_1}{E_j} \tag{10.25}$$

where E_j and R_j are the extract and raffinate flow rates leaving the jth stage, usually assumed to be in thermodynamic equilibrium. If $E_0 \approx E_1 \approx \ldots E_j$ and $R_1 \approx R_2 \ldots R_{j+1}$, then the subscripts on E and R may be dropped, and the ratio R/E is nearly constant. In this case, the operating line, Equation (10.25), is also linear, and $(Ey_0 - Rx_1)/E$ is constant.

Under these conditions, the extraction factor $E_e = K_{D_i}E/R$ or $E_e = D_iE/R$ is also constant,* and the Kremser [66] group method applies:

* E_e is dimensionless. If K_{D_i} is used, then E/R is a molar ratio. If D_i is used, then E/R is a mass ratio.

$$\phi_E = \frac{E_e - 1}{E_e^{N+1} - 1} \quad (10.26)$$

where ϕ_E is the solute fraction in the entering feed that is not extracted, N is the required number of theoretical (or equilibrium) stages to extract $1-\phi_E$ fraction of the feed, and E_e is the extraction factor, which is constant.

Example: 10.1

A countercurrent LLE cascade is needed to remove 99% of solute species A from an aqueous phase. The aqueous feed rate is 100 kg/h, and the feed contains 5 mass% species A. The distribution coefficient, on a mass ratio basis, is nearly constant, and D_i equals 1.4 kg water/kg solvent. How many theoretical stages are needed if pure solvent can be provided to the cascade at a rate of 90 kg/h?

Solution

$E_e = D_iE/R$ = 1.4(90)/100 = 1.26, and the fraction not extracted is $\phi_E = 0.01$. Rearranging Equation (10.26) gives

$$N + 1 = \ln[(E_e + \phi_E - 1)/\phi_E]/\ln(E_e) = \ln(27)/\ln(1.26) = 14.26$$

N = 13.26 theoretical stages.

10.6 INDUSTRIAL EXTRACTION EQUIPMENT

In-depth treatment of extraction equipment can be found in several books. Godfrey and Slater [67] provide more current details, but the treatments provided by Lo, Baird, and Hanson [7] and Skelland and Tedder [68] are also useful.

10.6.1 Mixer Settlers

Mixer-settlers are simply tanks configured to permit mixing in one followed by decantation in a second. Each stage consists of a mixer and settler pair (i.e., two tanks). When several mixer-settler stages are configured countercurrently, they constitute a cascade as indicated in Figure 10.4.

The advantages of mixer settlers are (1) simple maintenance and operation, (2) high tolerance for undissolved solids (e.g., as often occurs in the mining industry), (3) high tolerance for interfacial precipitates, (4) simple adjustment of mixing from stage to stage, and (5) easy measurement of concentration profiles throughout the cascade. The disadvantages of mixer-settlers are (1) potentially high inventory and (2) longer residence times than with other types of contactors. This latter disadvantage can be particularly serious if one is processing materials that degrade the solvent (e.g., fission products with a high radiation field).

Mixer-settlers are widely used, particularly in the mining industry. Vendors are available, and they are easily designed. In the laboratory, small-scale, mini-mixer-settlers are available that offer as many as 16 countercurrent stages and are capable of achieving steady state using 500 mL of feed or less.

10.6.2 Reciprocating Plate Columns

In reciprocating plate columns, the height equivalent to a theoretical stage ($HETS$) is a strong function of the reciprocating speed, Af, the product of the reciprocation amplitude and frequency. Karr columns actually exhibit optimal values for Af where the ($HETS$) is clearly minimized. These

minima are a function of both the physical properties of the liquid-liquid system and the column geometry, particularly the column diameter.

The (*HETS*) for reciprocating plate extraction columns has been correlated [69] using

$$\Gamma_L = 24.4 C_{dt}^{-0.075} N_{\text{Re}}^{-0.015} N_{We}^{-0.525} N_{Sl}^{-1.15} \left(\frac{U_d}{U_c} \right)^{0.210} \tag{10.27}$$

where $\Gamma_L = HETS/D$, $(Af) < (Af)_{opt}$, and $(Af)_{opt}$ is the reciprocating speed that minimizes the (*HETS*).

At reciprocating speeds greater than $(Af)_{opt}$, the correlation

$$\Gamma_U = 28.8 C_{dt}^{0.651} C_{dr}^{-0.997} N_{Bo}^{0.776} \left(\frac{U_c}{U_d} \right)^{0.582} \tag{10.28}$$

describes the observed behavior, where $\Gamma_U = HETS/D$.

Equations (10.27) and (10.28) can be accurately combined using a method suggested by Churchill[70] to yield an overall correlation:

$$\frac{HETS}{D} = \Gamma_L \left(1 + \left[\frac{\Gamma_U}{\Gamma_L} \right]^{20} \right)^{1/20} \tag{10.29}$$

Figure 10.7 compares experimental data with predictions using this correlation. The optimal values for (*Af*) that minimize (*HETS*) depend strongly on the column diameter, and the (*HETS*) minima are more pronounced for larger-diameter columns. In general, the (*HETS*) increases with column diameter, and it becomes increasingly important to operate at $(Af)_{opt}$ for larger-diameter columns.

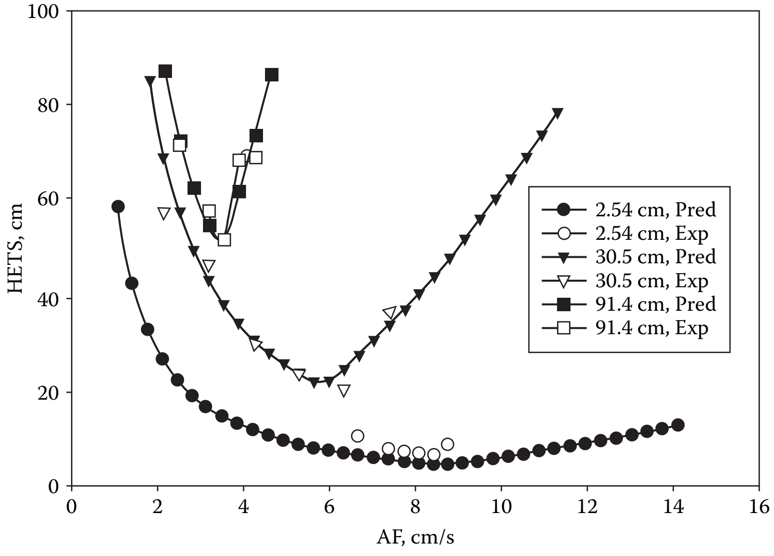

FIGURE 10.7 Predicted *HETS* for reciprocating columns using Equation (10.29). The column diameter affects the optimal reciprocating speed and the sensitivity of the *HETS* to that speed. The larger a column diameter, the more important it is to operate at the optimal reciprocating speed, *Af*.

Rearranging Equation (10.27) gives the following dependencies:

$$HETS \propto D^{0.385}\sigma^{0.525}(Af)^{-1.15}U_T^{0.235}\rho_c^{-0.465}(\Delta\rho g)^{-0.146} \tag{10.30}$$

for $(Af) < (Af)_{opt}$. Similarly, rearrangement of Equation (10.28) gives these dependencies:

$$HETS \propto D^{0.892}\sigma^{-0.776}(Af)^{+1.99}U_T^{1.30}\rho_c^{+1.65}(\Delta\rho g)^{-0.872} \tag{10.31}$$

for $(Af) < (Af)_{opt}$. Analysis of these dependencies can be helpful when comparing these correlations with those developed by other investigators.

The minimum ($HETS$) for a column can be estimated from an estimate of $(Af)_{opt}$. The latter quantity may be obtained by differentiating Equation (10.29) and setting $\partial HETS / \partial(Af) = 0$:

$$\begin{aligned}(Af)_{opt} &= \left\{\frac{\Gamma_U}{\Gamma_L}(Af)^{-3.15}\right\}^{-1/3.15} \\ (Af)_{opt} &= \left\{1.24 D^{0.515}\sigma^{-1.30}U_T^{1.06}\rho_c^{2.12}(\Delta\rho g)^{-0.8}\mu_c^{0.015}\left(\frac{U_c}{U_d}\right)^{0.794}\right\}^{-1/3.15}\end{aligned} \tag{10.32}$$

which predicts $(Af)_{opt} \pm 6\%$.

Example: 10.2

Estimate the minimum $HETS$ for a 2-in diameter reciprocating plate column. The liquid-liquid interfacial tension is 30 dyne/cm. The solvent phase density and viscosity are 0.82 g/cm^3 and 1.3 cP, respectively. The aqueous phase density and viscosity are 1 g/cm^3 and 1.129 cP, respectively. Water is the continuous phase, and its linear velocity down the column is U_c = 0.40 cm/s. The velocity of the dispersed solvent phase is U_d = 0.12 cm/s.

Solution

$$U_T = U_c + U_d = 0.40 + 0.12 = 0.52 \text{ cm/s}$$

$$\Delta\rho = |\rho_d - \rho_c| = |0.82 - 1.0| = 0.18 \text{ g/cm}^3$$

Substituting into Equation (10.32) gives $(Af)_{opt} = 10$ cm/s. Substitution of $(Af)_{opt}$ and the other properties into Equations (10.27) through (10.29) gives

$$C_{dt} = D\Delta\rho g / \rho_c U_T^2 = 5.08(0.18)980.66/[1(0.52^2)] = 3316$$

$$C_{dr} = D\Delta\rho g / (Af)^2\rho_c = 5.08(0.18)980.66/[(10^2)1] = 8.967$$

$$N_{Re} = \rho_c U_T D / \mu_c = 1.0(0.52)(5.08)/[1.129(10^{-2})] = 234$$

$$N_{We} = D U_T^2 \rho_c / g_c\sigma = 5.08(0.52^2)1.0/[1.0(30)] = 0.046$$

TABLE 10.2
Internet Sites Providing Solvent Extraction Services

Provider	Service	Internet Address
QVF Process Systems, Inc.	Equipment vendor	www.qvfps.com
Sulzer Chemtech USA, Inc.	Equipment vendor	www.nutter1.com

Visimix Software	Mixing parameter estimates	on-line.visimix.com

$$N_{Sl} = Af / U_T = 10/0.52 = 19.2$$

$$N_{Bo} = D^2 \Delta\rho g / g_c \sigma = 5.08^2(0.12)980.66/30 = 151.8$$

$$\Gamma_L = 1.613,\ \Gamma_U = 1.636,\ \text{and } HETS = 8.5 \text{ cm.}$$

10.7 INTERNET SITES

Several Internet sites that feature solvent extraction information are listed in Table 10.2.

10.8 ECONOMIC ANALYSIS FOR VERTICAL CONTACTORS

The use of solvent extraction technology results in capital expenses to install the equipment and operating expenses. Contact equipment vendors (see Table 10.2) for quotes on specialized solvent extraction equipment. Preliminary capital cost for continuous differential contactors can be obtained by sizing them and then cost estimating them as vertical pressure vessels with internals, e.g., using Guthrie's [71, 72] methods. Mixer-settlers are simply a collection of mixing and settling tanks assembled with appropriate piping. Examples are listed below. Processing highly radioactive systems requires nuclear-grade equipment, which essentially doubles their cost.

Choose materials of construction based on corrosion considerations. Column diameters are determined by specifying linear velocities for the two phases. Column heights are determined by estimating the actual number of stages based on the theoretical stage requirements and average stage efficiency. Internals in pulse columns are very similar to those in distillation towers, especially for sieve trays. Therefore, distillation correlations can be used to estimate FOB purchased and installed costs for continuous differential contactors, if they are assumed to be pulse columns.

From Guthrie,[71] tray FOB purchase costs, E_i', for sieve trays can be estimated using the correlation

$$E_i' = E_i(F_S + F_m) \tag{10.33}$$

where F_S is 1.0, 1.4, or 2.2 for trays with 24-, 18-, and 12-in spacing, respectively. The tray material factor, F_m, is 0.0, 1.7, or 8.9 for carbon steel, stainless steel, and monel, respectively. The factor E_i is the FOB purchased cost for carbon steel sieve trays, 24-in spacing, either shop or field installed. It is correlated to the column dimensions if shop or field installed using the correlations in Table 10.3. Table 10.4 provides correlations for estimating the FOB purchased equipment costs for vertical process vessels (e.g., extraction columns) and horizontal process vessels (e.g., surge tanks).

TABLE 10.3
Correlations for Estimating fob Purchased Costs for Internals (e.g., Distillation Trays, Absorber Packings, Solvent Extraction Columns, and Others. Referenced to Mid-1968 Dollars with (M&S = 273.1). Correlated Using Information from Guthrie [71]

Item	Correlation
Sieve Trays, 24-in spacing, shop installed[a,b]	$E_i = C_4(HT - 10)\left(\frac{M\&S}{273.1}\right)$
	$C_4 = \begin{cases} 8.665D - 1.218 & D < 4 \text{ ft} \\ 16.67D - 33.35 & 4 \le D \le 6 \text{ ft} \\ 23.33D - 73.31 & 6 < D \le 7 \text{ ft} \\ 25D - 75 & 7 \le D \le 10 \text{ ft} \end{cases}$
	D = nominal column diameter, ft
	HT = nominal column height, ft, actual trays plus 10 ft
Sieve Trays, 24-in spacing, field installed[c]	$E_i = C_4(HT - 10)\left(\frac{M\&S}{273.1}\right)$
	$C_4 = 20D - 60 \quad D > 10$ ft
	D = nominal column diameter, ft
	HT = nominal column height, ft, actual trays plus 10 ft

[a] Add 0.08 E_i as indirects for freight, taxes, and insurance.
[b] Add 0.05 E_i to estimate shop labor for installation.
[c] Add 0.58 E_i for field labor and 0.75 E_i for indirects.

Example: 10.3

Estimate the fob purchased cost of a stainless steel pulse column when the Marshall & Swift (M&S) index is 1200. The column is 30 ft high and 2 ft in diameter. Internals are estimated as sieve trays with 1.5-ft spacing.

Solution

From the column dimensions, the bare module cost for the internals, if they are constructed of carbon steel and have 24-in spacing, would be

$$C_4 = 8.665(2) - 1.218 = 16.112$$

$$E_i = 16.112(20)(1200/273.1) = \$1{,}416 \text{ for the internals.}$$

Since the internals have 1.5-ft spacing and are of stainless steel,

$$E_i' = \$1{,}416(1.4 + 1.7) = \$4{,}390 \text{ fob.}$$

For the column, we have $C_3 = 33.143/30 + 0.127 = 1.23177$:

$$E = 2000(2.0/1.23177)^{1.047}(1200/273.1) = \$14{,}598 \text{ if the column is of carbon steel.}$$

TABLE 10.4
Correlations for Estimating Base Equipment Costs for Process Vessels. Referenced to Mid-1968 Dollars with (M&S = 273.1). Correlated Using Guthrie's Figures (Low Pressure, Carbon Steel Basis)

Item	Correlation
Vertical process vessels[a]	$E = 2000\left(\frac{D}{C_3}\right)^{1.047}\left(\frac{M\&S}{273.1}\right)$ $C_3 = \begin{cases} 20.867/HT + 0.778 & HT < 15 \text{ ft} \\ 33.143/HT + 0.127 & HT \geq 15 \text{ ft} \end{cases}$ D = nominal column diameter, ft HT = nominal column height, ft, actual trays plus 10 ft
Horizontal process vessels[b]	$E = 1375\left(\frac{D}{C_3}\right)^{0.9747}\left(\frac{M\&S}{273.1}\right)$ $C_3 = \begin{cases} 20.867/HT + 0.778 & HT < 15 \text{ ft} \\ 33.143/HT + 0.127 & HT \geq 15 \text{ ft} \end{cases}$ HT = nominal horizontal length of vessel, ft D = nominal diameter of horizontal vessel, ft

[a] Distillation columns, absorbers, scrubber, strippers, flash drums, etc.
[b] Accumulator drums, surge vessels, decanters, etc.

Because it is stainless, $E' = 3.67E$ = \$53,575, and the total fob purchase cost is $E' + E_i' = 53,575 + 4,390 = \$57,965$.

10.8.1 List of Symbols

A	= the amplitude of the reciprocating cycle, measured from the mean position to an extreme, or one-half of the stroke length, cm
(Af)	= the reciprocating speed, cm/s or cm/min
$(Af)_{opt}$	= the reciprocating speed yielding the minimum *HETS* value, cm/s
$\hat{a}_i$	= chemical activity of species i
$C_{i,s}$	= stoichiometric molar concentration of species i, moles/L, $V^E = 0$
C	= true molar concentration of species i, moles/L, $V^E \neq 0$
C_{dr}	= $D\Delta\rho g/(Af)^2\rho_c$, a reciprocating drag coefficient
C_{dt}	= $D\Delta\rho g/\rho_c U_T^2$, a column drag coefficient
D	= the column diameter, cm, or difference point in Equation (10.24)
f	= the reciprocating frequency s^{-1}
$\hat{f}_i$	= the fugacity of species i in a liquid phase
g	= gravity acceleration, 980.66 cm/s^2
g^E	= excess Gibbs energy, J/mol
g_c	= gravity constant, 1.0 g-cm/d-s^2
h	= plate spacing in column mass transfer zone, cm
$HETS$	= height equivalent to a theoretical stage, cm
$K_{\hat{a}_j}$	= thermodynamic equilibrium constant for complex j

K_{z_j} = product of true mole fractions for complex *j*
K_{ϕ_j} = product of true volume fractions for complex *j*
$K_{\gamma'_j}$ = product of true volume fraction-based activity coefficients for complex *j*
K_{γ_j} = product of true mole fraction-based activity coefficients for complex *j*
m_j = diluent coordination number in *j*th complex
n_j = solute coordination number in *j*th complex
N_{Bo} = a Bond number
N_{RE} = $\rho_c U_T D / \mu_c$, a Reynolds number
N_{Sl} = Af / U_T, a Strouhal number
N_{We} = $DU_T^2 \rho_c / g_c \sigma$, a Weber number
P_i^{sat} = pure component vapor pressure for species *i*, mm H_g
R = universal gas constant, J/mol-K
T = temperature, K
U_c = the continuous phase superficial velocity in cm/s
U_d = the dispersed phase superficial velocity in cm/s
U_T = net superficial velocity of phases = $U_d + U_c$, cm/s
V_i = molar liquid volume for species *i* assuming $V^E = 0$
$\chi_{i,s}$ = stoichiometric mole fraction of species *i*
z_i = true mole fraction of species *i*
z_{i_1} = true mole fraction of *i*th monomer
β_j = empirical parameter
$\Delta\rho$ = $|\rho_d - \rho_c|$, g/ml
Γ_L = suboptimal *HETS/D* correlations for $(Af) < (Af)_{opt}$
Γ_U = the superoptimal *HETS/D* correlation for $(Af) > (Af)_{opt}$
γ_j = true mole fraction-based activity coefficient for species *j*
$\gamma_{i,s}$ = stoichiometric activity coefficient for species *i*
μ_c = viscosity of the continuous phase, cP
$\phi,_{i,s}$ = stoichiometric volume fraction of species *i*
ϕ_i = volume fraction of species *i* if $V^E = 0$
ρ_e = density of the continuous phase, g/ml
ρ_d = density of the dispersed phase, g/ml
ρ_d = interfacial tension, d/cm

11.1 SCOPE AND FORMAT OF THE CHAPTER

Any chemical process can be characterized in terms of three major components: prereaction, reaction, and postreaction. Usually (but not necessarily) the first and last comprise only physical operations such as mixing, heating, vaporization, distillation, crystallization, extraction, absorption, adsorption, and so on. No chemical reaction is involved except in cases where physical separation is facilitated or enhanced by a deliberately imposed reaction (to be distinguished from the reaction of interest). The middle component constitutes the actual chemical reaction occurring in the process, i.e., the reaction of interest. The reaction can be of any type, involving one or more phases, and is performed in reactors of various designs. The design depends on the system used, such as gas, liquid, gas-liquid, liquid-liquid, gas-solid, gas-liquid-solid, and so forth. In the 1930s and 1940s, the analysis and design of reactors was usually referred to as *applied reaction kinetics*. Then, around 1960, the term *chemical reaction engineering* was used (by Octave Levenspiel) to describe this area of chemical engineering.

Chemical reaction engineering (CRE) has grown in over half a century as a highly sophisticated area of chemical engineering. The first attempts were centered round the development of common principles that cut across various industries. As chemical engineers applied these principles to other emerging areas such as biochemical processes, electrochemical processes, photochemical processes, sonochemical processes, and others, new theories had to be developed to accommodate the special needs of different areas. Thus a new trend became discernible where CRE retained its core value and structure but many specialized areas (e.g., biochemical reaction engineering, electrochemical reaction engineering, photochemical reaction engineering, and microreactor engineering) began to spin off with roots in CRE. This inclusiveness of CRE has been its hallmark over the last 30 years.

The present chapter applies the fundamental principles of CRE to specialized examples of practical interest. Many standard texts on CRE start with a detailed presentation of reactors for homogeneous reactions and then extend the treatment to multiphase reactors. In the present chapter, homogeneous reactors constitute only a small part of the treatment and are covered under one of several case studies included. The bulk of the treatment is devoted to multiphase reactions and reactor characteristics. A broad outline of the scope of the chapter is presented in Figure 11.1.

The following format is used. Important physicochemical aspects of CRE (commonly known as reaction analysis) are briefly outlined in Section 11.2, to provide the fundamental framework for the analysis and design of reactors involving one or more phases, referred to generally as single-phase or multiphase reactors, respectively. These include treatment of simple and complex (multiple) reactions, stoichiometry, reaction rates (with a brief reference to the concept of the rate-determining step), and experimental techniques.

For single-phase (homogeneous) reactions, there are no phase boundaries. Mass transfer limitations are not controlling except in very fast reactions. On the other hand, where two or more phases are present, mass or heat transfer across an interface may be the controlling step. Depending on the type of reaction system involved [e.g., gas-liquid, liquid-liquid, gas-solid (catalytic), gas-solid (noncatalytic), and gas-liquid-solid], specific methods of analysis have been developed. Obtaining reliable laboratory data for such heterogeneous reactions is more difficult than for homogeneous reactions. One simple way to collect intrinsic kinetic data, not falsified by transport disguises, is to use the so-called gradientless reactors. All these aspects of *reactions with an interface* are outlined in Section 11.3.

Then, in Section 11.4, a practically oriented survey is presented of several industrial rectors. The treatment begins with a classification of reactors based on the mode of energy input. A full quantitative treatment of this subject is called *reactor analysis* or *modeling*. Such an undertaking is complicated and is not germane to the present effort.

The more important classes of reactors are discussed in Section 11.5 as specific *case studies* of importance. Most case studies include a description of the theory involved, determination of the rate-controlling step, process design (including reactor modeling), estimation of design parameters, and

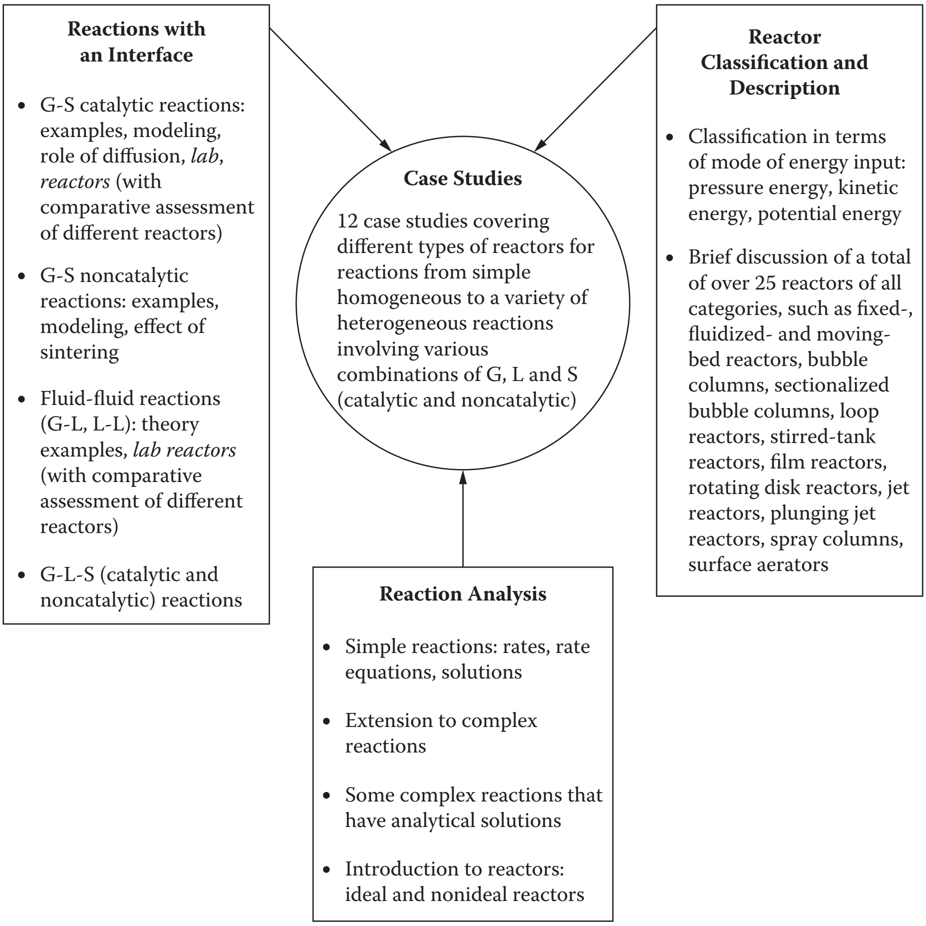

FIGURE 11.1 Scope and format of the chapter.

optimization. A special feature of the present chapter is its treatment of reactors in terms of rigorous case studies following a qualitative description of numerous reactors commonly used in industry.

Sometimes reaction rates can be enhanced by using multifunctional reactors, i.e., reactors in which more than one function (or operation) can be performed. Examples of reactors with such multifunctional capability, or *combo* reactors, are distillation column reactors in which one of the products of a reversible reaction is continuously removed by distillation thus driving the reaction forward; extractive reaction; biphasing; membrane reactors in which separation is accomplished by using a reactor with membrane walls; and simulated moving-bed (SMB) reactors in which reaction is combined with adsorption. Typical industrial applications of multifunctional reactors are esterification of acetic acid to methyl acetate in a distillation column reactor, synthesis of methyl-*ter*-butyl ether (MTBE) in a similar reactor, vitamin K synthesis in a membrane reactor, oxidative coupling of methane to produce ethane and ethylene in a similar reactor, and esterification of acetic acid to ethyl acetate in an SMB reactor. These specialized reactors are increasingly used in industry, mainly because of the obvious reduction in the number of equipment. These reactors are considered by Fair in Chapter 12.

Aspects of CRE not covered in this chapter include computational fluid dynamics (CFD). Total integration of CRE and CFD will generate much more reliable and theoretically sound procedures for reactor design but may not happen for the next 15 to 20 years. Meanwhile, incremental infusions of CFD in CRE will add increasing rigor to existing design procedures and methods for combining

complex chemistry with reactor design. Process control, stability, unsteady-state analysis of reactors, and estimation procedures for design parameters are not covered in this chapter. With continuously increasing interaction of CRE with CFD, the present empirical methods of estimation will almost certainly be replaced by more theoretical ones.

11.1.1 Nomenclature

In view of the special format of this chapter, and the need to use a number of symbols (both regular and Greek) and subscripts, especially for the case studies, the following lists have been prepared: (1) a common list for Sections 1 through 4 and (2) individual lists for the case studies. Many items have been defined only in terms of the main symbols, with more detailed specifications through appropriate subscripts listed under the heading *Subscripts*. However, in the interest of clarity, subscripts have also been used in the main lists where necessary.

11.2 REACTION AND REACTOR FUNDAMENTALS

11.2.1 Scope

The design of a chemical reactor always starts with the analysis of the reaction involved, identification of the best system for its commercial operation [homogeneous, gas-solid (catalytic), gas-liquid, gas-liquid-solid (slurry), and so on], and design of reactor for the chosen system. Note that the system is often pre-fixed by the nature of the reaction itself, but it may be possible to alter the original system in several ways, e.g., intentional addition of a liquid phase, use of an immobilized homogeneous catalyst in place of its more common soluble analog, use of a trickle-bed reactor instead of the slurry reactor in which the laboratory experiments might have been performed, and so forth. Depending on the system, the definition of the reaction rate and the units of rate constants will vary. The reaction itself may be simple or complex, and mathematical tools for handling these are necessary. These various aspects of reactions are briefly outlined in this section.

A variety of reactors are used, particularly for multiphase reactions. The more important aspects of these *reactions* are covered in Section 11.3, while Section 11.4 discusses multiphase *reactors.* For an appreciation of these reactors, an understanding of the fundamental types of reactors, called *ideal reactors,* is necessary. Thus, we end this section with a brief presentation of these reactors along with an introduction to the concept of nonideal flow—a feature of many industrial reactors.

11.2.2 Simple Reactions

A simple reaction such as

$$A \rightarrow R + S \qquad \text{R11.1}$$

is usually one in which only a single step is involved, defined by a single rate equation. This reaction may, however, actually proceed through several elementary steps such as

$$A + A \rightarrow A^* + A \qquad \text{R11.1a}$$

$$A^* + A \rightarrow A + A \qquad \text{R11.1b}$$

$$A^* \rightarrow R + S \qquad \text{R11.1c}$$

In this set of elementary steps, the intermediate (A*) is transient and not experimentally detectable. Thus, whereas this mechanistic representation is useful in understanding the nature of the reaction,

from the engineering point of view, the overall "single step" represented by R11.1 is adequate. Its mechanistic evolution is largely irrelevant. The rate at which this reaction proceeds is given by

$$rate = (constant)\ [A] \tag{11.1}$$

The concentration of A is raised to a power equal to the stoichiometric coefficient of A in the reaction (unity in this case). We refer to such reactions as *stoichiometric* reactions. If experimental data conform to the empirical form

$$rate = (constant)\ [A]^n \tag{11.2}$$

where n is some constant not equal to the stoichiometric coefficient, then the reaction is considered to be nonstoichiometric. The exponent on the concentration term, whether stoichiometric or nonstoichiometric, is called the *reaction order*. The proportionality constant is typically called the *rate constant*. However, because it is a function of temperature and pressure, the term "constant" is misleading and "coefficient" is a more correct choice (like, for example, mass or heat transfer coefficient and diffusion coefficient). However, "rate constant" is accepted.

11.2.3 Complex (Multiple and Multistep) Reactions

Let us now consider the following reaction in which several ethanolamines (mono-, di-, and tri-) are formed and referred to as a *multiple reaction:*

$$NH_3 + \underset{\setminus\,/ \atop \mathrm{O}}{H_2C\text{—}CH_2} \rightarrow NH_2\text{—}(CH_2CH_2OH)$$

$$NH_2(CH_2CH_2OH) + \underset{\setminus\,/ \atop \mathrm{O}}{H_2C\text{—}CH_2} \rightarrow NH{=}(CH_2CH_2OH)_2 \qquad \text{R11.2}$$

$$NH{=}(CH_2CH_2OH)_2 + \underset{\setminus\,/ \atop \mathrm{O}}{H_2C\text{—}CH_2} \rightarrow N{\equiv}(CH_2CH_2OH)_3$$

These intermediates are experimentally detectable. The literature refers to such a reaction as a *multistep reaction*. We prefer the term "multiple" and reserve "multistep" to a reaction scheme in which a number of steps, each requiring a different set of operating conditions, are employed to synthesize a compound starting from a given set of raw materials. Thus, the following scheme for synthesizing benzaldehyde (PhCHO) starting from toluene ($PhCH_3$) is a *multistep reaction:*

$$PhCH_3 + Cl_2 \rightarrow PhCH_2Cl + HC1$$

$$PhCH_2Cl + NaOH \rightarrow PhCH_2OH + NaCl \qquad \text{R11.3}$$

$$4PhCH_2OH + 2HNO_3 \rightarrow 4PhCHO + N_2O + 5H_2O$$

In this chapter, both simple and multiple reactions are considered.

11.2.4 Stoichiometry

Reaction rates (as we shall see later) are always expressed in terms of concentrations of the reacting species or their partial pressures. It is usually convenient to express the concentrations of the various

components in terms of the conversion of the key component and the initial concentrations of the others. This is done by simple stoichiometric considerations. For the general reaction

$$\nu_A A + \nu_B B \rightarrow \nu_R R + \nu_s S \qquad \text{R11.4}$$

the concentration equations in terms of the conversion X_A are listed in Table 11.1 along with equations for other important terms. Since there can be a change in volume due to a change in number of moles, temperature, pressure, or combinations thereof, the equations also include the effects of these factors.

11.2.5 Reaction Rates

The term *reaction rate* denotes the rate of a reaction in a general way. We now define it specifically as the moles reacting per unit of *reaction space* per unit time. The reaction space can be the empty volume of the reacting space, void volume of the catalyst bed, volume of the catalyst, weight of the catalyst, surface area of the catalyst, or volume of one or all of the phases present in a heterogeneous system. Where time is concerned, its definition depends on the type of reactor used. There are essentially two broad classes of reactors: batch and flow. In a batch reactor, time (t) corresponds to the elapsed time from the start of a run. In a flow reactor, it is given by

$$\bar{t} = \frac{V}{Q_0} = \frac{L}{u} \qquad (11.3)$$

that is, the ratio of reactor volume to flow rate (or reactor length to fluid velocity). For a reaction with no volume change, this is also referred to as the *residence time*. The various definitions of the rate and their interconversions are summarized in Table 11.2. A negative sign before the rate represents reactant disappearance, and a positive sign represents product formation.

Equation (11.2) can be expressed as follows:

$$\textit{Rate} = \textit{(kinetic term)(potential term)} \qquad (11.4)$$

where the kinetic term is the rate constant representing both the thermal and kinetic effects, and the potential term is the concentration representing the driving force. This form is the well-known power law equation. For reactions involving catalysts, a third term (the adsorption term) is also needed to account for surface catalysis. The exponent on the potential term represents the reaction order. The main feature of the kinetic term k is its temperature dependence, which is normally given by the well-known Arrhenius equation,

$$k = k^o e^{-E/R_g T} \qquad (11.5)$$

where k^o and E are the frequency factor and activation energy, respectively, of the reaction. A slightly more complex form given by

$$k = k^o T^m e^{-E/R_g T} \qquad (11.6)$$

has also been proposed but is almost never warranted. Several theories for explaining the rate constant have been proposed (see, e.g., Pilling and Seakins, 1995), but they are not considered here.

There are essentially two methods of determining the kinetic parameters k and n: differential and integral. In the differential method, $[A]$ is plotted as a function of time for a batch reactor or

TABLE 11.1
Concentration Equations in Terms of X_A for the General Reaction

$$v_A A + v_B B \rightarrow v_R R + v_s S$$

$$v_A A + v_B B \rightarrow v_R R + v_s S$$

i = B, R, or S
(+ for product, – for reactant)

Batch

$$[i] = \frac{N_i}{V}$$

$$V = V_0\left(\frac{N_T}{N_{T0}}\right)\left(\frac{P_0}{P}\right)\left(\frac{T}{T_0}\right)$$

$$= V_0(1+\varepsilon_A X_A)\left(\frac{P_0}{P}\right)\left(\frac{T}{T_0}\right)$$

$$= V_0 \text{ for constant volume}$$

Flow

$$[i] = \frac{F_i}{Q}$$

$$Q = Q_0\left(\frac{F_T}{F_{T0}}\right)\left(\frac{P_0}{P}\right)\left(\frac{T}{T_0}\right)$$

$$= Q_0(1+\varepsilon_A X_A)\left(\frac{P_0}{P}\right)\left(\frac{T}{T_0}\right)$$

$$= Q_0 \text{ for constant volume}$$

$$\delta_A = \frac{v_S + v_R - v_B - v_A}{v_A}$$

$$\varepsilon_A = y_{A0}\delta_A = \frac{V_{X_A=1-}V_{X_A=0}}{V_{X_A} = 0}$$

$$[i] = \frac{y_{i0}p_0}{R_g T_0}, \quad [A] = \frac{y_{A0}p_0}{R_g T_0}$$

$$[A] = \frac{[A]_0(1-X_A)}{1+\varepsilon_A X_A}$$

$$[i]\left\{\frac{[A]_0\left(\psi_i \pm \frac{v_i}{v_A}X_A\right)}{1+\varepsilon_A X_A}\right\}\left(\frac{P}{P_0}\right)\left(\frac{T_0}{T}\right)$$

$$\psi_i' = \frac{[i]_0}{[A]_0} = \frac{F_{i0}}{F_{A0}} = \frac{y_{i0}}{y_{A0}}$$

Note: When there is no volume change, $\varepsilon_A = 0$ and when the system is isothermal and isobaric, $P = P_0$ and $T = T_0$.

TABLE 11.2
Different Definitions of the Reaction Rate

$$\text{Rate} = -\frac{1}{M}\frac{dN_A}{dt} = k[A]^n$$

	Rate, *r*		Rate constant, *k*	
M	**Symbol**	**Units**	**Symbol**	**Units**
Reactor volume	r_A, r_{VA}	mol/m^3 reactor s	k_V	(m^3 reactor/mole)$^{n-1}$ (1/s)
catalyst volume	r_{vA}	mol/m^3 cat s	k_v	(m^3 reactor/mol)^n (mol/m^3 cat) (1/s)
catalyst weight	r_{wA}	mol/kg cat s	k_w	(m^3 reactor/mol)^n (mol/kg cat) (1/s)
catalyst surface	r_{SA}	mol/m^2 cat s	k_S, k'	(mol/m^2 cat) (m^3 reactor/mol)^n (1/s)
interfacial area	r'_A	mol/m^2 interface s	k'	(m^3/mol)^n (mol/m^2) (1/s)
Interconversions:	$k_V = (1 - \varepsilon_b)\, k_V$		ε_b = bulk voidage	
	$k_w = k_v/\rho_c$		ρ_c = density of catalyst, kg/m^3	
	$k_V = k'a$		a = interfacial area, m^2/m^3	

V/Q_0 for a flow reactor, and the rate is determined by differentiating the curve either graphically or analytically. In the integral method, however, different forms of the rate equation are assumed, and the integrated forms are verified against experimental data. Integrated forms for several types of reactions and rate forms are summarized in Table 11.3, and procedures for determining the rate parameters by both differential and integral methods are illustrated Figure 11.2.

A useful method of obtaining the kinetic parameters for a nonunimolecular reaction such as

$$\mathrm{A + B \rightarrow R + S} \qquad \text{R11.5}$$

is noteworthy. Let the rate equation be given by

$$-r_A = k_2[A]^m[B]^n \qquad (11.7)$$

where k_2 is the second-order rate constant, m and n are the orders with respect to A and B, respectively, and the overall order is $(m + n)$. The reaction will be pseudo-mth order if B is in excess and pseudo-nth order if A is in excess. In fact, a simple experimental way of determining the orders is to first use A in excess (thus ensuring practically no change in its concentration) and determine n, and then use B in excess and determine m.

Another practical feature of reaction analysis is that the rate equation can be written in terms of concentrations as in the equations presented above or in terms of partial pressures. The relationship between the two forms is explained in Table 11.4. It is important to distinguish between the various units and use the correct units in any formulation.

11.2.6 Extension to Complex (Multiple) Reactions

A relatively common industrial situation is one in which a number of components react with one another in more than one reaction, resulting in a complex reaction network. Mathematically, a complex system consisting of N components and M reactions can be represented as

$$\sum_{i-1}^{N} \nu_{ij} r_j = 0, \qquad j = 1,2,3, \ldots M \qquad (11.8)$$

where ν_{ij} is the stoichiometric coefficient of A_i in the jth reaction. The rate equation for this system may be expressed concisely as

TABLE 11.3
Analytical Solutions (Design Equations) for Simple Reactions in a Batch Reactor (Also Valid for PFR with t Replaced by $\bar{t}$)

Reaction	Rate Equation	Analytical Solution[a]
1. $A \to R$	$-r_A = k[A]$	$kt = \ln\left(\frac{1}{1-X_A}\right), \frac{[A]}{[A]_0} = e^{-kt}$
2. $2A \to R$	$-r_A = k[A]^2$	$k[A]_0 t = \left[\frac{X_A}{1-X_A}\right], \frac{[A]}{[A]_0} = \frac{1}{1+k[A]_0 t}$
3. $3A \to R$	$-r_A = k[A]^3$	$k[A]_0^2 t = \frac{1}{2}\left[\frac{1}{(1-X_A)^2} - 1\right], 2kt = \frac{1}{[A]^2} - \frac{1}{[A]_0^2}$
4. $A \to R$	$-r_A = k[A]^n$	$k[A]_0^{n-1} t = \frac{1}{(n-1)}\left[(1-X_A)^{1-n} - 1\right], n \neq 1$
5. $A + B \to R$ $\psi_B = 1$	$-r_A = k[A][B]$	$k[A]_0 t = \left[\frac{X_A}{(1-X_A)}\right], t = \frac{1}{k}\left(\frac{1}{[A]} - \frac{1}{[A]_0}\right)$
6. $A + B \to R$ $\psi_B \neq 1$	$-r_A = k[A][B]$	$k[A]_0 t = \frac{1}{(\psi_B - 1)}\ln\left[\frac{\psi_B - X_A}{\psi_B(1-X_A)}\right]$
7. $\upsilon_A A + \upsilon_B B \to R$ $\psi_B = \nu_B/\nu_A$	$-r_A = k[A][B]$	$k[A]_0 t = \frac{1}{\psi_B}\left[\frac{X_A}{1-X_A}\right]$
8. $A + 2B \to R$ $\psi_B = 2$	$-r_A = k[A][B]^2$	$k[A]_0^2 t = \frac{1}{8}\left[\frac{1}{(1-X_A)^2} - 1\right]$
9. $A + B \to R$ $\psi_B = 1$	$-r_A = k[A][B]^2$	$k[A]_0^2 t = \frac{1}{2}\left[\frac{1}{(1-X_A)^2} - 1\right]$
10. $A + 2B \to R$ $\psi_B \neq 2$	$-r_A = k[A][B]^2$	$k[A]_0^2 t = \frac{1}{(2-\psi_B)^2}\left[\ln\frac{\psi_B - 2X_A}{\psi_B(1-X_A)} + \frac{2X_A(2-\psi_B)}{\psi_B(\psi_B - 2X_A)}\right]$
11. $\upsilon_A A + \upsilon_B B \to R$ $\psi_B \neq \upsilon_B/\upsilon_A$	$-r_A = k[A][B]$	$k[A]_0 t = \frac{1}{\left[\psi_B - \left(\frac{\upsilon_B}{\upsilon_A}\right)\right]}\ln\left[\frac{\psi_B - \left(\frac{\upsilon_B}{\upsilon_A}\right)X_A}{\psi_B(1-X_A)}\right]$
12. $\upsilon_A A + \upsilon_B B \to R$ $\psi_B = \upsilon_B/\upsilon_A$	$-r_A = k[A]^n[B]^m$	$k[A_0]^{m+n-1} t = \frac{1}{\psi_B(m+n-1)}\left[\frac{1}{(1-X_A)^{m+n-1}} - 1\right]$

[a] LHS = $k[A_0]^{n-1}t$, where k has the units of an nth [or $(m + n)$]-order reaction, $\left(\frac{\text{m}^3}{\text{mol}}\right)^{n-1}\frac{1}{s}$; $\psi_B = \frac{[B]_0}{[A]_0}$.

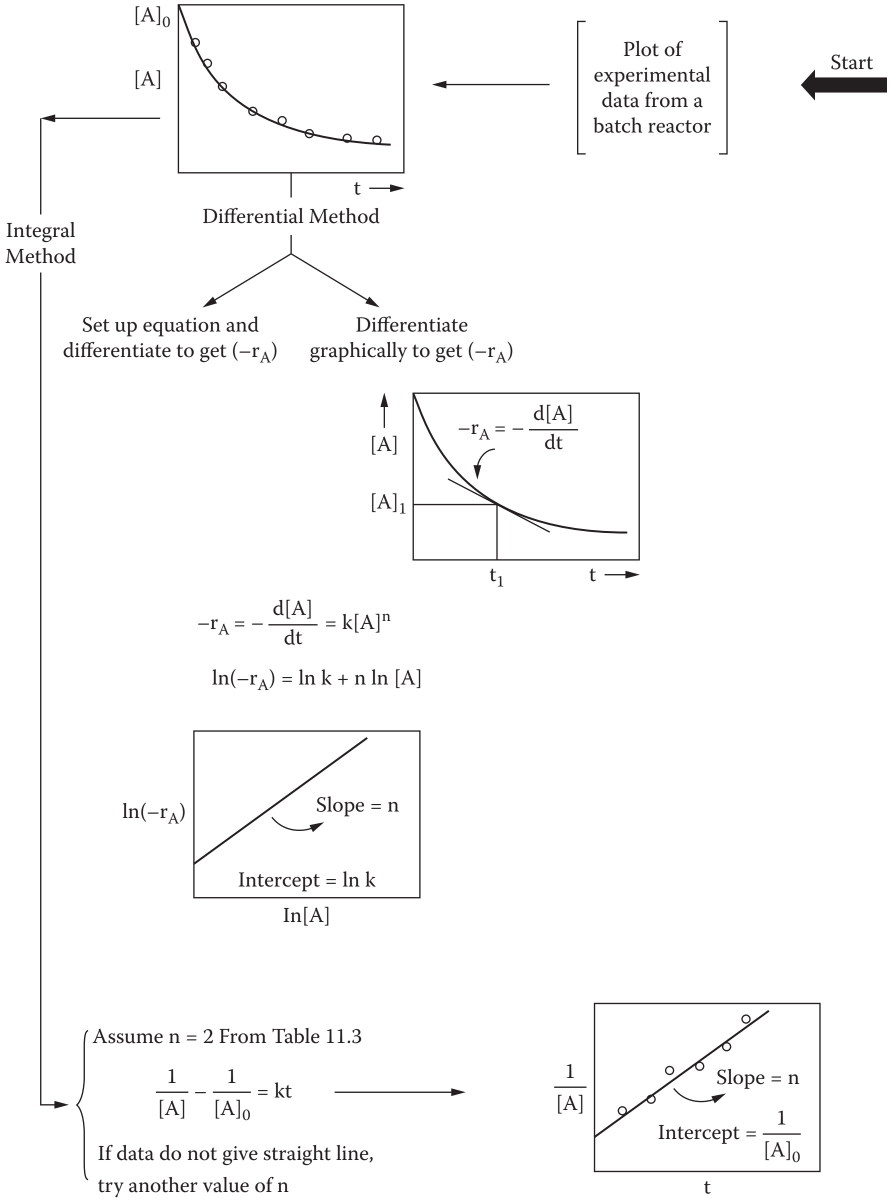

FIGURE 11.2 Determination of reaction rate parameters from differential and integral reactor data.

TABLE 11.4
Rate Equation in Terms of Partial Pressures for an Illustrative Reaction $A \to R + 2S$, and Its Use in Extracting Kinetic Parameters

Reaction:[a]

$$A \to R + 2S$$

Rate equation:

$$-r_A = -\frac{d[A]}{dt} = k[A]^n \tag{1}$$

For isothermal constant-volume operation, Table 11.1 gives

$$V = V_0(1+\varepsilon_A X_A)\left(\frac{P_0}{P}\right)\left(\frac{T}{T_0}\right), \text{ or}$$

$$X_A = \frac{1}{y_{A0}\delta_A P_0}(P - P_0) \tag{2}$$

$$= \frac{1}{P_{A0}\delta_A}(P - P_0)$$

Expressed in concentration units,

$$[A] = [A]_0(1 - X_A) \tag{3}$$

Combining Equations (2) and (3),

$$[A] = \frac{P_{A0} - [(P - P_0)/\delta_A]}{R_g T} \tag{4}$$

Now, $\delta_A = 2$, and $p_{A0} = P_0$ (if pure A is used), thus

$$[A] = \frac{3P_0 - P}{2R_g T} \tag{5}$$

Combining Equations (1) and (5),

$$\frac{dP}{dt} = \breve{k}(3P_0 - P)^n \tag{6}$$

where

$$\breve{k} = k(2R_g T)^{1-n} \tag{7}$$

Integration of Equation (6) for $n = 1$ gives

$$\ln\frac{2P_0}{3P_0 - P} = \breve{k}t \tag{8}$$

Thus, if the reaction is first order, either the differential method [Equation (6)] or the integral method [Equation (8)] can be used. If n – 1, only the differential method can be used.

[a] Classical example: gas-phase decomposition of di-*t*-butyl peroxide (Peters and Skorpinski, 1965; see also Fogler, 1999; Doraiswamy, 2001).

$$\frac{d(\mathbf{c}V)}{dt} = \nu\mathbf{r} \tag{11.9}$$

where $\mathbf{c}$ is a vector ($N \times 1$ matrix) of component concentrations, ν is an ($N \times M$) matrix of stoichiometric coefficients, and $\mathbf{r}$ is a vector ($M \times 1$ matrix) of reaction rates.

11.2.6.1 Independent Reactions

The reaction network as represented by Equation (11.9) refers only to those among all possible reactions that may be regarded as independent. A set of reactions is said to be independent if no reaction from the set can be obtained by algebraic additions of other reactions (as such or in multiples thereof), and each member contains one new species exclusively. For any given set of reactions (including those that are not independent), the number of independent reactions is the rank of the reaction matrix (see Aris 1965; 1969; Nauman 1987; Doraiswamy 2001).

11.2.6.2 Reaction Coordinate

Where complex reactions are concerned, conversion of a reactant is much less important than the actual moles converted in each step. This has the advantage of reducing the number of equations to be solved. Thus, for the reaction

$$A + 2B \rightarrow 2R \qquad \text{R11.6a}$$

$$2C + 3D \rightarrow S \qquad \text{R11.6b}$$

we can write

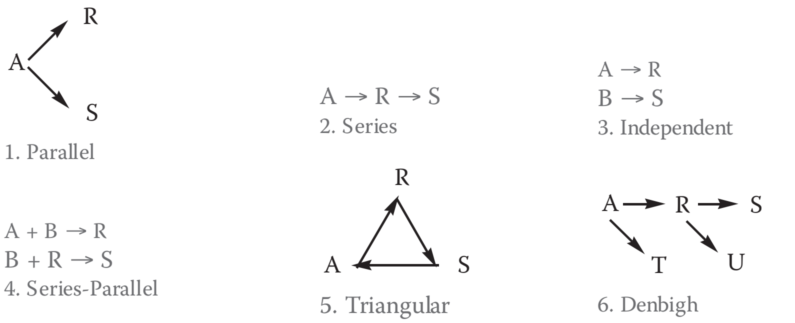
$$-\frac{N_A - N_{A0}}{1} = -\frac{N_B - N_{B0}}{2} = \frac{N_R - N_{R0}}{2} = \xi_1 \tag{11.10}$$

$$-\frac{N_C - N_{C0}}{2} = -\frac{N_D - N_{D0}}{3} = \frac{N_S - N_{S0}}{1} = \xi_2 \tag{11.11}$$

where ξ_1 and ξ_2 are called the *reaction coordinates* for reactions R11.6a and b, respectively. The compositions of all of the components are written in terms of these coordinates. Then, the following facts emerge: the number of equations is six if written in terms of the rates of disappearance/formation of the individual components, and two if written in terms of the reaction coordinates. This reduction in number is particularly important in networks involving numerous reactions (in the hundreds in petroleum cracking).

11.2.6.3 Some Common Classes of Complex Reactions

Network analysis can be simplified for well known classes of complex reactions such as parallel reactions, series (or consecutive) reactions, independent reactions, series-parallel reactions, triangular reactions, and the so-called Denbigh reaction. These reactions may be represented as follows:



R11.7

Analytical solutions can often be found (see, e.g., Levenspiel 1999; Doraiswamy 2001). These are for batch reactors (also applicable to plug-flow reactors). Solutions for mixed-flow reactors (see Section 11.2.7.2) will be different.

11.2.7 Ideal Reactors

11.2.7.1 Batch Reactor

The material balance for any reactor can be written as

$$\textit{Input} - \textit{output} = \textit{accumulation} + \textit{disappearance (or formation)} \tag{11.12}$$

For a batch reactor, the input and output terms are absent, and we have for reactant *A*

$$-r_A = \frac{dN_A}{dt}\frac{1}{V} \tag{11.13}$$

Integration with no volume change, with $N_A = N_{A0}(1 - X_A)$, gives the following:

*n*th order

$$k[A]_0^2 t = \frac{1}{n-1}(1 - X_A)^{1-n},\ n \neq 1 \tag{11.14}$$

First order

$$kt = 1n\left(\frac{1}{1 - X_A}\right) \tag{11.15}$$

The corresponding general equation for a reaction with volume change is

$$t = [A]_0 \int_0^{X_A} \frac{dX_A}{(-r_A)(1 + \varepsilon_A X_A)} \tag{11.16}$$

11.2.7.2 Continuous Flow Reactors

A reactor is now considered through which *A* is continuously passed and the products continuously withdrawn with no accumulation. The simplest case is the plug-flow reactor (PFR) in which elements of the fluid move unidirectionally as plugs, with no feedback from the downstream to the upstream side. Since the composition changes with distance, the material balance will hold only for a finite volume element *dV* with a conversion of dX_A and gives

$$F_{A0}dX_A = (-r_A)dV \tag{11.17}$$

On integration and assuming no volume change, this gives

$$\frac{V}{F_{A0}} = \int_0^{X_A} \frac{dX_A}{(-r_A)} \tag{11.18}$$

or in terms of residence time as

$$\bar{t} = \frac{V[A]_0}{F_{A0}} = [A]_0 \int_0^{X_A} \frac{dX_A}{(-r_A)} \tag{11.19}$$

Integration of this equation leads to Equation (11.14) for an *n*th order reaction and Equation (11.15) for a first-order reaction, with $\bar{t}$ replacing *t*. With volume change, the corresponding equation is (11.16). Thus the batch and plug-flow reactors are exactly identical.

A mixed-flow reactor (MFR), also known as the continuous stirred tank reactor (CSTR), is fully mixed at the molecular level, and the composition of the exiting stream is identical to that within the reactor. In this case, the material balance of Equation (11.12) is applied for the entire reactor and not just for a differential element as in a PFR. No integration is needed; the equation becomes

$$Q_0[A]_0 - (-r_{Ae})V = Q_e[A]_e \tag{11.20}$$

where $(-r_{Ae})$ is the final (exit) rate. Assuming $Q_o = Q$, we get

$$\tau = \frac{[A]_0 X_{Ae}}{-r_{Ae}} \tag{11.21}$$

that for a first-order reaction becomes

$$X_{Ae} = \frac{k\bar{t}}{1 + k\bar{t}} \tag{11.22}$$

The flows in PFR and MFR can be precisely defined by simple mathematical equations, and the batch reactor is simply the batch version of the PFR. A reactor is now considered where the flow is between plug and fully mixed, i.e., a nonideal reactor. Two common examples of such partially mixed reactors are the recycle reactor and the tanks-in-series reactor. In the recycle reactor, part of the outlet from a reactor is recycled at the inlet, thus establishing some mixing between the downstream and the upstream fluids. In the tanks-in-series reactor, several mixed-flow reactors are operated in series. A single MFR is fully mixed, whereas an infinite number of MFRs (or a

sufficiently large number) is identical to plug flow. The degree of mixing in the two partially mixed reactors can be controlled by the recycle ratio (*R*) in one case and the number of tanks (*N*) in the other. Yet another nonideal reactor is the variable volume reactor, in which only a fraction of the batch reactor contents is emptied. In other words, V^* (= V/V_M, where V_M is the maximum volume) is fixed at a value between 1 (when the reactor functions as an MFR) and 0 (when it functions as a batch reactor). The relationship between the principal parameters of the three reactors is given by

$$V^* = \frac{R}{1+R} = \frac{1}{N} \tag{11.23}$$

11.2.7.3 The Role of Mixing

The concept of mixing is inherent in the recycle and tanks-in-series reactors, since deviations from plug or fully mixed flow are expressed in terms of *R* and *N*. Rigorous accounting of mixing must, however, be based on more fundamental concepts of mixing. In many situations, not all elements of a fluid flowing through a reactor leave the reactor at the same time. That is, the residence times for different elements vary. The residence time distribution (RTD) is denoted by a curve that represents the amount of fluid with times between t and $t + dt$ flowing out in the exit stream. When normalized with respect to the total flow (i.e., expressed as fraction of the total flow), this RTD satisfies the condition

$$\int_0^\infty \delta(t)dt = 0 \tag{11.24}$$

where $\delta(t)$ is the distribution function. The mean residence time is then given by

$$\bar{t} = \int_0^\infty t\delta(t)dt = 0 \tag{11.25}$$

For the two ideal cases referred to earlier, those corresponding to plug flow and fully mixed flow, the distribution functions take the following forms:

Plug flow (Dirac delta function):

$$\delta(t) = g(\bar{t}) \tag{11.26}$$

which shows $\delta(t) = 0$ at all times except at $t = \bar{t}$.

Mixed flow (exponential distribution):

$$\delta(t) = \frac{1}{\bar{t}}\exp\left(-\frac{t}{\bar{t}}\right) \tag{11.27}$$

The two distributions are explained in Figure 11.3.

In the equations presented above, the term "fully mixed" represents mixing at the molecular level. There is another mixing condition in which clumps or aggregates of molecules enter the reactor and flow through it without interacting with one another. Within each clump, however, there is complete mixing of molecules, and the residence time of each molecule is the same as that of

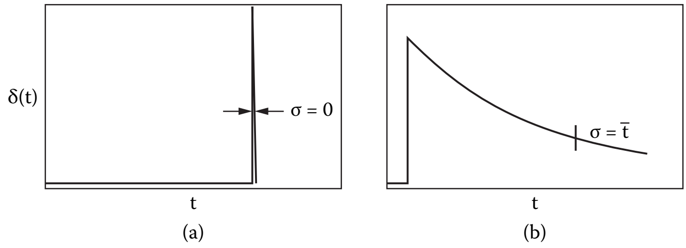


FIGURE 11.3 Plots showing Dirac delta and exponential distributions (for plug-flow and mixed-flow reactors, respectively).

the clump itself. The clumps are fully separated from one another, and this flow is known as *segregated flow*. Assuming that each clump behaves as a batch reactor and that the clumps are exponentially distributed, the following expression for the exit reactant concentration as a function of time can be derived for an *n*th-order reaction:

$$\left(\frac{[\bar{A}]}{[A]_0}\right)_e = \frac{1}{\bar{t}}\int_0^{\infty}[1 + (n-1)[A]_0^{n-1}kt]^{1/1-n}e^{-t/\bar{t}}dt \tag{11.28}$$

11.3 REACTIONS WITH AN INTERFACE

Many industrially important reactions are characterized by an interface across which heat/mass transfer occurs. They are called *heterogeneous reactions*. They include fluid-fluid reactions, gas-solid catalytic reactions, gas-solid noncatalytic reactions, and solid-solid reactions.

11.3.1 Gas-Solid Catalytic Reactions

Over 70% of the chemicals produced today use a catalyst. The total annual purchasing price of catalysts amounts to about $10 billion, and each dollar's worth of catalyst often produces $100 to $1000 worth of products.

Catalysts are generally insoluble solids (heterogeneous catalysts, including bound catalysts), but they can also be soluble (homogeneous catalysts). Table 11.5 lists a few processes employing solid catalysts. The mechanisms for homogeneous catalysts are quite well understood today, and consequently the design of a homogeneous catalyst from first principles is possible. The advantages of homogeneous catalysts can often be transmitted to their heterogeneous counterparts (with an interface), e.g., immobilize a homogeneous catalyst on a solid support. We can realize the advantages of a solid catalyst (e.g., dispensing with the need to recover and purify the catalyst and permitting the use of the popular packed-bed reactor) and of homogeneous catalysts (e.g., their enzyme-like selectivity and greater amenability to design from first principles). Such immobilized catalysts are also discussed here.

11.3.1.1 Catalysis by Solids

Solid catalysts are widely used such as in the sulfuric acid, ammonia, fertilizer, petroleum, and petrochemical industries. The trend is to produce more organic chemicals by catalytic processes (usually employing solid catalysts). These catalysts can be classified in two ways.

1. Those that represent categories that cut across different types of reactions, such as zeolites.
2. Those that are specific to different classes of reactions, such as hydrogenation, oxidation, isomerization, and so on.

TABLE 11.5
Some Examples of Industrially Important Catalytic Reactions/Reactors

Desulfurization of petroleum feedstock (FBR), catalytic cracking (MBR or Fl BR), hydrodewaxing (FBR), steam reforming of methane or naphtha (FBR), water-gas shift (CO conversion) reaction (FBR-A), ammonia synthesis (FBR-A), methanol from synthesis gas (FBR), oxidation of sulfur dioxide (FBR-A), isomerization of xylenes (FBR-A), catalytic reforming of naphtha (FBR-A), reduction of nitrobenzene to aniline (FBR), butadiene from n-butanes (FBR-A), ethylbenzene by alkylation of benzene (FBR), dehydrogenation of ethylbenzene to styrene (FBR), methyl ethyl ketone from sec-butyl alcohol (by dehydrogenation) (FBR), formaldehyde from methanol (FBR), disproportionation of toluene (FBR-A), dehydration of ethanol (FBR-A), dimethylaniline from aniline and methanol (FBR), vinyl chloride from acetone (FBR), vinyl acetate from acetylene and acetic acid (FBR), phosgene from carbon monoxide (FBR), dichloroethane by oxichlorination of ethylene (FBR), oxidation of ethylene to ethylene oxide (FBR), oxidation of benzene to maleic anhydride (FBR), oxidation of toluene to benzaldehyde (FBR), phthalic anhydride from o-xylene (FBR), furane from butadiene (FBR), acrylonitrile by ammoxidation of propylene (Fl BR)

Note: FBR = fixed-bed reactor (usually multitubular), FBR-A = adiabatic fixed-bed reactor, Fl BR = fluidized bed reactor, MBR = moving-bed reactor.

Adapted from Doraiswamy, 2001.

Table 11.6 adapted from Doraiswamy (2001) provides a partial list of these categories. The main features and applications of these two categories of catalysts are discussed in more detail by Doraiswamy (2001). Of these zeolites, TS-1 catalysts and homogeneous catalysts immobilized on solid supports deserve special mention.

Zeolites were first employed in the petroleum industry and then the petrochemicals industry through Mobil's ZSM-5 catalysts. They are crystalline aluminosilicates possessing characteristic pore and cage structures. Chemical transformations have three restrictions imposed by the lattice structure, collectively referred to as *shape selectivity*:

1. Reactant selectivity (where only certain reactant molecules can enter the pores)
2. Product selectivity (where only certain product molecules can leave the pores)
3. Transition state selectivity (where only certain transition state dimensions are viable)

Zeolites function as Brönsted or Lewis acid catalysts or (less frequently) as basic catalysts. Examples of the former are alkylation and isomerization of aromatics, such as the isomerization of xylenes; an example of the latter is the use of cesium zeolite in the synthesis of the key intermediate, 4-methylthiazole, used in the preparation of the anthelmintic, thiabendazole.

TS-1 catalysts are zeolites containing titanium silicate used in the oxidation of organic substrates by hydrogen peroxide. Only those cations that meet certain specific steric requirements can fit into the tetrahedral positions of the zeolite lattice. One such cation is titanium. TS-1 catalysts are very powerful and selective oxidizing catalysts and are potentially among the most useful catalysts developed. For example, phenol can be oxidized to catechol and hydroquinone.

Because homogeneous catalysts lend themselves to *a priori* design (although much still must be done in this direction) and solid catalysts do not, "bottling" of a homogeneous catalyst within a solid provides a good practical means of combining the advantages of the two types of catalysts. There are four classes of such immobilized, bottled, or "heterogenized" homogeneous catalysts, as shown in Table 11.7 (Doraiswamy, 2001) along with important subcategories of each. These catalysts find wide application in the case of enzymes. A particularly important class of heterogenized catalysts is the supported aqueous phase (SAP) catalyst. This is a distinctive class, since here the catalyst is first solubilized in the aqueous phase (which in itself is an important advance), in contrast to the common case where it is soluble in the organic phase and is then heterogenized

TABLE 11.6
Classification of Solid Catalysts in Organic Synthesis

Solid Catalysts			
Principal Types of Catalysts	**Principal Types of Reactions**	**Heterogenized Catalysts**	**Role of Solvent/Additive**
Improved traditional catalysts	Oxidation (Sheldon, 1981; Jorgensen, 1989)	Supported liquid phase catalysts (Rony and Roth 1975; Chan and Rinker 1978; Doraiswamy and Sharma 1984; Arhancet et al. 1990, 1991)	Physical effects (Gilbert and Mercier 1993)
Zeolites (Corma 1991; Perot and Guisnet 1990; Hoelderich and vanBekkum 1991)	Hydrogenation (Johnstone et al. 1985; Kijenski et al. 1988; Kumbhar et al. 1994)	Catalysts bound to polymer or inorganic supports (including zeolites) (Bailey and Langer 1981; Sherrington and Hodge 1988; Clark et al. 1992)	Chemical effects (Gilbert and Mercier 1993)
Asymmetric catalysts (Aitken and Kilenyi 1992; Federsel 1993; Sheldon 1981)	Various other reactions, e.g., alkylation, isomerization, etc.	Immobilized enzyme catalysts (Tanaka et al. 1980)	
Ion-exchange resins (Olah et al. 1986; Chakrabarti and Sharma 1993)

[supported organic phase (SOP) catalyst]. Water-soluble homogeneous catalysts often have the advantage that the product is returned to the organic phase while the catalyst remains in the aqueous phase, thus minimizing separation problems. This advantage continues in the supported version. A useful application of SAP catalysts is the use of water-soluble homogeneous catalyst (SAP-Ru-BINAP-4SO_3Na) supported on controlled pore glass in the enantioselective hydrogenation of 2-(6'-methoxy-2'-naphthyl) acrylic acid to naproxen (Wan and Davis, 1993a, b).

This brief overview of solid catalysts addresses only the nature, class, and catalytic properties of a variety of catalysts. Modeling the kinetics of a reaction occurring on a solid surface is a challenging task and is firmly rooted in the principles of surface science. As this is still an evolving area, empirical shortcuts are often invoked. Furthermore, for solid catalysts, the reactant(s) must first diffuse into the solid, and product(s) must diffuse out of it. Also, the heat evolved or required must be transported between the solid and the fluid bulk. Hence, diffusion accompanied by reaction becomes a major consideration. These *microenvironmental* aspects of solid catalysts are briefly described below.

11.3.1.2 Kinetics of Reactions on Solid Surfaces

In formulating rate equations for homogeneous reactions, concentrations were used to represent the qualitative presence of different components. What is important in catalytic reactions is the "surface concentration" or fractional coverage of the surface by the adsorbed species. Because there is no easy way of directly measuring surface coverage, theoretical equations are used to relate the fractional surface coverage to the corresponding concentration or partial pressure in the homogeneous phase from where the molecules strike the surface and are adsorbed on it. These equations are known as *isotherms*, the most common being the Langmuir isotherm. This isotherm is based on the assumption that the surface behaves ideally. An ideal surface is one in which

1. All active centers on the surface, i.e., centers on which catalysis can occur, are equally active, and the heat of adsorption is independent of surface coverage by previously adsorbed molecules, and
2. There is no interaction between the adsorbed molecules.

For the case of a single molecular species *A*, the equation is

$$\theta_A = \frac{K_A p_A}{\left(1 + K_A p_A\right)} \tag{11.29}$$

and for a number of competitively adsorbing species, *A, B, C,* …,

$$\theta_A = \frac{K_A p_A}{\left(1 + K_A p_A + K_B p_B + K_C p_C + \ldots\right)} \tag{11.30}$$

where K_A, K_B, K_C, … are adsorption equilibrium constants of *A, B, C*, …, atm^{-1}, and p_A, p_B, p_C, … are the partial pressures of *A, B, C*, …, atm. In addition to equations for θ_A, θ_B, θ_C, …, it is also necessary to have expressions for the fraction of the surface not covered by any molecule (since the rate of adsorption will also depend on this). This fraction is generally represented by θ_v (fraction of vacant sites) and, for a system consisting of molecules *A, B, C*, …, is given by

$$\theta_v = \frac{1}{\left(1 + K_A p_A + K_B p_B + K_C p_C + \ldots\right)} \tag{11.31}$$

If the different species involved adsorb noncompetitively, each on a different class of sites, then there is no competition for the same sites. Thus, for the noncompetitive adsorption of two species *A* and *B*, the expressions for θ would be

$$\theta_A = \frac{K_A p_A}{\left(1 + K_A p_A\right)} \tag{11.32}$$

$$\theta_B = \frac{K_B p_B}{\left(1 + K_B p_B\right)} \tag{11.33}$$

The equations get more complicated as the ideal surface assumptions are relaxed, but the Langmuir isotherm is adequate for most engineering purposes. Surface nonideality is discussed, among others, by Boudart and Djeja Mariadasseu (1984), Thomas and Thomas (1999), and Doraiswamy (1991).

Methods of formulating rate equations using the Langmuir isotherm have been extensively documented (e.g., Yang and Hougen, 1950; Barnard and Mitchell, 1964; Satterfield, 1970, 1991; Doraiswamy and Sharma, 1984; Froment and Bischoff, 1990; Butt, 1999; Thomas and Thomas, 1999). They all depend on the concept of the rate-determining step.

11.3.1.2.1 The Rate-Determining Step

The rate-determining step is often defined as the slowest of a series of steps that occur. In catalysis, adsorption of reactant, surface reaction, and desorption all occur in series. Because all of these occur at steady state, they should all proceed at the same rate. Therefore, the word "slowest" is a misnomer. The controlling step is really the step that consumes most of the driving force. Even in the case where all of the steps are fast enough to have reached equilibrium, i.e., the steady overall rate = ($rate_{forward} - rate_{reverse}$), there will be a controlling step. This is the step for which the ratio of the two rates is significantly different from 1. For all other steps, the forward and reverse rates are both so high that the ratio tends to be almost unity.

11.3.1.2.2 Formulation of Models for Competitive Adsorption

Consider the reaction

$$A \rightarrow R \tag{R11.8}$$

Assuming the surface reaction to be the controlling step, the rate equation is given by

$$-r_A = k\theta_A \tag{11.34}$$

Incorporating the Langmuir expression for θ_A,

$$-r_A = \frac{kK_A p_A}{\left(1 + K_A p_A + K_R p_R\right)} \tag{11.35}$$

where the units of k are the units of the rate. This is a typical so-called Langmuir–Hinshelwood–Hougen–Watson (LHHW) model.

For the reaction

$$A \rightarrow R + S \qquad \text{R11.9}$$

again assume that surface reaction is controlling, but note that two product molecules are formed. Thus, a vacant site must be available next to the one on which A is adsorbed, to accommodate the second molecule. This leads to the equation

$$-r_A = k\theta_A\theta_v \tag{11.36}$$

Substituting for θ_A and θ_v, we get

$$-r_A = \frac{k\ K_A p_A}{\left(1 + K_A p_A + K_R p_R + K_S p_S\right)^2} \tag{11.37}$$

For the reaction

$$A + B \rightarrow R + S \qquad \text{R11.10}$$

the rate equation (for surface reaction control) is

$$-r_A = \frac{k\ K_A\ K_B\ p_A\ p_B}{\left(1 + K_A p_A + K_B p_B + K_R p_R + K_S p_S\right)^2} \tag{11.38}$$

Where one of the molecules, say A, is dissociated, it can be shown that $K_A P_A$ should be substituted by $\sqrt{K_A p_A}$.

All LHHW equations can be written in a general consolidated form as

$$\text{Rate} = \frac{\text{(kinetic term) (potential term)}}{\text{(adsorption term)}^{\text{n}}} \tag{11.39}$$

where n is the number of sites involved. Yang and Hougen (1950) have tabulated expressions for each of the three terms for four major types of reactions. In addition to surface reaction control models, they have also considered adsorption and desorption control models. When one of the reactants is not adsorbed, say B in R11.10, then θ_B is replaced simply by p_B and Equation (11.38) is suitably modified. These are the Eley–Rideal models. Selected equations involving different rate-controlling steps, as formulated from Yang and Hougen's tables, were listed by Doraiswamy (2001).

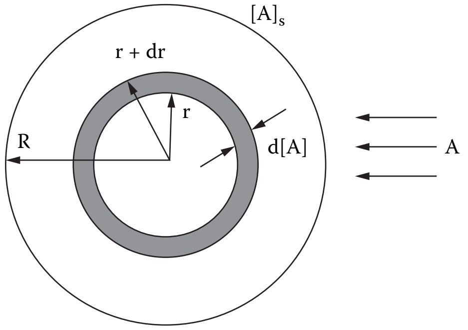

FIGURE 11.4 A differential section of a spherical pellet.

11.3.1.2.3 Formulation of Models for Noncompetitive Adsorption

Consider reaction R11.10 and assume that A and R are competitively adsorbed on one set of surface sites and B and S on another set of sites. A and R do not compete with B and S for the same sites. Then, from equations similar to (11.32) and (11.33), we can write

$$-r_A = \frac{k\ K_A\ K_B\ p_A\ p_B}{\left(1+K_A p_A + K_R p_R\right)\left(1+K_B p_B + K_S p_S\right)} \tag{11.40}$$

11.3.1.2.4 Steps in Selecting an LHHW Model

The first step is to develop equations for all possible controlling steps. They will include, among many possibilities, dissociation of one or more of the reactants, the common single-site mechanism for reactant decomposition, the dual-site mechanism where two sites are involved in the decomposition, and half-site mechanism where two molecules are adsorbed on a single site. Having formulated sufficient models (usually 15 to 20 are even excess of 100), various experimental and sophisticated statistical methods are available for selecting the most probable model, as described in many texts (e.g., Froment and Bischoff, 1990). A comprehensive stepwise procedure (not discussed here) is suggested by Doraiswamy (2001).

11.3.1.3 Role of Diffusion within the Pellet (Internal Diffusion)

For a reaction within a solid catalyst, the reactant must first diffuse into it, leading to a lowering of its concentration in the inner regions of the solid. Clearly, even as A diffuses inward, it is reacting to form the product, but at a progressively diminishing rate as it moves inward. The actual rate constant is the true or intrinsic rate constant multiplied by an *effectiveness factor,* which is a function of the rate constant, diffusion coefficient, and pellet shape and size. Being a codeterminant of the rate, it is an important factor in the analysis and design of catalytic reactors.

11.3.1.3.1 Isothermal Effectiveness Factors

Consider a first-order reaction in a spherical pellet (Figure 11.4). The following continuity equation can be written:

$$\frac{d^2\left[\hat{A}\right]}{d\hat{R}} + \frac{2}{\hat{R}}\frac{d\left[\hat{A}\right]}{d\hat{R}} = \phi_{s1}^2\left[\hat{A}\right]^n \tag{11.41}$$

where ϕ_{s1} is called the Thiele modulus for a first-order reaction in a spherical pellet and is defined by

$$\phi_{s1} = R\sqrt{\frac{k_v}{\mathbf{D}_{eA}}} \tag{11.42}$$

Equation (11.41) can be solved for the boundary conditions

$$\begin{aligned} \left\lfloor \hat{A} \right\rfloor &= 1 \qquad \text{Surface} \\ \frac{d\left\lfloor \hat{A} \right\rfloor}{d\hat{R}} &= 0 \qquad \text{Center} \end{aligned} \tag{11.43}$$

to give

$$\left\lfloor \hat{A} \right\rfloor = \frac{\sinh\left(\phi_{s1}\hat{R}\right)}{\hat{R}\sinh\phi_{s1}} \tag{11.44}$$

An effectiveness factor is now defined as

$$\varepsilon = \frac{\text{actual rate based on average concentration within the pellet}}{\text{rate based on surface concentration throughout the pellet}} \tag{11.45}$$

leading to

$$\begin{aligned} \varepsilon &= \frac{3}{\phi_{s1}}\left(\frac{1}{\tanh\phi_{s1}} - \frac{1}{\phi_1}\right) \\ &= \frac{3}{\phi_{s1}^2}\left(\phi_{s1}\text{cotanh}\phi_{s1} - 1\right) \end{aligned} \tag{11.46}$$

Similar equations can be derived for a flat plate and a cylinder. Instead of writing different equations for different shapes, the following single continuity equation can be written for a first-order reaction by defining a generalized reduced length parameter ξ (*r/R* for a sphere or a cylinder and ℓ/L for a flat plate):

$$\frac{d^2\left[\hat{A}\right]}{d\xi} + \frac{\beta}{\xi}\frac{d\left[\hat{A}\right]}{d\xi} = \phi_1^2\left[\hat{A}\right] \tag{11.47}$$

where β is a shape factor with values of 2 for a sphere, 1 for a cylinder, and 0 for a flat plate. The Thiele modulus ϕ_1 (with the shape suffix *s* removed) is a generalized modulus for all shapes for a first-order reaction given by

$$\phi_1 = s\sqrt{\frac{k_v}{\mathbf{D}_{eA}}} \tag{11.48}$$

where now *s* is a new length parameter (sometimes also called the *shape factor*) defined as (Aris 1957)

$$s = \frac{\text{volume of shape}}{\text{external area of shape}} \tag{11.49}$$

and is equal to $R/3$ for a sphere, $R/2$ for a cylinder, and L for a flat plate (where $2L$ is the plate thickness). The modulus can be further generalized to represent a reaction of any order in a catalyst of any shape by defining it as

$$\phi = s\sqrt{\frac{(n+1)k_v[A]_s^{n-1}}{2\mathbf{D}_{eA}}} \tag{11.50}$$

Note that both the shape and order suffixes have now been removed. A plot of ε vs. ϕ_1 is shown in Figure 11.5.

The Thiele modulus requires knowledge of the true rate constant, which may not always be available. It is more conveniently defined based on the actual measured rate of a reaction. This is called the Weisz modulus (1954) and, for a general shape with s as the diffusion length, is defined as

$$\phi_a = s^2\frac{(\text{actual rate})}{\mathbf{D}_{eA}[A]_S} = s^2\left[\frac{(\text{true rate})}{\mathbf{D}_{eA}[A]_S}\right]\varepsilon \tag{11.51}$$

A plot of ε vs. this modulus ϕ_a is included in Figure 11.5.

From Figure 11.5, there are two asymptotic regions—one at low values of the modulus (the kinetic control regime) and the other at high values of the modulus (the diffusion control regime). The intermediate regime corresponds to mixed control, both by reaction and diffusion. The point

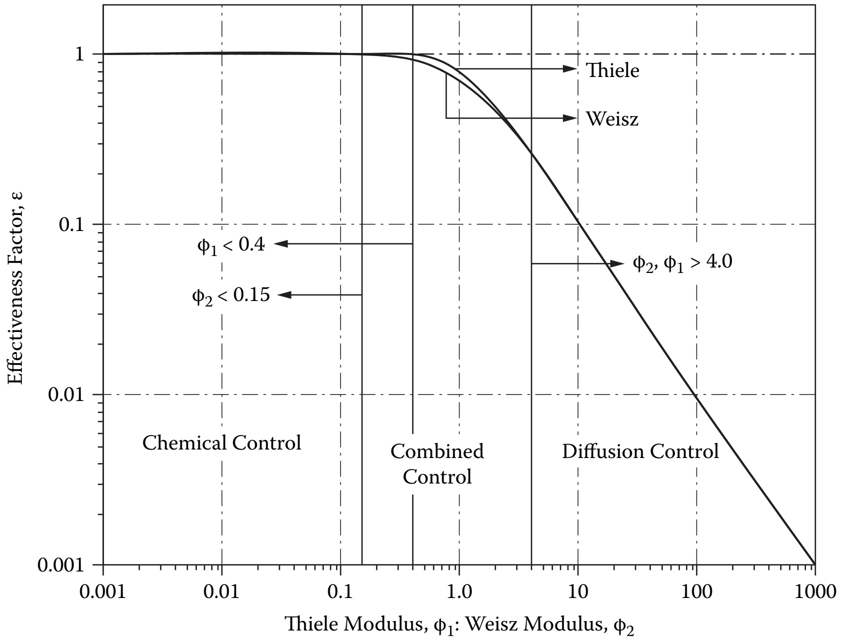

FIGURE 11.5 Effectiveness factor as a function of Thiele modulus and Weisz modulus for a simple isothermal reaction (using the generalized length s) (Doraiswamy, 2001).

of transition from chemical to diffusion control is a practically useful value, since it represents a pellet of optimal dimension. A larger pellet would attract diffusional resistance, whereas a smaller one would involve a higher pressure drop in the reactor. The various regions are clearly marked in the figures. The effectiveness factor concept developed here is based on power law models for the reaction rate. Attempts to extend the analysis to LHHW kinetics (e.g., Roberts and Satterfield, 1965, 1966; Aris, 1975; Satterfield, 1991; Doraiswamy and Sharma, 1984; Doraiswamy, 1991) are not discussed here.

11.3.1.3.2 Nonisothermal Effectiveness Factors

The equations developed above can be extended to nonisothermal situations, i.e., to reactions for which the heat effects cannot be neglected for highly exothermic reactions. The basic equation used here is the mass-energy balance:

$$\begin{pmatrix}\text{Heat generated by reaction of}\\ \text{A in the pellet}\end{pmatrix} = \begin{pmatrix}\text{Heat transferred from}\\ \text{the pellet to the surface}\end{pmatrix}$$

$$\mathbf{D}_{eA}\left(\left[A\right]_S - \left[A\right]\right)\left(-\Delta H_r\right) = k_{T,er}\left(T - T_S\right) \tag{11.52}$$

In dimensionless form, this becomes

$$\hat{T} = \frac{T}{T_S} = 1 + \beta_m\left(1 - \left[\hat{A}\right]\right) \tag{11.53}$$

where

$$\beta_m = \frac{\left(-\Delta H_r\right)\mathbf{D}_{eA}\left[A\right]_S}{k_{T,er}T_S} \tag{11.54}$$

The parameter β_m is a measure of the heat evolved (or absorbed), being close to zero for athermal reactions. The nondimensional continuity equation follows:

$$\frac{d^2\left[\hat{A}\right]}{d\xi^2} + \frac{\beta}{\xi}\frac{d\left[\hat{A}\right]}{d\xi} + \phi^2\left[A\right]^n\left[\alpha_S\beta_m\frac{1-\left[\hat{A}\right]}{1+\beta_m\left(1-\left[\hat{A}\right]\right)}\right] \tag{11.55}$$

In deriving this equation, the rate constant (appearing in ϕ) is written at surface conditions:

$$k_v = k_{vS}\exp\left[\alpha_S\left(1 - \frac{1}{\hat{T}}\right)\right] \tag{11.56}$$

where

$$\alpha_S = \frac{E}{R_g T_S} \tag{11.57}$$

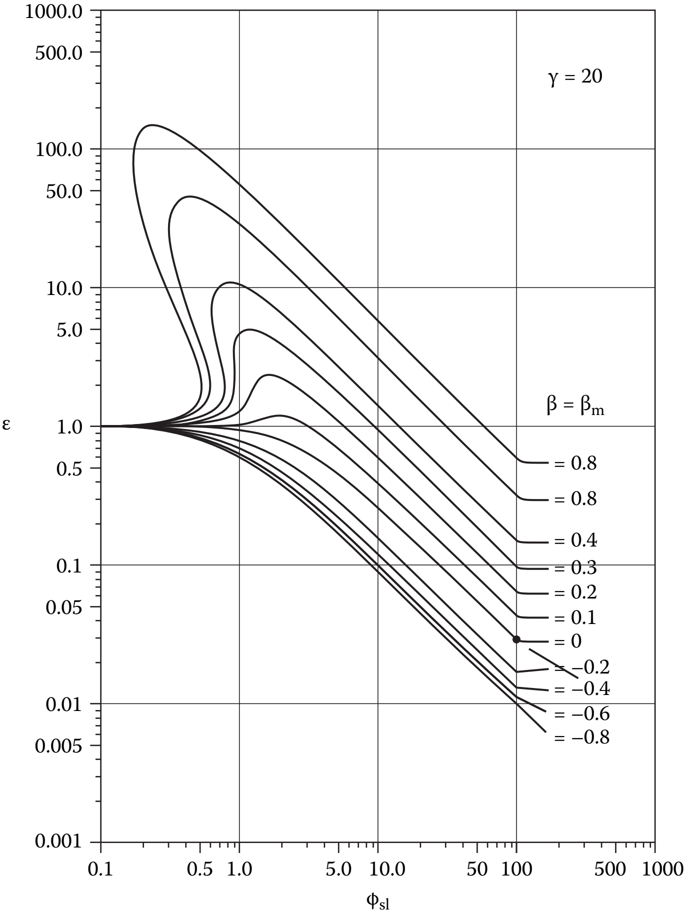

FIGURE 11.6 Effectiveness factor plots for a simple nonisothermal reaction in a spherical pellet (Weisz and Hicks, 1962).

The solution to this equation is graphically displayed in Figure 11.6 (Weisz and Hicks, 1962). β_m is a parameter in the solution. Extension of the analysis to LHHW kinetics introduces another parameter, $K_A p_A$ (see Rajadhyaksha et al., 1976), and an analytical solution is quite straightforward. A striking feature of the plots presented in the figure is that at high values of γ (= $\alpha_s \beta_m$), multiple solutions are possible (see Aris, 1975, for a detailed discussion). This corresponds to the region of very high effectiveness factors. Operating in this region (known as *operating at the edge*) is obviously very beneficial but requires very precise control strategies. In the future, operating at the edge may become common practice.

11.3.1.4 Role of External Diffusion

In the preceding section, it was assumed that the concentration at the surface is known. In other words, the surface concentration can be taken as equal to the concentration in the bulk of the fluid phase. This is true only if there is essentially no mass transfer resistance across the film (or boundary layer) surrounding the pellet. If such a resistance is present, the actual surface concentration will be lower for the reactant and higher for the product than in the fluid bulk. A Sherwood number for mass transfer would then be needed in the analysis. Several empirical correlations have been proposed that relate the Sherwood number (for mass transfer) to the Reynolds number (for flow) and Schmidt

number (for mass properties) and the Nusselt number (for heat transfer) to the Prandtl number (for thermal properties) and the Reynolds number (see Wen and Fan, 1975; Doraiswamy and Sharma, 1984).

Using the Sherwood number for the mass transfer coefficient for bulk-to-surface transfer, the following expression can be developed for a flat plate:

$$\varepsilon = \frac{\tan\phi_{p1}}{\phi_{p1}\left(1 + \frac{\phi_{p1}\tanh\phi_{p1}}{Bi_m}\right)} \tag{11.58}$$

A practical way of plotting this equation is to use the observed quantity $\phi_a = \varepsilon\phi_1^2$, where ϕ_1 is independent of shape. Such a plot (with Bi_m as parameter) has been presented by Carberry (1976).

11.3.1.5 Relative Roles of Internal and External Diffusion

The following observations can be made regarding the relative roles of heat and mass transfer in internal and external diffusion (Carberry, 1976). These roles depend on the state of the bulk fluid, gas, or liquid.

Gas-solid (catalytic) reactions. Mass transfer is likely to be more important within the pellet than in the external film, and heat transfer more important in the film than within the pellet. In other words, intraphase mass transfer and interphase heat transfer would normally be the dominant transport processes. Thus the pellet can reasonably be assumed to be isothermal.

Liquid-solid (catalytic) reactions. Heat transfer is likely to be more important within the pellet than in the surrounding film, and mass transport more important in the film than within the pellet. In other words, intraphase heat transfer and interphase mass transfer would normally be the dominant transport processes.

11.3.1.6 Effects of Various Factors on Catalyst Effectiveness

The equations and plots presented in the foregoing sections largely pertain to the diffusion of a single component followed by reaction. There are several other situations of industrial importance on which considerable information is available. They include biomolecular reactions in which the diffusion-reaction problem must be extended to two molecular species, reactions in the liquid phase, reactions in zeolites, reactions in immobilized catalysts, and extension to complex reactions (see Aris, 1975; Doraiswamy, 2001). Several factors influence the effectiveness factor, such as pore shape and constriction, particle size distribution, micro-macro pore structure, flow regime (bulk or Knudsen), transverse diffusion, gross external surface area of catalyst (as distinct from the total pore area), and volume change upon reaction. Table 11.8 lists the major effects of all these situations and factors.

11.3.1.6.1 Practical Effects of Diffusion in Complex Reactions

The analysis of complex reactions was briefly reviewed in Section 11.2.2. Diffusion can also greatly influence such complex reactions. In fact, an understanding of the role of diffusion can be incorporated in the design of the reactor system to increase or decrease the rate of certain steps and thus enhance the selectivity of the desired product. Some salient features of the effect of diffusion on some selected complex schemes are outlined in Table 11.9.

11.3.1.6.2 Criteria Based on Measurable Quantities for Eliminating Transport Disguises

In determining the true kinetic parameters of a reaction, all mass and heat transfer effects (or *disguises*, as they are sometimes called) must be eliminated. Several criteria (based on measurable

TABLE 11.8
Practical Effects of Various Factors on Effectiveness Factor in Simple Reactions

	Effect of	Nature of Effect	Reference
1.	Pore size distribution	Radial dispersion has negligible effect in kinetic regime but lowers ε in diffusion regime. Pore length dispersion has less effect.	Schmalzer (1969)
2.	Flow regime	Knudsen diffusion is much more detrimental than bulk diffusion.	Scott (1962), Otani et al. (1965)
3.	External surface	Effect is large for pellets of low porosity. Desirable to coat only the surface with catalyst in such cases.	Carberry and Kulkarni (1973) Varghese et al. (1978)
4.	Nonuniforrn environment around pellet	Where temperature gradients in a reactor are steep, the environment around a pellet will not be uniform, but is practically uninfluenced by this.	Bischoff (1968) Copelowitz and Aris (1970)
5.	Change in volume	Falls with increase in ϕ and the volume change factor θ defined as $(v_B - 1)X_{AS}$.	Weekman and Gorring (1965)
6.	Negative order kinetics	The usual adverse effect of diffusion turns to advantage	Smith et al. (1975)
7.	Dilution of pellet by inert	Beyond a certain fraction of active catalyst in the pellet, ε increases in the diffusion regime.	Ruckenstein (1970) Vargese and Wolf (1980)
8.	Configurational diffusion (where molecules are of the same size as the pores) mainly in zeolites	Catalysts involving configurational diffusion usually undergo deactivation. The highest initial activity is obtained for pellets with a uniform pore size.	Weisz (1957) Hughes and Mann (1978) Rajagopalan and Luss (1979)
9.	Surface diffusion	Effect is most noticeable at high temperatures and low partial and total pressures. A modified Thiele modulus $\phi_{mod} = \phi_{p1}\,(1/1 + h_s)$, where $k_s = D_s K_A / D_{bA}$ can be used to prepare the usual effectiveness factor plot.	Barrer (1963) Roberts and McKee (1979) Kammermeyer and Rutz (1959) Krasuk and Smith (1965) Sohn et. al (1970)
10.	Temperature	See Section (11.3.1.3.2).	—
11.	Transverse diffusion	All treatments are restricted to axial diffusion. The effect of transverse diffusion can be significant, but usually is negligible at values of $\ell/R < 50$, and may have to be considered only for very thin slabs.	Bischoff(1965)

quantities) have been formulated for this purpose. Doraiswamy (2001) has tabulated criteria for mass and heat transfer effects both for internal and external transport limitations (see Table 11.10).

11.3.1.7 Laboratory Reactors for Accurate Kinetic Data

In designing various types of commercial reactors (fixed, moving, or fluidized), an equation representing the true intrinsic kinetics of the reaction at hand is required. To obtain in equation free of any diffusional intrusions, the choice is between (1) collecting data without paying too much attention to these disguises and then correcting them through appropriate correction factors like the effectiveness factor, and (2) ensuring that diffusional disguises are absent through the criteria listed in the table. Specially designed reactors can often accomplish this latter objective. Other important factors to be considered in selecting (constructing) a suitable laboratory reactor are ease of sampling and accuracy of measurements using these samples, isothermality of the reactor, accuracy of residence time measurement, the effects of catalyst decay on conversion and selectivity measurements, and construction difficulties and cost. Many of these features associated with a variety of laboratory reactors for reactions involving a solid catalyst have been explicitly discussed by Week-

TABLE 11.9
Effect of Diffusion on Some Industrially Important Classes of Complex Reactions

Reaction[a]	Pore Structure	Intrinsic Selectivity, Yield	Actual Selectivity, Yield	Main Features
1. Independent $A \xrightarrow{1} \textcircled{R}$ $B \xrightarrow{2} S$	Monodispersed	$s = \frac{k_{v1}}{k_{v2}}$	$s_a = \left(\frac{s}{-D}\right)$	Greater diffusional resistance for reaction 2 enhances y_{Ra}
2. Parallel $A \xrightarrow{1,\,m} \textcircled{R}$ $A \xrightarrow{2,\,n} S$	Monodispersed	$s = \frac{k_{v1}}{k_{v2}}$ $Y_R = \frac{1}{1 + p_{nm}}$ where $p_{nm} = \frac{k_{v2}}{k_{v1}[A]_s^{m-1}}$	$s_a = s^{1/2}$ $\frac{Y_{Ra}}{Y_R} = \frac{n+1}{1m - n + 1}$ (Roberts 1972; Pawlawski 1961)	Y_{RA} / Y_R decreases as p_{nm} and ϕ increase

3. Consecutive $A \xrightarrow{1} R \xrightarrow{2} S$		$Y_R = \frac{S}{1-s}\left[\left(1-X_A\right)^S - \left(1-X_A\right)\right]$		
	Monodispersed	$s = \frac{k_{v1}}{k_{v2}},\ S = \frac{1}{s}$	$S = \frac{1}{s^{1/2}}$	Selectivity decreases with increasing complexity of pore structure
	Biodispersed	$s\frac{k_{v1}}{k_{v2}},\ S = \frac{1}{s}$	$S = \frac{1}{s^{1/4}}$ (Carberry 1962; Doraiswamy and Sharma 1984)	
4. Parallel-consecutive[b] 	Monodispersed	$Y_{RB} = \frac{[R]}{[B]_0}$ $Y_{RA} = \frac{[R]}{[A]_0}$	Numerical solution for $(Y_{RA})_a$, $(Y_{RB})_a$	$(Y_{RB})_a$ decreases with increase in $[B]_0/[A]_0$; it increases monotonically with X_A for $[B]_0/[A]_0 <$ 1 (approx.), beyond which it shows a maximum

[a] 1,2 refer to reactions 1 and 2, respectively; m,n are reaction orders.

[b] A second reactant B is assumed to be present for reaction 4.

TABLE 11.10
Criteria for the Absence of Mass and Heat Transfer Effects in Gas-Solid Catalytic Reactions (Doraiswamy, 2001)*

Interphase	Intraparticle	Interphase and Intraparticle
Mass transfer	Isothermal	Isothermal
1. $\eta = 1 - \dfrac{k_a d_p^{1.5}}{11\sqrt{D_b u}}$	1. $\dfrac{d_p^2 r_a}{4D_{eA}[A]_S} < 1,\ n = 1$	1. $\alpha_b\beta_{mb} + 0.3n\alpha_b\left(\dfrac{(-\Delta H)_r\, r_a d_p}{2h_{fp}T_b}\right) \le 0.05n$
Ruthven (1968)	Weisz and Prater (1954); Weisz (1957)	Mears (1971a); see also Guha and Narsimhan (1972)
		Nonisothermal
2. $\dfrac{r_a d_p}{2[A]_b k_G} < \dfrac{0.15}{n}$	2. $\dfrac{d_p^2 r_a}{4D_{eA}[A]_s} < \lvert n\rvert,\ n \ne 0$	2. $\dfrac{r_a d_p^2}{4[A]_b D_{eA}} < \dfrac{1 + 0.33\alpha_b \dfrac{(-\Delta H_r)(-r_a)d_p}{2h_{fp}T_b}}{\lvert n - \alpha_b\beta_{mb}\rvert\left(1 + 0.33n\left(\dfrac{r_a d_p}{2[A]_b k_G}\right)\right)}$
	Stewart and Villadsen (1969); Mears (1971a)	Mears (1971a)

* r_a = observed rate (mol/m^3 cat s); k_a = observed rate constant (1/s); α_b = α at bulk conditions; (β_{mb} = β_m at bulk conditions; η = external effectiveness factor; θ = volume change parameter given by $(v_B - 1)y_{As}$, where ν_B is the stoichiometric coefficient in the reaction $A \to V_B B$ and y_{As} is the mole fraction of A at the catalyst surface. See Mears (1971b, 1976) for interparticle criteria (i.e., criteria for the reactor as a whole) such as that for the absence of axial diffusion.

man (1974) and in a more general way by Doraiswamy and Tajbl (1974), Doraiswamy and Sharma (1984), Hofmann (1986), Pratt (1987), and most recently by Doraiswamy (2001).

The internal diffusional effect can be avoided by performing experiments with catalysts of different sizes under otherwise identical conditions and determining that size above which there is a lowering of conversion due to internal diffusional resistance. The external mass transfer effect can be examined by operating the reactor at different feed velocities but at the same residence time (i.e., keeping *W/F* constant). The velocity beyond which the conversion levels off should be noted and used as the minimum velocity at which to operate an integral reactor. The same method holds for a fully mixed reactor, in which the agitation parameter is the extent of stirring.

Several reactors normally used to obtain kinetic data for a nondecaying catalyst under diffusion-free conditions (as established by tests just described) are shown in Figure 11.7. The integral reactor (operated under plug-flow conditions) is the simplest, but the conversion-residence time data obtained must be differentiated to get the rates (see Figure 11.2). The differential reactor consists of a very small amount of catalyst giving conversions of 1 to 2%. This enables direct determination of the rate corresponding to the average component partial pressures in the bed. Clearly, the analytical methods used for determining the compositions of the inlet and outlet streams must be accurate. Also, since the differential element used corresponds to a small axial section of the integral reactor, it is necessary to use synthetic feeds that will contain all the components of the process stream, including impurities. The main advantage is that the measurements give the rates directly. This advantage can be retained in a CSTR with the additional advantage that integral level conversions (usually in excess of 10%) can be obtained under "differential conditions." In other words, there is no need for differentiating integral conversion data (as in a typical integral reactor). The fully mixed condition can be realized in many ways, most importantly by placing the catalyst in baskets attached to the stirrer (the Carberry reactor), by attaching the catalyst to the pot provided with a suitable internal recirculation system (the Berty reactor), or by attaching the catalyst to the

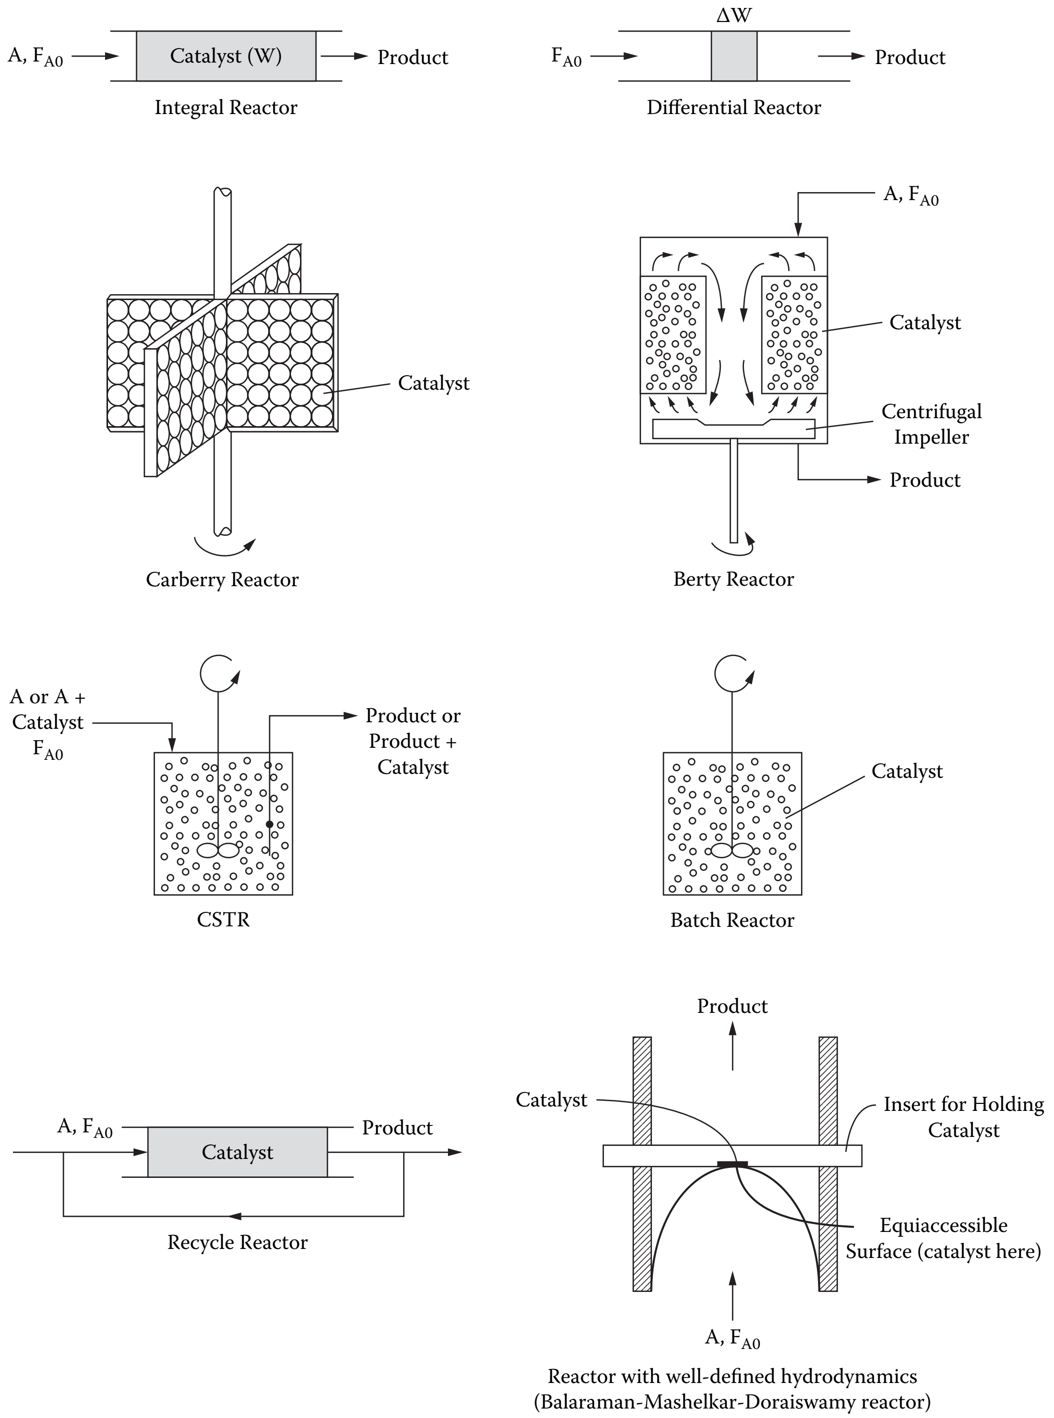

FIGURE 11.7 Some useful laboratory reactors for obtaining precise kinetic data for gas-solid catalytic reactions.

stirrer as in the Carberry reactor but rotating the pot provided with suitable baffles (the Choudhary–Doraiswamy reactor). In another design (Borman et al., 1994), perfect mixing is achieved by circulating the gas in the reactor using an axial flow impeller in a well streamlined enclosure. A batch reactor can also be used, but since this reactor is the batch equivalent of the continuous integral (plug-flow) reactor, the conversion-time data (as against the conversion-residence time data in the integral reactor) must be differentiated to extract the rates. Pulsed reactors can also be used in which a reactant pulse is passed through a catalyst bed and the rates extracted from a theoretical analysis of the data (see, e.g., Yushchenko et al. 1968; Luckner and Wills 1973; Doraiswamy and Sharma 1984). Since, in this case, a carrier gas is used to introduce the feed into the reactor, the velocities are usually high enough to eliminate external mass transfer effects.

All mixed and differential reactors operate essentially isothermally. Another way to accomplish isothermality and the fully mixed condition is to provide a recirculation loop to a PFR.

If the catalyst decays rapidly with time, then these reactors must be used with caution: the data should be obtained before decay occurs and vitiates the results. If this cannot be done, transport reactors should be used. In such a reactor, a suspension of the catalyst in the fluid is passed through a tube placed in a fluidizing bath for approaching isothermality. The main difficulties are ensuring uniformity of suspension in the feed stream and the need to separate the catalyst from fluid immediately after sampling to prevent further reaction. Gullett et al. (1990) slid a catalyst bed into a process gas stream and then automatically retracted it after a preset exposure time (which can be as low as 0.3 s). In all the reactors mentioned so far, it is assumed that the catalyst surface is equally accessible at all points. This is true only for special hydrodynamic situations, e.g., the stagnation region of a circular cylinder. Balaraman et al. (1980) proposed a reactor in which the catalyst is placed in this zone. The single-pellet reactor proposed by Hegedus and Petersen (1973a–c, 1974) is particularly useful for studying catalyst deactivation and the role of internal diffusion, but it is generally not recommended for routine kinetic studies.

Many of the reactors mentioned are available commercially, particularly the Berty reactor. They can be operated with a software and appropriate interfacing that can set and implement the experiments for each of a series of sequential runs (Mandler et al., 1983), resulting in the emergence of the most acceptable model for a reaction.

The main features of these reactors and their ratings, along with comments and selected references, are outlined in Table 11.11. They are based on the authors' conclusions and the rating scale [good (G), fair (F), and poor (P)] of Weekman (1974).

11.3.2 Gas-Solid Noncatalytic Reactions

Reactions between gases and solids include combustion of solid fuels, environmental control (pollution abatement), energy generation, mineral processing, chemical vapor deposition, and catalyst manufacture and regeneration. Representing the solid by s and gas by g, several categories are listed in Table 11.12 along with selected examples of each. The analysis and modeling of these reactions obviously depend on the specific category at hand, but common principles can be identified by considering the most general case,

$$\nu_A\, A\,(g) + \nu_B B\,(s) \rightarrow \nu_R R\,(g) + \nu_S S\,(s) \qquad \text{R11.11}$$

Thus our presentation will largely be confined to this class of reactions, although brief references will also be made to other classes, notably $A(g) + B(s) \rightarrow R(g)$, represented by the gasification of coal.

11.3.2.1 Modeling of Gas-Solid Reactions

The first model, the shrinking core model (SCM) or the sharp interface model (SIM), was proposed about half a century ago. Other models also describe the behavior of the solid as it undergoes

TABLE 11.11
Laboratory Reactors for Gas-Solid Catalytic Reactions: Their Principal Features and Ratings

	Main Features	Isothermality	Diffusion-Free Operation	Contact Time Determination	Rate Measurement	Comments	Selected References
1. Integral reactor	A single-tube fixed-bed reactor; temperature variation can be controlled by catalyst dilution; easiest to construct and operate; best heated/cooled in a fluidized sand bath	P[a]-F[c]	F	F	I[d]	Gives a practical "feel" for the scaled up version; dilution desirable but causes a "dilution effect" if greater than experimental error in measuring conversion; use the Sofekun-Rollins-Doraiswamy criterion to evaluate this effect, multiple taps can give multiple conversion data for each run.	Musick et al. (1972); van den Bleek et al. (1969); Sofekun et al. (1994)
2. Differential reactor	Small bed, 1–2 g catalyst; low conversion places heavy demand on accuracy	G[a]-F[b]	G	P-F	D	Use of recycle eliminates diffusional effects; an integral reactor can supply the required partially reacted feed	Pansing and Malloy (1962); Lunde and Kestner (1974)
3. Fully mixed reactor a. Rotating catalyst	Catalyst in basket(s) attached to stirrer (Carberry reactor)	G	G	F-G	D	Direct measurement of bed temperature almost impossible; otherwise an excellent design	Carberry (1964); Tajbl et al. (1966, 1967); Doraiswamy and Sharma (1984)
b. Stirred fluid, stationary catalyst	Fluid stirred with special stirrer (Berty reactor) or by rotating pot with baffles (Choudhary-Doraiswamy reactor)					Bed temperature readily measurable; uniform gas circulation through bed uncertain	Berty (1973); Choudhary and Doraiswamy (1972); Doraiswamy and Tajbl (1974)
c. Continuous stirred tank	Fluid + catalyst passed continuously through a stirred reactor, or just the fluid is passed with a fixed amount of catalyst restrained in the reactor	P-F	G	F-G	D	Difficulty in quickly separating catalyst from fluid in samples can lead to wrong composition values	
d. Recycle reactor	Large fraction of product is recycled	F-G	G	G	D	A recycle to feed ratio >20 ensures full mixing	Perkins and Rase (1958); Butt et al. (1962) see also Carberry (1976); Levenspiel (1999)

TABLE 11.12
Industrially Important Examples of Different Types of Noncatalytic Gas-Solid Reactions[a]

Type	General Reaction Scheme	Reaction
A	Solid + fluid → solid + fluid	Roasting of zinc ore
		$2ZnS(s) + 3O_2(g) \rightarrow 2ZnO(s) + 2SO_2(g)$
		Production of uranium tetrachloride by chlorination of
		$UO_2(s) + CCl_4(g) \rightarrow UCl_4(s) + CO_2(g)$
		Selective chlorination of iron in ilmenite
		$FeTiO_3(s) + CO(g) + Cl_2(g) \rightarrow FeCl_2(g) + CO_2(g) + TiO_2(s)$
B	Solid + fluid → solid	Nitrogenation of calcium carbide to produce cyanamide
		$CaC_2(s) + N_2(g) \rightarrow CaCN_2(s) + C(s)$
		Rusting reaction of iron
		$2Fe(s) + O_2(g) \rightarrow 2FeO(s)$
		Absorption of SO_2 by dry limestone injection
		$CaO(s) + SO_2(g) \rightarrow CaSO_3(s)$
C	Solid → fluid + solid	Calcination of limestone
		$CaCO_3(s) \rightarrow CaO(s) + CO_2(g)$
		Decomposition of magnesium hydroxide
		$Mg(OH)_2(s) \rightarrow MgO(s) + H_2O(g)$
D	Solid + fluid → fluid	Production of carbon disulfide
		$C(s) + S_2(g) \rightarrow CS_2(g)$
		Chlorination of rutile to titanium tetrachloride
		$TiO_2(s) + 2C(s) + 2Cl_2(g) \rightarrow TiCl_4(g) + 2CO(g)$
		Gasification of carbon
		$C(s) + H_2O(g) \rightarrow CO(g) + H_2(g)$
E	Solid → fluid	Decomposition of ammonium chloride
		$NH_4Cl(s) \rightarrow NH_3(g) + HCl(g)$
		Decomposition of ammonium sulfate
		$(NH_4)_2SO_4(s) \rightarrow 2NH_3(g) + SO_3(g) + H_2O(g)$
F	Fluid → solid + fluid	Mond process for nickel production
		$Ni(CO)_4(g) \rightarrow Ni(s) + 4CO(g)$
		Oxidation of silicon tetrachloride to silicon dioxide
		$SiCl_4(g) + O_2(g) \rightarrow SiO_2(s) + 2Cl_2(g)$
		Burning of titanium tetrachloride to rutile
		$TiCl_4(g) + O_2(g) \rightarrow TiO_2(s) + 2Cl_2(g)$

[a] General reaction: $\nu_A A + \nu_B B = \nu_R R + \nu_s S$.

reaction with a gas (or is reacting by itself to produce a gas). These categories (many not mutually exclusive) include shrinking (or expanding) core, volume reaction, reaction zone, particle-pellet (or grain), grain-micrograin, discrete, computational, and percolation models. The percolation models are based on the statistical physics of disordered media and include such phenomena as aggregation processes, scaling, network modeling of the pore space, discretization, and random walk representation of diffusion processes. For a review of percolation models, see Sahimi et al. 1990. Research on the other models continues because of their usefulness (see e.g., Szekely et al. 1976; Ramachandran and Doraiswamy 1982; Kulkarni and Doraiswamy 1986; Doraiswamy and Kulkarni 1987; Bhatia and Gupta 1993).

The simplest models are those in which the internal structure of a pellet is not considered, and its behavior as a whole is modeled. These are normally called the *macroscopic* or *basic* models. In other models, the behavior of the distinctive elements of a pellet, such as the grain, micrograin, or the pore, constitutes the central feature; such models account for structural changes during reaction. The so-called random pore models are the most common.

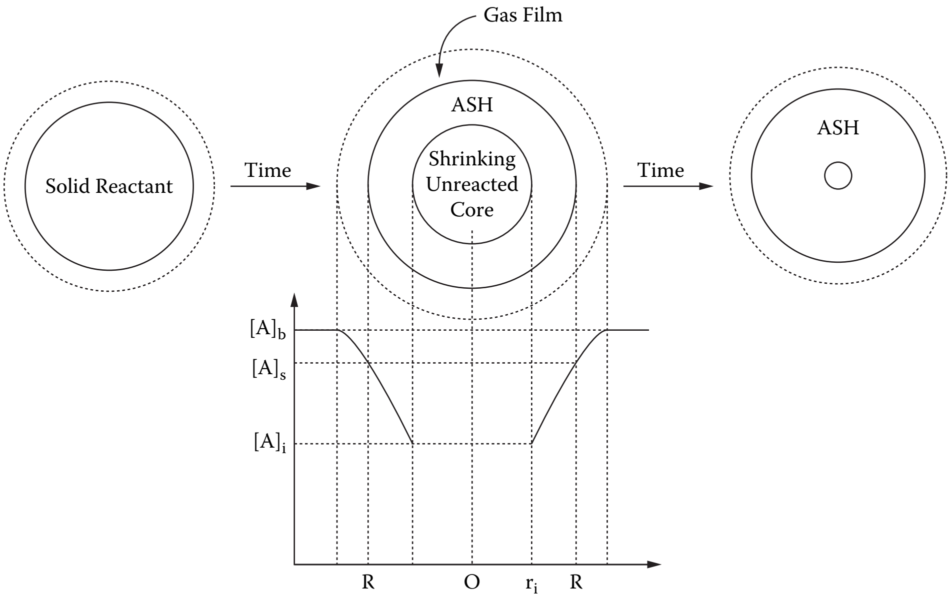

FIGURE 11.8 The shrinking core model (SCM) for gas-solid noncatalytic reactions.

11.3.2.1.1 Shrinking Core Model (SCM)

Figure 11.8 illustrates the basic features of SCM. The gas first diffuses through the film surrounding the pellet and reacts at the interface. As the reaction progresses, the interface moves inward, leaving behind a shell of the exhausted solid (called ash). In effect, the unreacted core shrinks until the entire solid has reacted. This behavior is possible only if the solid is nonporous. Otherwise, the gas will diffuse below the surface, and the reaction will no longer be confined to the interface.

The mathematical analysis of this model is facilitated by the pseudo-steady-state (PSS) assumption, i.e., the interface remains stationary while the mass flux equations are written. This is generally satisfied for gas-solid reactions. The following equations for makers of A diffusing per unit time for a single pellet, $\mathbf{R}_A$ can be written:

Diffusion through gas film:

$$\mathbf{R}_A = 4\pi R^2 k_G \tag{11.59}$$

Diffusion through ash layer:

$$\mathbf{R}_A = \frac{4\pi R\, r_i \mathbf{D}_{e,As}}{R - r_i} \tag{11.60}$$

Chemical reaction at the interface:

$$\mathbf{R}_A = 4\pi r_i^2 k_S \tag{11.61}$$

Noting that conversion in a spherical pellet is related to the ratio of the initial and interface radii by the equation

$$X_B = 1 - \left(\frac{r_i}{R}\right)^3 \tag{11.62}$$

Equations (11.59) through (11.61) are combined to give

$$\mathbf{R}_A = \left(\frac{1}{4\pi R^2 k_G} + \frac{R - r_i}{4\pi R r_i \mathbf{D}_{e,As}} + \frac{1}{4\pi r_i^2 k_s}\right)^{-1} \left[A\right]_s \tag{11.63}$$

To express the rate in terms of the solid reactant B, we write the following equation for the rate of movement of the sharp interface:

$$-\frac{d}{dt}\left(\left(4/3\right)\pi r_i^3 \frac{\rho_B}{M_B}\right) = \frac{\nu_B}{\nu_A}\mathbf{R}_A = \nu \mathbf{R}_A \tag{11.64}$$

Substituting Equation (11.63) for $\mathbf{R}_A$ in Equation (11.64) and integrating, we get an equation of the general form

$$\tau = f_1\left(X_A\right) + f_2\left(X_A\right) + f_3\left(X_A\right) \tag{11.65}$$

or

$$\tau = \tau_f + \tau_a + \tau_c \tag{11.66}$$

where τ_f, τ_a, and τ_c represent, respectively, the times required for complete conversion if film transfer, ash diffusion, or reaction alone were to be the controlling step. The functions f_1, f_2, and f_3, and the various τ_s, assume different forms for different geometries of the pellet and are defined in Table 11.13. The dependence of τ on pellet size varies for different controlling regimes: first-order in R for reaction control, second-order for ash diffusion control, and 1.5- to 2.0-order for film diffusion control.

Improvements and modifications of the above procedure have been suggested. In one method (Tine, 1985; Villa and Quiroga, 1989), by using Laplace transforms of the basic mass balance equations, the diffusion and reaction rate coefficients are integrated into a single coefficient. This is of limited use, because film diffusion is ignored in this development. Sometimes a porous film of a solid product is deposited on the ash layer, adding one more resistance to the overall process. An example is the reduction of ilmenite with hydrogen forming a porous film of iron on the ash (Briggs and Sacco, 1991). Thus, one has to be cautious in routinely applying the additivity of resistances principle for treating combined control as was done in developing Equation (11.65) or (11.66).

A practically useful extension of SCM is when a relatively fragile solid undergoes reaction by SCM, such as a pellet of lime encased in a strong shell. This creates an additional diffusional layer. The development of such a pellet and its modeling are described in Case Study 11.6.

An alternative approach is to express the results in analogy with those for catalytic systems, in terms of an effectiveness factor (Ishida and Wen, 1968). Unlike in catalytic pellets, here the rate changes with time. Hence, the effectiveness factor also changes with time (i.e., with r_i), and the following equation can be derived for a first-order reaction in a sphere:

TABLE 11.13
Time-Conversion Relationships for SIM for Different Particle Geometries[a]

$$\upsilon_A A(g)+\upsilon_B B(s)\rightarrow R(g)+S(s)$$

Controlling Regime	Functional forms for: Flat Plate	Cylinder	Sphere	τ
Film diffusion, $f_1(X_B)$	X_B	X_B	X_B	$\frac{\rho_B R}{\upsilon k_g [A]_b}$
Ash diffusion, $f_2(X_B)$	X_B^2	$X_B + (1-X_B)\ln(1-X_B)$	$1-(1-X_B)^{2/3}+2(1-X_B)$	$\frac{\rho_B R^2}{2\upsilon D_{e,As}[A]_b}$
Reaction, $f_3(X_B)$	X_B	$1(1-X_B)^{1/2}$	$1-(1-X_B)^{1/3}$	$\frac{\rho_B R}{\upsilon k_s [A]_b^n}$

[a] Conversion $X_B = 1-(r/R)^s$, where s = 1, 2, and 3 for flat plate, cylinder, and sphere, respectively.

$$\varepsilon=\left[1+\hat{R}_i Da\left(\frac{1}{Sh}+\frac{1-\hat{R}_i}{\hat{R}_i}\right)\right]^{-1} \tag{11.67}$$

where Sh (same as Bi_m) = $k_G R/\mathbf{D}_{e,As}$ and $Da = k_S R[A]_b^{m-1}/\mathbf{D}_{e,As}$ (with m = 1). The equation takes an implicit form for nonfirst-order reactions.

SCM is a phenomenological model that predicts the total conversion of a solid in a finite time and is well suited for many practical systems. However, it cannot account for such features as the leveling off of conversion at a value lower than the total conversion. Most importantly, it is not suitable for porous solids.

11.3.2.1.2 Volume Reaction Model

When the solid is porous, the reaction occurs throughout the pellet, with no sharp interface. If diffusion is assumed to be fast, the gas concentration will be uniform throughout the pellet, leading to the so-called homogeneous model. The rate of reaction can then be simply written as

$$r_A = k_v [A]^m [B]^n \tag{11.68}$$

The general conservation equations for the solid and reactant species for the volume reaction model in dimensionless form are as follows:

$$\nabla^2\left[\hat{A}\right]=\phi^2\left[\hat{A}\right]^m\left[\hat{B}\right]^n \tag{11.69}$$

$$-\frac{d\left[\hat{B}\right]}{d\hat{t}}=\left[\hat{A}\right]^m\left[\hat{B}\right]^n \tag{11.70}$$

where

$$\phi = \left[\frac{[A]_b^{m-1} [B]_0^n}{\mathbf{D}_{e,As}} \right]^{1/2} \tag{11.71}$$

and

$$\hat{t} = \nu k_s [A]_b^m [B]_0^{n-1} t \tag{11.72}$$

The boundary conditions are

$$\begin{aligned} &\hat{t} = 0, \quad \hat{R} = 1: \left[\hat{B}\right] = 1 \\ &\hat{t} > 0, \quad \hat{R} = 1: \frac{d\left[\hat{A}\right]}{d\hat{R}} = Sh\left(1 - \left[\hat{A}\right]\right) \quad \text{or} \quad \left[\hat{A}\right] = 1 \\ &\hat{t} > 0, \quad \hat{R} = 0: \frac{d\left[\hat{A}\right]}{d\hat{R}} = 0 \end{aligned} \tag{11.73}$$

No analytical solution for this set of equations is possible for arbitrary values of m and n. However, analytical solutions can sometimes be found. For example, for the homogeneous model corresponding to low values of ϕ (and hence uniform concentration of) A throughout the pellet, the solution is

$$X_B = \begin{cases} 1 - \exp\left(-\hat{t}\right) & \text{for } n = 1 \\ \hat{t} & \text{for } n = 0 \end{cases} \tag{11.74}$$

A practically important case is when $m = 1$. In this situation, Equations (11.69) and (11.70) can be combined into a single equation by defining a cumulative gas concentration as

$$\psi = \int_0^{\hat{t}} \left[\hat{A}\right] d\hat{t} \tag{11.75}$$

The transformed equation for the case of $m = n = 1$ is as follows (del Borghi et al., 1976; Dudukovic and Lamba, 1978; see also Ramachandran and Kulkarni, 1980):

$$\nabla^2 \psi = \phi^2 \left[1 - \exp\left(-\psi\right)\right] \tag{11.76}$$

with boundary conditions

$$\psi = \hat{t}, \quad \left(\frac{d\psi}{d\hat{R}}\right)_{\hat{R}=0} = 0 \tag{11.77}$$

This transformation is extremely useful for systems with no structural changes and for reactions with power law kinetics.

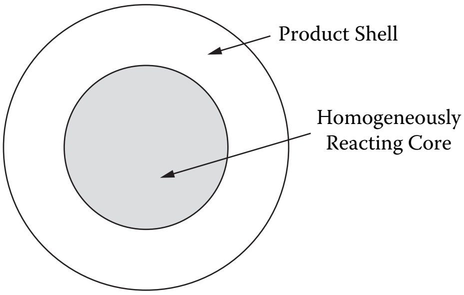

FIGURE 11.9 The two-zone model for gas-solid noncatalytic reactions.

The importance of reaction orders m and n has been examined at length (see, e.g., Doraiswamy and Sharma, 1984). The case of $m = 1$, $n = 0$ (i.e., zero order with respect to the solid reactant) is particularly important, since the gas concentration can drop to zero within the pellet, depending on the value of ϕ. In fact, a critical value given by

$$\phi_{cr} = \frac{6}{2/Sh + 1} \tag{11.78}$$

exists beyond which the concentration of A can fall to zero at some point within the pellet. For $\phi < \phi_{cr}$, the concentration would be finite at all points in the pellet, and Equation (11.75) describes the conversion-time behavior.

11.3.2.1.3 The Zone Models

The homogeneous model behaves in part as a shrinking core model when the reaction-diffusion interaction is such that the outer layers become exhausted, leading to the formation of an ash layer as in SIM. The difference, however, is that the reaction is not topochemical; i.e., it is not confined to the interface but occurs throughout the reactant matrix (core) as in the homogeneous model (Figure 11.9). Ishida and Wen (1968) have derived equations for this so-called two-zone model. A more general model is, however, one in which a reaction zone is sandwiched between the ash layer and the unreacted core (Bowen and Cheng, 1969). The model, sketched in Figure 11.10, is characterized by three stages (Mantri et al., 1976): (1) zone formation starting from the pellet surface until it has reached a thickness determined by the reaction-diffusion interaction for the system, (2) zone travel to the interior leaving a layer of ash as the shell, and (3) zone collapse as it merges with the core (thus becoming a two-zone model), the reaction continuing in the core until the entire solid is exhausted. The experimental results of Prasannan and Doraiswamy (1982) on the oxidation of zinc sulfide reveal three stages of the reaction. The zone width is clearly a function of the Thiels modulus. Their model reveals that, when the zone thickness is zero, it reduces to SIM, and when it is of the pellet dimension, it reduces to the homogeneous model. In an extension of this model to reversible reactions, Khan (1999) postulates two reaction zones.

11.3.2.1.4 The Particle-Pellet or Grain Models

Although such models are based on the granular structure of the pellet, the first version did not account for changes in the grain size. Hence, they can broadly be considered as spanning the macroscopic models in which pore evolution is ignored and the structural models in which the progress of reaction is explicitly related to pore evolution with time (i.e., to structural changes). The basic feature of these models, sketched in Figure 11.11, is that the grains constituting a pellet are spherical and of the same size, that each grain reacts according to SIM, and that the size of the grain does not change with reaction (thereby implying no voidage change with reaction and hence no pore evolution).

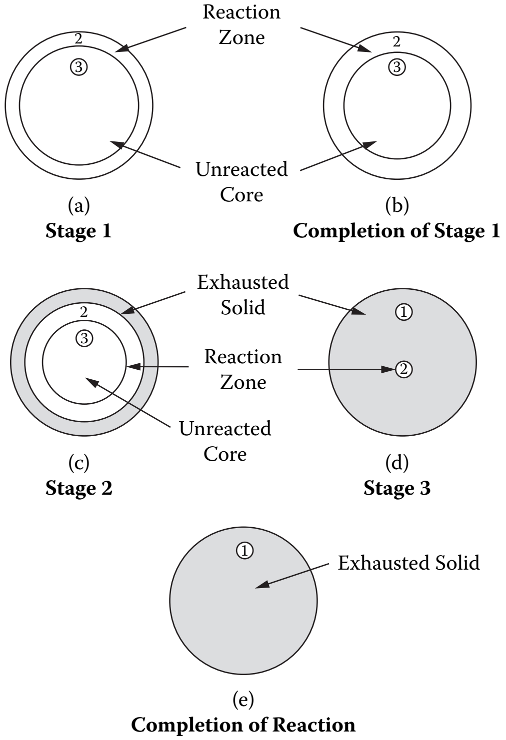

FIGURE 11.10 The three-zone model for gas-solid noncatalytic reactions.

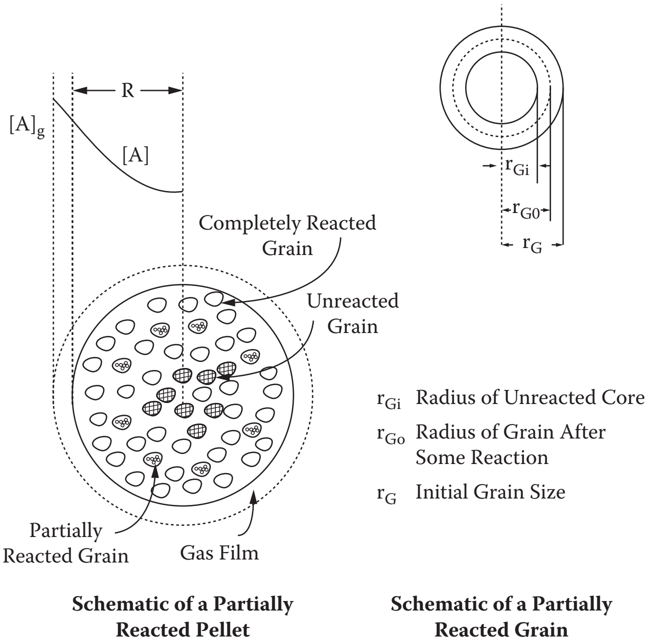

FIGURE 11.11 The particle-pellet model for gas-sold noncatalytic reactions.

The mathematical formulation of the model requires consideration of the rate processes within an individual grain, and the overall mass balance for the gaseous reactant in the pellet and its stoichiometric relationship with the extent of solid consumed. As far as the individual grain is concerned, the rates of diffusion through the reacted portion of the grain and of reaction at the interface can be obtained in analogy with Equations (11.60) and (11.61) as

$$\mathbf{R}_{GA} = \frac{4\pi \mathbf{D}_{eG} r_{Gi} r_{G0}}{r_{Gi} - r_{G0}} \left([A]_S - [A]_i \right) \tag{11.79}$$

$$\mathbf{R}_{GA} = 4\pi r_{Gi}^2 k_S [A]_i \tag{11.80}$$

Eliminating the unknown concentration $[A]_i$ at the interface, we obtain the overall rate per unit grain as

$$\mathbf{R}_{GA} = \frac{4\pi r_{Gi}^2 k_s [A]}{\left(1 + r_{Gi} k_s / \mathbf{D}_{eG}\right)\left(1 - r_{Gi} / r_{G0}\right)} \tag{11.81}$$

Once the rate of reaction for the individual grain is known, the overall pellet equation can be written:

$$\nabla^2 [A] = \mathbf{R}_{GA} \frac{3\left(1 - \varepsilon_p\right)}{4\pi r_{G0}^3} \tag{11.82}$$

where the term in parentheses refers to the grains in the pellet volume. The term $\mathbf{R}_{GA}$ involves a knowledge of the interfacial position r_{Gi} within each grain, which is a function of both the time and position within the pellet. To evaluate this, a stoichiometric balance on the solid reactant B can be written for an individual grain in analogy with Equation (11.65) as

$$-\frac{d}{dt}\left[\frac{4}{3}\pi r_{Gi}^3 \frac{\rho_B}{M_B}\right] = \mathbf{R}_{GA} \tag{11.83}$$

The term $[A]$ appearing in $\mathbf{R}_{GA}$ [Equation (11.82)] in this equation fixes the position of the individual grain in the pellet.

The appropriate boundary conditions to the problem are

$$\begin{aligned} r = R:&\quad \mathbf{D}_{e,As} \frac{d[A]}{dr} = k_G \left([A]_b - [A]_S \right) \\ r = 0:&\quad \frac{d[A]}{dr} = 0 \\ r = 0:&\quad r_{Gi} = r_{G0} \end{aligned} \tag{11.84}$$

In general, these equations require numerical solution.

Considering the physical features of the model, two parameters are involved: τ_G, the time required for complete conversion of the grain in the $[A]$ environment; and τ_p, the time for complete conversion of the particle by diffusion if the grain conversion process is extremely fast. In the limiting case of grain diffusion controlling, the simple homogeneous model is recovered. The

individual grains could follow the shrinking core model with ash diffusion or reaction controlling. Because the processes within the grain determine the system behavior, the conversion-time relationship is independent of the pellet dimensions. On the other extreme, when diffusion within the pellet controls, one observes shrinking core behavior with ash diffusion control, and typically the system behavior is dependent on the pellet dimensions ($t \propto R^2$). In the intermediate region where τ_G and τ_p are of the same order of magnitude, one expects the pellet behavior to lie within the limiting cases of shrinking core with reaction and ash diffusion control.

The grain models are useful in cases where pellets are formed by compaction of particles in very fine sizes. This is not so in some naturally occurring minerals, in which case fictitious grains are assumed. Also, the model, in its simplest form, does not explain S-shaped behavior and leveling off of conversion.

11.3.2.1.5 Other Models

Nucleation effects are often significant in systems such as reduction of metallic oxides. In these systems, the process proceeds with the generation of nuclei, which subsequently grow and finally overlap. When the nuclei generation rate is faster, the whole surface becomes covered with the metallic phase, and the reaction proceeds topochemically. On the other hand, for a slow generation rate, the metal-oxide interface is irregular, and different considerations prevail in estimating the conversion-time relationships. The following empirical model, proposed by Arvani (1941), is often valid:

$$X_B = 1 - \exp\left(-at^b\right) \tag{11.85}$$

where a and b are constants. Modified forms have been suggested by Erofeev (1961), Ruckenstein and Vavanellos (1975), Rao (1979) and Bhatia and Perlmutter (1980), and experimental data of Neuberg (1970) and El-Rahaiby and Rao (1979) validate the model.

11.3.2.2 Extensions to the Basic Models

Some basic macroscopic models were described in the previous sections, including the slightly more rigorous particle-pellet model. These models ignored several complexities, mainly the effects of bulk flow, nonisothermicity, and variations in structure due to reaction. The first two can be included in the basic models and become extensions of them. The effects of structural changes can, however, be better defined in newer models that incorporate them at a more basic level.

11.3.2.2.1 Bulk-Flow or Volume-Change Effects

In addition to diffusion, bulk flow can occur within a reacting pellet (Beveridge and Goldie, 1968; Gower, 1971; Sohn and Sohn, 1980). This effect is considerably magnified for reactions with volume change such as

$$C(s) + CO_2(g) \rightarrow 2CO(g) \qquad \text{R11.12}$$

$$FeCl_2(s) + H_2(g) \rightarrow Fe(s) + 2HCl(g) \qquad \text{R11.13}$$

Note that reaction R11.12 is different from those in which the molar volume of the solid itself changes, leading to a structural change as the reaction progresses. Both effects can occur simultaneously, as in the second reaction shown above.

For reactions with a change in the gas volume, a continuity equation can be written with appropriate boundary conditions (analogous to those for catalytic reactions by Weekman and

Goring, 1965) and nondimensionalized to incorporate the effect through a dimensionless quantity for volume change. The final asymptotic solution (Sohn and Sohn, 1980) obtained is

$$\frac{\ln(1+\theta)}{\theta}\frac{\hat{t}}{\phi^2}=1-\frac{(\beta+1)(1-X_B)^{2/(\beta+1)}-2(1-X_B)}{(\beta-1)}=f(X_B) \tag{11.86}$$

where β is the shape factor and ϕ and θ are, respectively, the Thiele modulus and a volume change modulus defined as

$$\phi=\frac{sV_p}{A_p}\sqrt{\frac{k_V}{2\mathbf{D}_{e,As}}}$$
$$\theta=\left(\frac{\nu_R}{\nu_A}-1\right)X_A \tag{11.87}$$

Clearly, $\theta = 0$ for a reaction with no volume change.

These equations are, however, not applicable to nonisothermal reactions. SIM equations are based on the applicability of the PSS assumption, which is not applicable to nonisothermal reactions.

11.3.2.2.2 Effect of Nonisothermicity

Although SIM generally cannot be applied to analyze a nonisothermal reaction, it is well suited for certain decomposition reactions (Narsimhan, 1961; Hills, 1968; Campbell et al., 1970), such as

$$A(s)\rightarrow R(s)+S(g) \tag{R11.14}$$

The phase rule suggests one degree of freedom. Each temperature, therefore, has a fixed value of partial pressure of the product gas S. Once this value is reached, the reaction starts, and the front moves inside. The process typically yields SIM behavior and is controlled either by heat or gas diffusion through the product layer. For heat transfer through the product layer controlling, the interface stays isothermal, and the equation for SIM with $\mathbf{D}_{e,As}$ replaced by the corresponding heat transfer parameters in the definition of represents the conversion-time behavior. Where gas diffusion is controlling, the variation of $\mathbf{D}_{e,As}$ with temperature should be accounted for. This variation usually takes the form $\mathbf{D}_{e,As} = T^{1.5–2.0}$ in the bulk diffusion regime with $D_{e,As} = T^{0.5}$ in the Knudsen regime. Luss and Amundson (1969) have provided a more rigorous analysis that incorporates the transient heat accumulation term and gives the interface temperature as a function of the interfacial position r_i.

11.3.2.3 Models That Account for Structural Variations

The main structural changes that occur in a solid are those due to reaction and sintering.

11.3.2.3.1 Effect of Reaction

The reaction effect is mainly the result of the difference in molal volumes of the product and reactant solids, leading to voidage and therefore diffusivity changes as the reaction progresses. To incorporate these effects in any model, it is necessary to relate the overall solids conversion to voidage and diffusivity. An important feature of the structural effect is that when the porosity at the surface of the solid becomes zero (pore closure), the governing equations predict incomplete conversion, so often observed in gas-solid reactions (and not predicted by the basic models).

One way to account for structural changes is to allow for changes in the grain size in the particle-pellet model (Garza-Garza and Dudukovic, 1982a, b). A more useful way is to incorporate

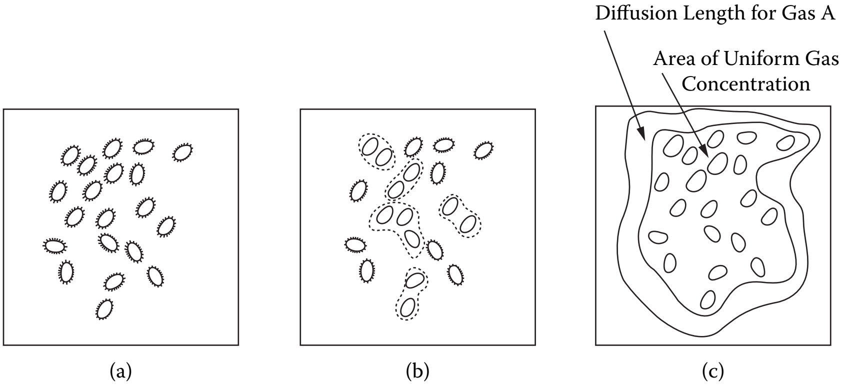

FIGURE 11.12 The random pore model of gas-solid noncatalytic reactions: stages in surface development.

the effect through changes in pore size distribution. The simplest of such models is the single pore model of Ramachandran and Smith (1977a) and Chrostowski and Georgakis (1978). In the Ramachandran–Smith approach, changes in a single pore are assumed to reflect changes in the pellet as a whole. The pore contracts, expands, or remains unchanged depending on whether there is an increase, decrease, or no change in the solid volume due to reaction. The model yields a simple conversion-time relationship based on the pore radius and length and the radius of the associated solid. Ulrichson and Mahoney (1980) have extended this model to incorporate the effects of bulk flow and reversibility of the reaction.

Perhaps the most realistic model is the random pore model of Bhatia and Perlmutter (1980; 1981a, b; 1983), which assumes that the actual reaction surface of the reacting solid B is the result of the random overlapping of a set of cylindrical pores. Surface development as envisaged in this model is illustrated in Figure 11.12. The first step in model development is therefore the calculation of the actual reaction surface, based on which the conversion-time relationship is established in terms of the intrinsic structural properties of the solid. In the absence of intraparticle and boundary layer resistances, the following relationship is obtained:

$$\hat{t} = \frac{k_S [A]_b^m S_0 t}{1-\varepsilon_0} = \frac{dX_{B1}}{S^*(X_{B1})} = \frac{\beta'}{2}\int_0^{X_B}\int_0^{X_{B1}}\left[\frac{1}{S^{*2}(X_B)} + \frac{Z_\nu - 1}{S^{*2}_p(X'_B)}\right]dX'_B dX_{B1} \tag{11.88}$$

where X_{B1} and X_B' are dummy variables; S^* and S_p^* refer, respectively, to dimensionless reaction surface area and pore surface area; and

$$\beta' = \frac{2k_s \nu_A \rho_B (1-\varepsilon_0)}{\nu_B M_B \mathbf{D}_{e,As} S_0} \tag{11.89}$$

This characterizes the diffusional resistance to the flow of gas (zero for kinetic control and infinity for product layer diffusion control). Expressions for S^* and S^*_p depend on the reaction model used. Thus:

For the grain model,

$$S^*(X_B) = (1 - X_B)^g \tag{11.90}$$

$$S_p^*(X_B) = \left[1 + (Z_v - 1)X_B\right]^g \tag{11.91}$$

where g is the grain shape factor (2/3 for the sphere, 1/2 for the cylinder, and 0 for the flat plate).

For the random pore model,

$$S^*(X_B) = (1 - X_B)\sqrt{1 - \psi' \ln(1 - X_B)} \tag{11.92}$$

$$S_p^*(X_B) = \left[1 + (Z_v - 1)X_B\right]\sqrt{1 - \psi' \ln\left[1 + (Z_v - 1)X_B\right]} \tag{11.93}$$

where ψ' is a structural parameter defined by

$$\psi' = \frac{1}{\ln\left(\dfrac{1}{1 - \varepsilon_0}\right)} \tag{11.94}$$

for uniform pore radius. The equation becomes complicated for a nonuniform radius (see Bhatia and Perlmutter, 1983). Substituting the expressions for any of these models in Equation (11.88) and integrating leads to the desired conversion-time relationship. Although the random pore model appears more realistic, the predictions of the grain model are surprisingly close to those of this model. Several improvements, many marginal, have been suggested (see Bhatia and Gupta, 1993).

11.3.2.3.2 Effect of Sintering

The use of high temperatures in certain reactions, such as those in gas cleaning using lime-based adsorbents or exothermic reactions with generation of large amounts of heat, leads to sintering of the solid. It becomes more severe at higher temperatures (usually over 800 K), causing a decrease in the effective diffusivity of the solid or an increase in grain size leading to a lower specific area. Also, there could be a decrease in porosity and an increase in the tortuosity factor, both leading to a lowering of the effective diffusivity. Empirical models have been used for sintering, such as exponential decay for diffusivity and first-order decay for surface area (Ranade and Harrison, 1979, 1981). The combined effects of the two have been considered by Kim and Smith (1974), Chan and Smith (1976), and Ramachandran and Smith (1977b). The following is recommended:

$$\mathbf{D}_e = \frac{1}{F(f_p)}\left[1 - (1 - \varepsilon_0)\left(\frac{r_{Gi}}{r_{G0}}\right)^3\right]^2 (1 - f_p) \tag{11.95}$$

where f_p is the fraction of pores removed and is given by

$$\frac{df_p}{dt} = k_p(1 - f_p) \tag{11.96}$$

where k_p is the rate constant for pore removal.

TABLE 11.14
Functional Forms of $f(X_B)$ for Different Gas-Solid Noncatalytic Reaction Models

Number	Functional Form $f(X_B)$	Reaction Model
1	$(1 - X_B)^{-n}$	Volume reaction model
2	$-1 - \dfrac{(1-X_B)^{1/3} + (1-X_B)^{2/3}}{Sh}$	Grain model
3	$-1 - \dfrac{(1-X_B)^{1/3}}{Sh} + \dfrac{(1-X_B)^{2/3}}{Sh\left[Z_V + (1-Z_V)(1-X_B)^{1/3}\right]}$	Grain model with structural variations
4	$\dfrac{1}{n}\left(\dfrac{1}{1-X_B}\right)\ln\left(\dfrac{1}{1-X_B}\right)^{(1-n)/n}$	Nucleation model

11.3.2.4 A General Model That Can Be Reduced to Specific Ones

A general mathematical formulation that is applicable to most models described in the earlier sections begins with the volume reaction model described by Equations (11.69) through (11.72). Then, for a reaction first order in the gaseous component, we recast these equations as

$$\frac{1}{\xi^\beta}\frac{\partial}{\partial \xi}\left(\alpha \xi^\beta \frac{\partial[\hat{A}]}{\partial \xi}\right) = \phi^2 \frac{\partial X_B}{\partial \hat{t}} \tag{11.97}$$

$$\frac{dX_B}{d\hat{t}} = \frac{\lfloor \hat{A} \rfloor}{f[X_B]} \tag{11.98}$$

where α refers to the diffusivity ratio $\mathbf{D}_{e,As}/\mathbf{D}_{e,As0}$, X_B is the solid conversion, and ϕ is the Thiele modulus [Equation (11.87)]. Using the cumulative gas concentration defined by Equation (11.75), the following final equation can be developed:

$$f(X_B)\frac{d^2}{d\xi^2} + \beta \frac{f(X_B)}{\xi}\frac{dX_B}{d\xi} + f'(X_B)\left(\frac{dX_B}{d\xi}\right)^2 - k(X_B) = 0 \tag{11.99}$$

The solution of this equation gives conversion profiles. The equation is sufficiently general, since several different models can be incorporated in it. Typical forms of $f(X_B)$ for some of the more frequently used models are presented in Table 11.14. Prasannan et al. (1986) employed a collocation procedure to solve this equation for the models considered in the table.

11.3.3 Fluid-Fluid Reactions

Fluid-fluid (gas-liquid and liquid-liquid) reactions are of great industrial importance and include gas-liquid, liquid-liquid, gas-liquid-solid (noncatalytic and catalytic), and solid-liquid systems.

TABLE 11.15
Examples of Industrially Important Gas-Liquid Reactions

Regime 1: Very slow reaction
Air oxidation of a variety of aliphatic and alkyl aromatic compounda; air oxidation of *p*-nitrotoluene sulfuric acid; substitution chlorination of a variety of organic compounds; reaction between isobutylene and acetic acid; oxidation of ethylene to acetaldehyde (Wacker processes); hydrochlorination of olefins; absorption of phosphine in an aqueous solution of formaldehyde and hydrochloric acid; acetic acid from the carbonylation of methanol; oxidation of tri-alkyl phosphine; dimerization of olefins.

Regime 2: Slow reaction
Absorption of CO_2 in carbonate solution; absorption of O_2 in aqueous acid solutions of CuCl at concentrations less than 1 $\times 10^{-4}$ mol/cm^3; oxidation of organic compounds; preparation of the C-13 isotope.

Regime between 1 and 2
Absorption of CO_2 in carbonate buffer solutions in packed columns; oxidation of black liquor in the paper and pulp industry; absorption of CO_2 in carbonate solution; wet air oxidation of soluble compounds in waste water.

Regime 3: Fast reaction
Absorption of CO_2 and COS in aqueous solutions of amines and alkalies; absorption of oxygen in aqueous acidic and neutral solutions of cuprous chloride, and in cuprous and cobaltous amine complexes in aqueous and polar solutions; absorption of oxygen in aqueous alkaline solutions of sodium dithionite (hydrosulfite); absorption of oxygen in aqueous sodium sulfite; absorption of $NO/NO_2/N_2O_4$ in water and aqueous solutions containing reactive species; reaction between dissolved NO and O_2; absorption of oxygen and ozone in aldehydes; absorption of isobutylene, 2-butene, and 2-methyl-2-butene in aqueous solutions of sulfuric acid; absorption of isobutylene in aqueous solutions containing thallium (III) ions; absorption of lean phosphine in aqueous solutions of sodium hypochlorite and concentrated sulfuric acid; absorption of ozone in aqueous and non-aqueous solutions, with or without dissolved organic chemicals; oxidation of cyanide ions in aqueous alkaline solutions and organic media containing olefinic substances; waste water treatment; oxidation of organometallic compounds; hydrogenation of unsaturated compounds with homogeneous catalysts; absorption of Cl_2 in aqueous solutions containing phenolic substances and aromatic nitro and sulfuric compounds; absorption of Cl_2 in aqueous and non-aqueous solutions of ketones.

Regime 4: Instantaneous reaction
Absorption of CO_2 in aqueous solutions of MEA; absorption of H_2S and mercaptans in aqueous solutions of alkanolamines and caustic soda; absorption of carbon monoxide in aqueous cuprous ammonium chloride solutions; absorption of lower olefins in aqueous solutions of cuprous ammonium compounds; absorption of pure chlorine in aqueous solutions of sodium carbonate or sodium hydroxide; conversion of dithiocarbamates to thiuram disulfides; sulfonation of aromatic compounds with lean SO_3; recovery of bromine from lean aqueous solutions of bromides; reactions of importance in pyrometallurgy; absorption of CO_2 in aqueous solutions of caustic alkalies and amine; absorption of O_2 in aqueous solutions of sodium dithionite; absorption of O_2 in aqueous sodium sulfite solutions; absorption of O_2 in alkaline solutions containing the sodium salt of 1,4-napthaquinone- 2-sulfonic acid (NQSA); special case: role of diffusion in the absorption of gases in blood in the human body.

Representative lists for gas-liquid and liquid-liquid reactions are given in Tables 11.15 and 11.16, respectively. Doraiswamy and Sharma (1984) have covered in detail the theory of mass transfer with simple and complex reactions. A summary of simple irreversible reactions is given below.

11.3.3.1 Theory of Mass Transfer Accompanied by Irreversible Chemical Reaction

The gas phase contains *A* and the liquid phase contains reactive species *B*. *A* is sparingly soluble in the *B* phase, and the reaction occurs exclusively in the *B* phase. The overall reaction involves two steps.

TABLE 11.16
Examples of Industrially Important Liquid–Liquid Reactions

Regime 1: Very slow reaction
Alkaline hydrolysis of a variety of organic compounds; nitration of chlorobenzene; alkylation of benzene with straight-chain olefins; reduction of aromatic nitro compounds to corresponding aromatic amines with aqueous Na_2S or Na_2S_x.

Regime 2: Slow reaction
Pyrometallurgical operations: open-hearth steel furnace; reaction of dinitrochlorobenzene; removal of mercaptans from petroleum fractions; alkaline hydrolysis of esters; nitration of aromatic compounds; nitration of higher olefins; liquid-liquid reactions in phosphorous chemistry; special case: measurement of the solubility of A in the B phase.

Regime between 1 and 2
Alkaline hydrolysis of acetate ester; sulfonation of benzene, toluene, and *p*-xylene.

Regime 3: Fast reaction
Alkaline hydrolysis of formate and halo-substituted acetic acid ester; manufacture of cyclohexanone oxime; manufacture of dithiocarbamate;, alkylation of isobutane with butenes and of toluene and xylenes with acetaldehyde (or acetylene); nitration of toluene; extraction of metals.

Regime 4: Instantaneous reaction
Extraction of free fatty acids from naturally occurring glycerides; removal of HCl from chlorinated organic compounds; recovery of aliphatic acids; HF and HCl from aqueous solutions; nitration of phenol; solvent extraction in mineral processing; interfacial polycondensation and esterification; manufacture of organo-phosphate pesticides.

1. Mass transfer of *A* from the gas phase to the liquid phase; assuming that the resistance to mass transfer is confined to the *B* phase, the rate of mass transfer is then given by

$$R_A a = k_L a\left(\left[A^*\right]-\left[A\right]_0\right) \tag{11.100}$$

2. The irreversible chemical reaction between the dissolved *A* and the liquid-phase reactive species *B*:

$$A(1) + Z\,B(1) \rightarrow \text{products} \qquad \text{R11.14}$$

The rate of chemical reaction is given by

$$R_A a = \in_L k_{mn} \left[A\right]^{*m} \left[B\right]_0^n \tag{11.101}$$

where $\in_L$ is the fractional liquid-phase holdup. Since the reaction occurs exclusively in the liquid phase and the rate is expressed on the basis of total reactor volume, the usual rate expression is multiplied by $\in_L$.

The combined effect of mass transfer and chemical reaction depends on the relative rates of these steps. The possibilities are conveniently classified into four regimes: regime 1, very slow reactions; regime 2, slow reactions; regime 3, fast reactions; and regime 4, instantaneous reactions. The concentration profiles in these regimes are shown in Figure 11.13. In very slow and slow reaction regimes, no reaction occurs in the liquid film, and the steps of mass transfer and chemical reaction occur in series. In regime 1, the rate of chemical reaction is the controlling step, whereas the reverse is true in regime 2. In regime 3, diffusion and reaction occur in parallel, and all the reaction is completed in the diffusion film. In other words, all of *A* is consumed in the film and no

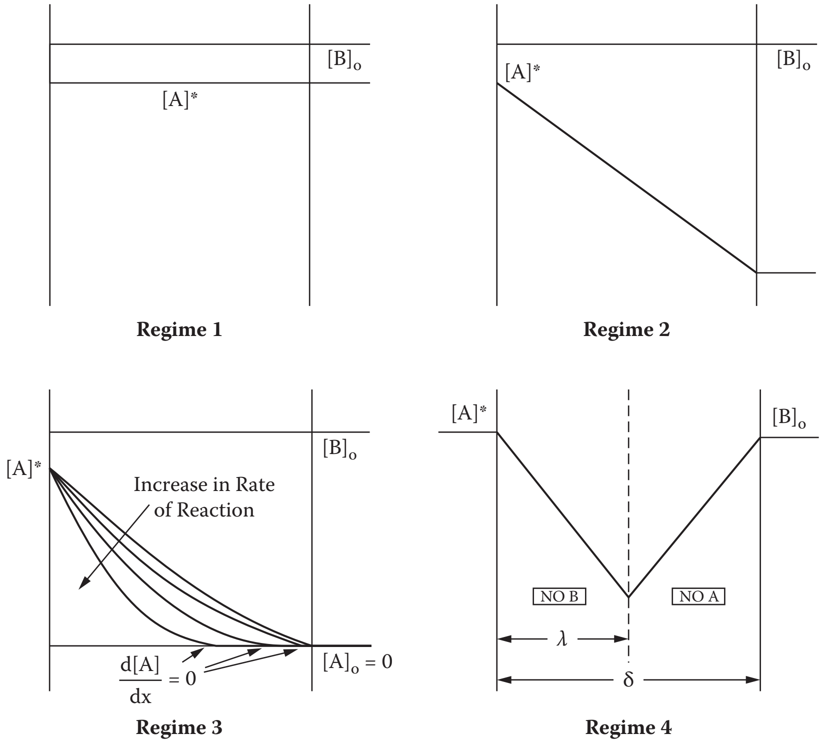

FIGURE 11.13 The different operating regimes in gas-liquid reactions.

A enters the bulk liquid. Furthermore, it can be seen from Figure 11.13 that the concentration profile of *B* is flat in the first three regimes. This means that the rate of diffusion of *B* is faster than the chemical reaction in the film. In regime 4, the reaction between *A* and *B* is instantaneous and occurs as soon as they meet at the reaction plane. The overall rate is controlled by the diffusion of *A* and *B* to the reaction plane.

Doraiswamy and Sharma (1984) have given detailed derivations for the overall rates of reaction and the conditions to be satisfied in each regime of operation. The final equations and conditions are summarized in Table 11.17. It is likely that a reaction falls in the intermediate range or more than one regime. For these cases, expressions for the overall rates are given in Table 11.18. Recently, Doraiswamy (2001) has given similar tables for some complex reactions.

11.3.3.2 Laboratory Reactors for Fluid-Fluid Reactions

For designing fluid-fluid reactors (described in Section 11.4), there are two basic requirements: (1) the flow behavior in reactors that governs the distribution of concentrations (including partial pressures) and temperature along the length and transverse directions and in all the phases, and (2) knowledge of overall rates at a given point in the reactor (with known concentrations and temperature). For the examples of industrial importance indicated in Tables 11.15 and 11.16, the equations for overall rates are given in Tables 11.17 and 11.18. For the estimation of overall rates of reaction, three types of information are needed: (1) physical properties of the system such as diffusivity, solubility, density, viscosity, and so on; (2) hydrodynamic parameters such as effective interfacial area, a, and true mass transfer coefficient k_La; and (3) kinetic parameters such as rate constants, orders with respect to different reactants, and activation energy. The chapter by Harvey in this book suggests how to obtain the desired data. The work by Reid et al. (1977) is also helpful. The hydrodynamic parameters a and k_La depend on the type of reactor, flow rates of various phases,

TABLE 11.17
Theory of Mass Transfer Accomplished by an Irreversible Chemical Reaction: Overall Rates of Reaction and Conditions to Be Satisfied for the Four Regimes of Operation

No.	Regime	Conditions to be Satisfied	Overall Rate of Operation
1	Regime 1 (very slow reaction)	1. $k_L a[A]^* \gg \in_L k_{mn}[A]^{*n}[B]_0^n$ 2. $\sqrt{M} \ll 1$	$R_A a = \in_L k_{mn}[A]^{*n}[B]_0^n$
2	Regime 2 (slow reaction)	1. $k_A a[A]^* \ll \in_L k_{mn}[A]^{*n}[B]_0^n$ 2. $\sqrt{M} \ll 1$	$R_A a = k_L a\{[A]^* - [A]_0\}$
3	Regime 3 (fast reaction)	1. $\sqrt{M} = \sqrt{\frac{2}{m+1}\mathbf{D}_A k_{mn}[A]^{*n}[B]_0^n} > 3$ 2. $\sqrt{M} = \frac{[B]_0}{Z[A]_0}\sqrt{\frac{\mathbf{D}_B}{\mathbf{D}_A}} = \phi_a$	$R_A a = a[A]^*\sqrt{\frac{2}{m+1}\mathbf{D}_A k_{mn}[A]^{*(n-1)}[B]_0^n}$
4	Regime 4 (instantaneous reaction)	$\sqrt{M} \gg \frac{[B]_0}{Z[A]^*}\sqrt{\frac{\mathbf{D}_B}{\mathbf{D}_A}}$	$R_A a = k_L a[A]^*\left[1 + \frac{[B]_0}{Z[A]^*}\sqrt{\frac{\mathbf{D}_B}{\mathbf{D}_A}}\right]$

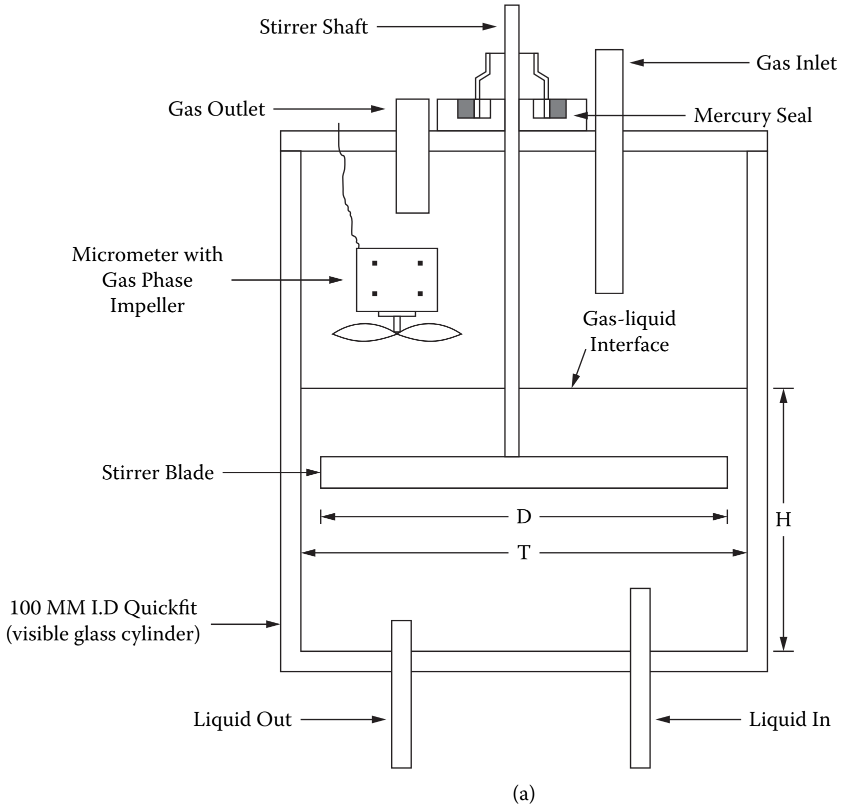
and power consumption per unit volume. This subject is complex, and fundamental methods are not available in the published literature for the estimation of hydrodynamic parameters from basic principles. Often, empirical/semiempirical correlations have been reported in the literature. Several references, along with qualitative descriptions of fluid-fluid contactors, are given in Section 11.4.

The kinetic parameter can be estimated in laboratory reactors. For solid-fluid systems, this subject was described in Section 11.3.1.6. For fluid-fluid reactions, the commonly employed laboratory reactors include stirred cell, wetted wall column, rotating drum, laminar jet, stirred contractor, and others. These are schematically shown in Figure 11.14. In practically all of these reactors, the value of the fluid-fluid interfacial area is known. These reactors have been described by Treybal (1980) and Doraiswamy and Sharma (1984). As an illustration, the stirred cell will be described first, followed by a comparison with other laboratory reactors. The discussion of the stirred cell is restricted to gas-liquid systems, but it is also applicable (with minor variations) to liquid-liquid systems.

A schematic representation of a stirred cell is shown in Figure 11.14a. The cell consists of distinct regions of gas and liquid phases separated by a flat gas-liquid interface. Both the phases are stirred independently, usually from different drives. The impeller speeds are varied over a wide range but always ensuring that the interface remains flat so that the gas-liquid interfacial area can be taken equal to the cross-sectional area. There are several advantages to keeping the gas phase pure. First, for pure gases, the gas phase resistance is absent, and hence a gas-phase impeller need not be used. Second, the concentration of the gas phase can easily be varied by manipulating the total pressure. Third, for pure components, the extent of backmixing in the gas phase is not an issue. Finally, and most importantly, the rate of reaction can be easily followed by measuring the gas-phase pressure with respect to time. If there are restrictions in using a pure gas phase, its partial pressure is varied by adding an inert gas. The gas flow rate is adjusted such that the extent of conversion is small (low conversion to minimize the importance of gas-phase mixing). The gas-side resistance is eliminated by manipulating the

TABLE 11.18
Overall Rates of Reaction for Overlapping Regimes

1. Regime 1 and 2, m = 1, n = 1	$R_A a = \dfrac{[A]^*}{\left[\dfrac{1}{k_L a}\right] + \dfrac{1}{\varepsilon_L k_{mn} [A]^{*m-1} [B]_0^n}}$
2. Regime 2 and 3	$R_A a = a[A^*]\sqrt{\dfrac{2}{m+1}\mathbf{D}_A k_{mn} [A]^{*m-1} [B]_0^n + k_L^2}$ or
3. Regime 1, 2 and 3 (m = 1, n = 1)	$R_A a = \dfrac{k_L a[A]^* \sqrt{M}}{\tanh\sqrt{M}}$ $R_A a = \dfrac{a[A]^*}{\dfrac{1}{\sqrt{\mathbf{D}_A k_2 [B]_0 + k_L^2}} + \dfrac{a}{\varepsilon_L k_2 [B]_0}}$
4. Regime 3 and 4	$R_A a = \Phi k_L a[A]^*$ where $\Phi = \sqrt{M}\left[\dfrac{(\phi_a - \phi)}{(\phi_a - 1)}\right]^{0.5}$ $\Phi_a = 1 + \dfrac{[B]_0}{Z[A]^*}\sqrt{\dfrac{D_B}{D_A}}$
5. Regime 1, 2, 3 and 4 together with gas side resistance (m = 1, n =1)	$R_A a = \Phi_L a[A]^*$ where $\Phi_a = \sqrt{\dfrac{M^2}{4(\phi_a - 1)} + \dfrac{M\phi_a}{\phi_a - 1} + 1} - \dfrac{M}{2(\phi_a - 1)}$ $M = \dfrac{\mathbf{D}_A k_2 [B]_0}{k_L^2}$ $\phi_a = _ + \sqrt{\beta^2 + \gamma}$ $\beta = 0.5(1 + f_1/f_3) + \sqrt{M}/f_3 - \sqrt{M}$ $\gamma = \sqrt{M}\,(1 + f_1/f_3)$ $f_1 = k_G / H_A k_L$ $f_2 = \dfrac{\mathbf{D}_B [B]_0}{Z\mathbf{D}_A [A]_0}$ $f_3 = f_1 / f_2$



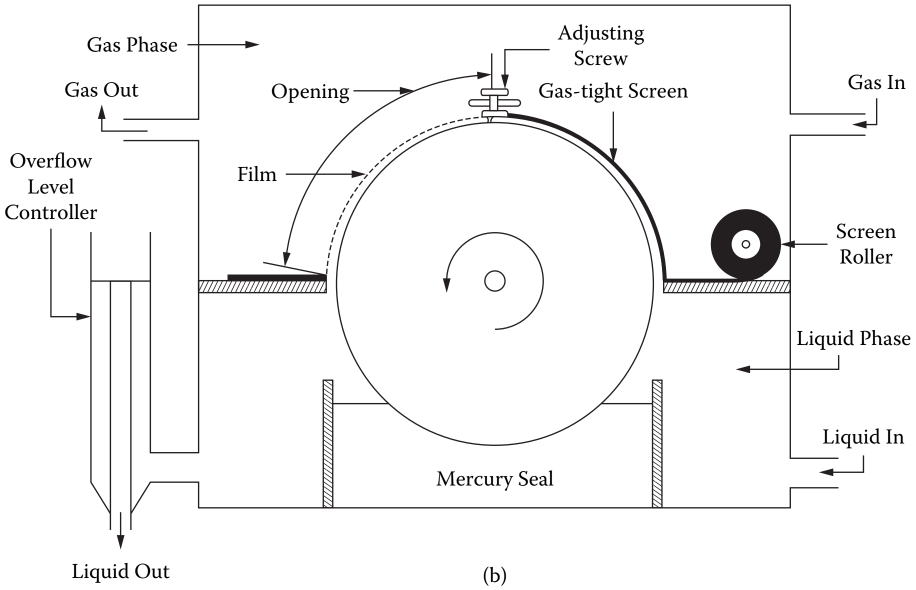


FIGURE 11.14 The stirred cell for obtaining precise kinetic data for fluid-fluid reactions: (a) stirred cell, (b) rotating drum, (c) cylindrical wetted wall, (d) wetted sphere, (e) laminar jet, and (f) stirred contactor. (c)

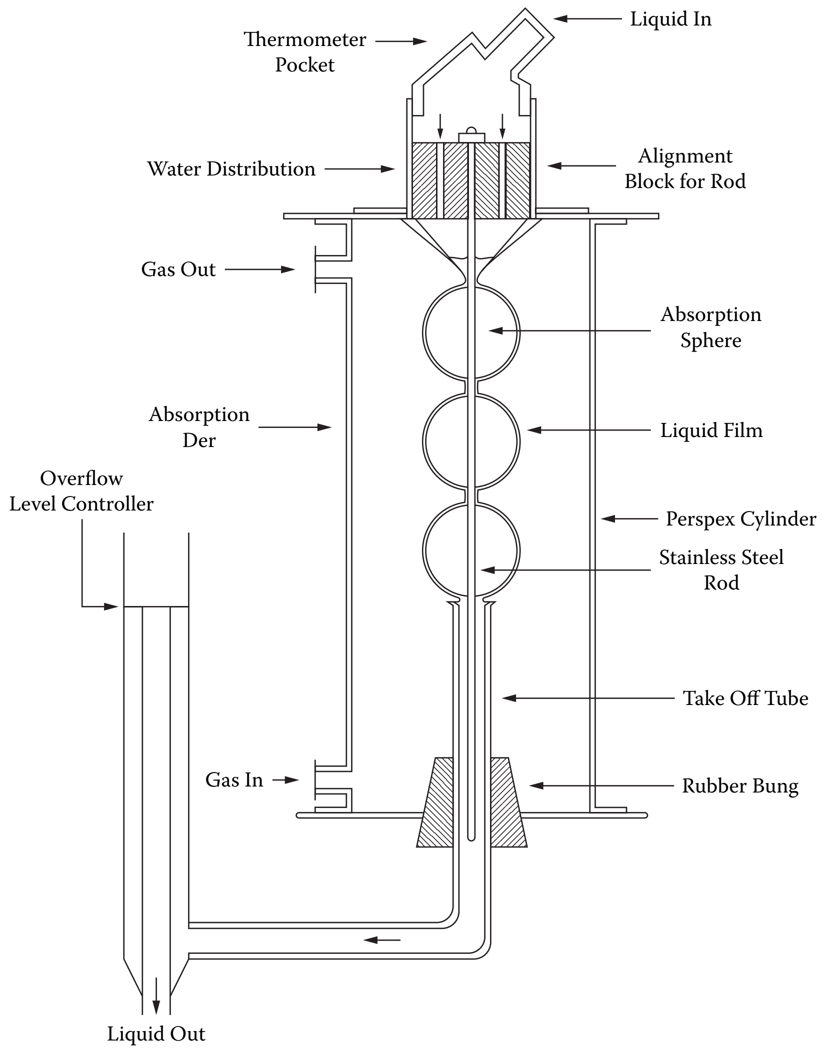
FIGURE 11.14 *Continued.*

gas-phase impeller speed. The rate of reaction is estimated by following the liquid-phase concentration.

From Table 11.17, it can be seen that the kinetic parameters are included in the rate equations for regimes 1 and 3, whereas the rate equations for regime 2 and 4 represent completely mass transfer-controlled operations. Therefore, for obtaining the kinetic parameters, it is important that the experiments in a stirred cell satisfy the conditions of either regime 1 or regime 3. A given stirred cell is characterized by vessel diameter (**T**), impeller diameter (D), and impeller design and location from the gas-liquid interface.

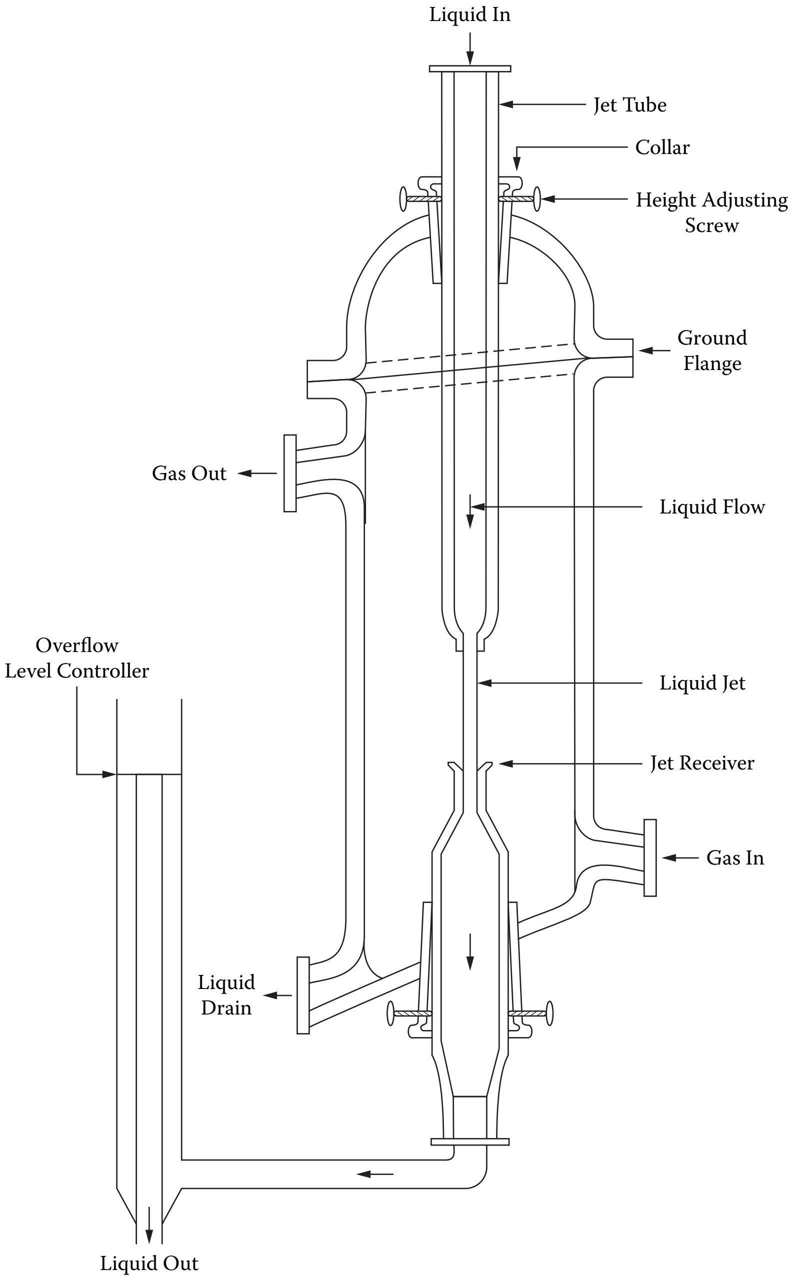
A typical stirred cell may have T = 100 mm, D = 90 mm, and a two-bladed paddle with W/D = 0.1 located 10 mm below the interface. The gas-phase impeller may be powered by a motor as shown in Figure 11.14a. A stepwise procedure for obtaining the kinetic parameters is outlined as follows:



(d)

FIGURE 11.14 *Continued.*

1. For the gas-liquid system under consideration, the diffusivities of the gas-phase solute in both the phases and the liquid-phase reactant in the liquid phase are estimated. The solubility is also determined.
2. The values of the mass-transfer coefficient are measured at various impeller speeds using a model gas-liquid system such as CO_2–H_2O. Using these results of k_L vs. N, a similar relationship is obtained for the given gas-liquid system using the square root diffusivity relationship. Thus, at any impeller speed, the specific rate of absorption under mass transfer-controlled conditions (regime 2) can be obtained and is equal to $k_L[A]$ *.
3. For a given gas-liquid system, the gas side should either be pure or used at a very high flow rate so that issues related to gas-phase back-mixing are eliminated. Furthermore, the gas-phase impeller speed is varied such that, beyond a particular impeller speed, the rate becomes independent of speed, ensuring that the gas-phase resistance is eliminated.
4. For a given gas-liquid system, the specific rate of absorption, R_A, is measured, and the enhancement factor is estimated using the following equation:



(e)

FIGURE 11.14 *Continued.*

$$\eta = \frac{R_A}{k_L[A]^*} \tag{11.102}$$

5. If $\eta < 1$, the absorption occurs between regimes 1 and 2. To achieve the conditions of regime 1, the impeller speed is increased such that R_A becomes independent of it, or ϕ becomes much less than 1. In regime 1, the overall rate of absorption (Table 11.17) is

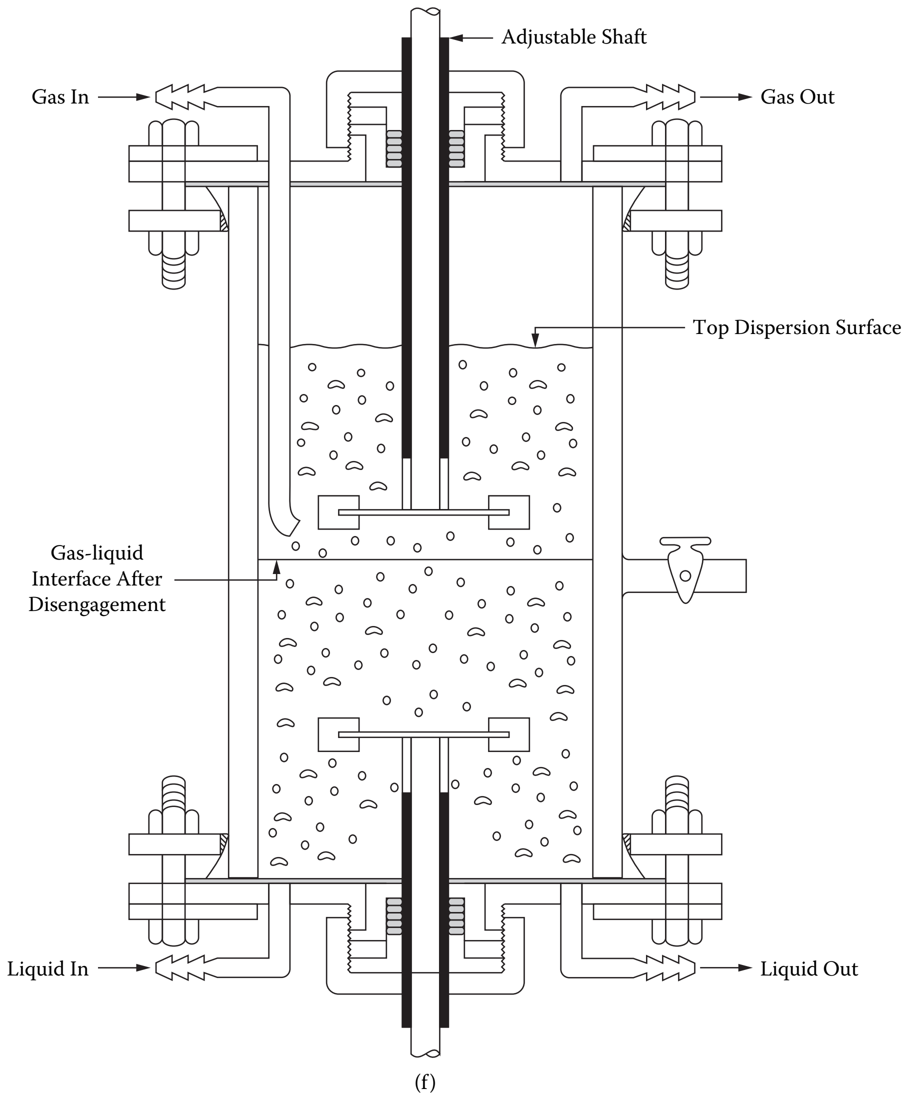


FIGURE 11.14 *Continued.*

given by Equation (11.101), in which $\in_L$ is the ratio of liquid volume to total cell volume. The measurements of $R_A a$ over a wide range of gas-phase partial pressures (and hence $[A^*]$) and liquid-phase concentrations ($[B]_0$) give the values of the respective orders m and n and hence the rate constant k_{mn}. Experiments are also performed over a sufficient temperature range of practical interest to calculate the activation energy.

6. If $\phi \geq 1$, absorption occurs between regimes 2 and 3, and the specific rate is given in Table 11.18. Under these conditions, the impeller speed (and hence k_L) is reduced so that ϕ becomes greater than 3 and the absorption operation becomes fast, i.e., reaction-controlled (regime 3). The other condition $\sqrt{M}$ <6< ϕ_a (Table 11.18), is also checked. The rate of absorption per unit liquid volume is given by

$$R_A a = a\left[A^*\right]\sqrt{\frac{2}{m+1}\mathbf{D}_A k_{mn}\left[A^*\right]^{m-1}\left[B\right]_o^n} \tag{11.103}$$

TABLE 11.19
Dependence of Stirred Cell Performance (Rate of Absorption per Unit Volume) on Operating Parameters in All the Four Regimes

Regime	Impeller Speed (N)	k_L	A	D_A	$[A^*]$	$[B]_0$	Volume of Liquid
1	No	No	No	No	$\propto [A^*]^m$	$\propto [B]_0$	Yes
2	Yes	$\propto k_L$	$\propto a$	$\propto \sqrt{\mathbf{D}_A}$	$\propto [A^*]$	No	No
3	No	No	$\propto a$	$\sqrt{\mathbf{D}_A}$	$\propto [A^*]^{\frac{m+1}{2}}$	$\propto [B]_0^{n/2}$	No
4	Yes	$\propto k_L$	$\propto a$	$\propto \frac{\mathbf{D}_A}{\mathbf{D}_B}$	No	$\propto [B]_0$	No

The variation of $[A^*]$ and $[B]_0$ over a wide range gives the values of m, n, and k_{mn}. The activation energy is also estimated.

The experimentally observed orders are $(m + 1)/2$ and $n/2$ in regime 3, whereas they are m and n in regime 1, although in both cases the operation is chemical reaction controlled. Obviously, the regime of operation should be known. It was mentioned earlier that, in regime 1, $\phi << 1$, whereas in regime –3, $\phi > 3$. In addition, another condition can be obtained from the equations for the overall rate of reaction given in Table 11.17. The overall rate is expressed per unit volume of total reactor, which includes all the phases. Thus, for a stirred cell, the rate is expressed per unit of total cell volume including liquid and gas phases. From the rate equation for regime l, the rate is proportional to the liquid fraction (ε_L) or the liquid volume taken for the reaction. Since the values of the effective interfacial area (cross-sectional area divided by total cell volume) and k_L are independent of liquid volume, the overall rate does not depend on the liquid volume in regimes 2, 3, and 4. These observations are listed in Table 11.19. Furthermore, the reaction-controlled regime 1 does not show any dependence on k_L (and hence impeller speed) and interfacial area. In regimes 2 and 4, the rate is proportional to k_L (and hence impeller speed), and in regimes 2, 3, and 4, the rate is proportional to a. All these dependencies are summarized in Table 11.19. The dependencies on $[A^*]$ and $[B]_0$ can be determined from the rate equations given in Table 11.19.

In addition to the stirred cell, other laboratory reactors commonly used include rotating drum contactor, wetted wall column, wetted sphere column, laminar jet, and stirred contactor. These equipments are shown schematically in Figures 11.14b–f. All have several common features, the principal one being a well defined gas-liquid interfacial area and the ability to vary the area per unit reactor volume (a). In the stirred cell, it is achieved by varying the liquid height. As an alternative way, a solid circular baffle is placed at the gas-liquid interface. Holes are drilled on the baffle plate so that the hole opening area becomes the interfacial area. For varying a, baffle plates are made with different free (hole) areas.

In the rotating drum contactor (Figure 11.14b), the value of a is adjusted by sliding the gas-tight screen, thus permitting the opening over a wide range from fully closed (no interfacial area) to fully open where half the cylinder is exposed to the gas. In the wetted wall column (Figure 11.14c), a film is formed over a certain height of the rod, below which a tight collar removes the liquid and discharges it into the liquid pool at the bottom. The interfacial area is varied by changing the film height by positioning the collar. In the wetted sphere column (Figure 11.14d), a is varied by changing the number of spheres (Pigford and Pyle, 1951). In the four

laboratory reactors just described, the range of k_L is practically the same. The value of k_L is varied by changing the liquid flow rate in the wetted wall column and wetted sphere column. In the stirred cell and rotating drum, the impeller and drum speeds are, respectively, manipulated for changing k_L.

As mentioned earlier, laboratory reactors are used for determining the intrinsic kinetic parameters. This objective is achieved by adjusting the parameters so the overall absorption operation falls in either regime 1 or regime 3, both being reaction controlled. It is preferable to obtain the regime 1 condition wherever possible. This is because, in regime 1, knowledge of diffusivity is not needed, and the reaction orders do not become modified (refer to Table 11.19). Although this may not be possible for all fluid-fluid reactions, in many cases regime 1 conditions can be obtained by lowering the value of $\sqrt{M}$. This objective is achieved mainly by selecting laboratory reactors that typically enhance k_L by a factor of 2 to 4. These include the laminar jet (Figure 11.14e) and stirred contactors. Typical ranges of k_L, a, contact time, and so forth of different laboratory reactors are given in Table 11.20.

In the laminar jet, a and k_L are varied by changing the jet length and liquid flow rate, respectively. The stirred contactor (Figure 11.14f) is similar to the stirred cell (Figure 11.14a), the chief differences being in impeller design and speed. In the stirred cell, the interfacial area is the cross-sectional area and the impeller speed is carefully adjusted to keep the interface visually flat. In the stirred contactor, turbines are used at high speed so that the contact area is in the form of bubbles. Very high values of k_La can be obtained in such a contactor so that the mass transfer resistance can be eliminated. However, it may be pointed out that the stirred contactor can be used only in regime 1, because the value of a cannot be estimated (this is the only laboratory reactor where *a priori* estimation of a is not yet possible).

As in the case of gas-solid catalytic reactors (Table 11.11), fluid-fluid reactors can also be rated in terms of ease of operation and cost. Such a rating is presented in Table 11.20. Further details about these reactors are given by Danckwerts (1970) and Doraiswamy and Sharma (1984).

11.3.4 Solid-Liquid Reactions

Several solid-liquid reactions are of commercial importance; sometimes the solid is slightly soluble or completely insoluble. Examples of the first category are dyeing with reactive dyes, sulfonation and nitration of aromatics at lower temperatures, recovery of paraffins by adductive crystallization with urea, and alkaline hydrolysis of solid esters such as dimethyl fumarate and nitrobenzoic acid esters. Those of the second category include manufacture of organometallic compounds (e.g., Grignard reagent), hydration of lime, generation of acetylene by reaction of water with CaC_2, and acidization of dolomite. Mass transfer associated with the liquid film surrounding the solid particles is then important. Doraiswamy and Sharma (1984) provide a detailed treatment of many aspects of these reactions.

11.3.5 Gas-Liquid-Solid Reactions

Such reactions are extremely important, particularly those where the solid acts as a catalyst and where the solid participates in the reaction. Examples are given in Tables 11.21 and 11.22, respectively. The basic principles of these reactions are explained in Case Studies 11.10 and 11.11, respectively.

Laboratory reactors for fluid-solid and fluid-fluid reactions were described in Sections 3.1.6 and 3.3.2, respectively. The discussion in these sections is also useful for gas-liquid-solid reactions. A combination of the Carberry reactor (Figure 11.7) and a stirred cell (Figure 11.14A) is useful for noncatalytic and catalytic reactions. Some discussion of these issues is presented in Case Studies CS8 and CS11 as well as by Joshi et al. (1985) and Joglekar et al. (1991).

TABLE 11.20
Laboratory Reactors for Fluid-Fluid Reactions: Their Principal Features and Ratings[a]

		Residence Time	Surface Renewal Time	Effective Interfacial Area m^2/m^3	Interfacial Area per Unit Liquid Volume m^2/m^3	Range of $k_L \times 10^5$ m/s	Ease of Operation	Accuracy of Liquid Phase Residence Time/Liquid Phase Mixing	Ease of Sampling and Accuracy of Measurement	Construction Difficulties and Cost

Hydrogenation of carbohydrates; hydrogenation of α-methyl styrene; hydrogenation of phenyl acetylene; hydrogenation of adiponitrile; hydrogenolysis of methyl esters of fatty acids; hydrogenation of olefinic compounds; hydrogenation of fatty oils; hydrogenation of nitro compounds to amines; reduction of nitrite/nitrate to hydroxylamine salt; Fischer-Tropsch synthesis; hydrogenation of crotonaldehyde; hydrogenation of allyl alcohol; oxidation of aqueous sodium sulfide; oxidation of alcohols in aqueous alkaline media; reduction of uranium by hydrogen; hydrocracking of α-cellulose; dehydrogenation of secondary alcohols to ketones; polymerization with Ziegler-Natta catalyst; simultaneous hydrogenation of ethylene and propylene; production of calcium acid sulfite; direct coal liquefaction; hydrodemetallization; hydrogenation of glucose; hydrogenation of butynediol; desulfurization of petroleum fractions; desulfurization of coal.

11.4 CLASSIFICATION OF REACTORS AND THEIR DESCRIPTION

11.4.1 Introduction

Reactors must often be designed to consider both chemical reactions and physical operations such as micromixing, macromixing, heat transfer, mass transfer, gas-liquid dispersing, liquid-liquid dispersing, and so forth. For all cases, energy is supplied in various ways to the equipment. The equipment can be classified on the mode of energy supply: (1) pressure energy, (2) kinetic energy, and (3) potential energy.

Class 1 equipment are also called column-type equipment. Under this category, there are the various multiphase contactors. Gas-liquid contactors include bubble columns, packed bubble columns, internal-loop and external-loop air-lift reactors, sectionalized bubble columns, plate columns, and others. Solid-fluid (liquid or gas) contactors include static mixers, fixed beds, expanded beds, fluidized beds, transport reactors or contactors, and so forth. For instance, fixed-bed geometry is used in unit operations such as ion exchange, adsorptive and chromatographic separations, and drying and in catalytic reactors. Liquid-liquid contactors include spray columns, packed extraction

columns, plate extraction columns, static mixers, and so on. Similar equipments are widely used in gas-liquid-solid, gas-liquid-liquid, and gas-liquid-liquid-solid contactors.

In multiphase contactors, the dispersed phase is either bubbles, drops, particles, or combinations thereof. The continuous phase is either liquid or gas. The governing features of the dispersed phase are its size and velocity distributions, both of which have a major impact on the performance of these equipments. The other governing parameters include column diameter, column height, sparger design, and internal design. Furthermore, in class 1 equipment, the energy is supplied through the introduction of phases. For instance, in the case of bubble columns and gas-fluidized beds, the gas is supplied against the static pressure of the multiphase dispersion, and the energy input rate is given by the following equation:

$$E_i = Q_G \bar{\rho}_D H_D g \tag{11.104}$$

where $\bar{\rho}_D$ is the average density of the dispersion, and E_i is the pressure energy. Class 1 equipments, therefore, are classified under pressure energy.

Class 2 equipments include mainly stirred-tank reactors, in which impellers supply energy to the reactant(s). The fluid leaving the impeller has kinetic energy. The energy is used for a variety of objectives such as producing liquid-liquid, gas-liquid, solid-liquid, and higher-order dispersions. Stirred reactors, in which one or more impellers generate the desired flow and mixing, are among the most widely used reactors. Stirred reactors offer unmatched flexibility and control over the transport processes in the reactor. The performance of a stirred reactor can be optimized by appropriate adjustments of the reactor hardware and the operating parameters (reactor and impeller shapes; number, type, location and size of impellers; degree of baffling; control the performance of stirred reactors; and so on).

In class 3 equipments, the energy supplied is in the form of potential energy associated with the liquid. For instance, in the conventional packed column (used for either distillation or absorption), the liquid is pumped to the top of the column and distributed over the packing. If the gas is introduced at the bottom, the gas phase has the pressure energy; however, it is usually negligible as compared with the potential energy of the liquid. Even if the gas and liquid phases flow cocurrent downward, the major contribution to the energy is by the liquid phase. Since the liquid flows as films, these equipments (class 3) may also be termed *film contactors*. Other equipments in this category include trickle-bed reactors and falling-film reactors/evaporators. In packed columns, a variety of packing shapes (and of course sizes and materials of construction) are used in practice; these include Raschig rings (in old installations), Berl saddles, partition rings, intelox saddles, Pall rings, hipack rings, and structured packing. Equally important is the uniformity of liquid distribution. The more important ones (under each class) are described below. Table 11.23 presents a list of reactors under each category.

11.4.2 Pressure Energy

11.4.2.1 Gas-Liquid Reactors

11.4.2.1.1 Bubble Columns

The bubble column used as a reactor consists of a vertical cylindrical vessel with height-to-diameter ratio in the range of 1 to 20 (often 3 to 10). Gas is introduced at the bottom via a sparger. Spargers include sieve plate, ring, spider, radial sparger, ejector, injector, and so on. Schematic diagrams of a bubble column and spargers are shown in Figures 11.15 and 11.16, respectively. The column top is expanded to facilitate foam breakage and to reduce the entrainment of liquid in the exit gas. The bubble column is operated either in a semicontinuous mode (gas, continuous; liquid, batch) or in a continuous mode (gas and liquid both continuous). In the latter case, the liquid phase may flow either cocurrent or countercurrent to the gas.

TABLE 11.23
Classification of Reactors Belonging to Different Modes of Energy Input

Pressure Energy

Gas-Liquid Reactors

Bubble column, packed bubble column, sectionalized bubble column, plate column, external- and internal-loop air-lift reactors, static mixer, venturi scrubbers

Liquid-Liquid Reactors

Spray column, packed extraction column, liquid-liquid adaptations of loop reactors, plate extraction column, static mixers.

Solid-Liquid Reactors

Fluidized-bed reactor, fixed-bed reactor

Gas-Solid Catalytic Reactors

Fixed-bed reactors (multi-tubular and staged adiabatic), fluidized-bed reactors (bubbling bed, turbulent bed, fast, and transport or pneumatic), radial flow reactor, gauz reactor

Gas-Liquid-Solid Reactors

Fluidized-bed reactor, slurry reactor

Kinetic Energy

Single-stage and multistage stirred-tank reactors, self-inducing reactor, jet-loop reactor, plunging- jet reactor, surface aerator

Potential Energy

Packed column, trickle-bed reactor, film reactors (falling film, agitated film, scraped/wiped film), rotating disk (or rotating packed-bed) reactor

In bubble columns, since the gas bubbles are dispersed in the continuous liquid phase, fractional gas holdup (ε_G) is an important design parameter, affecting column performance. The most direct and obvious effect is on the column volume, since a significant fraction of the volume is occupied by the gas. The indirect influences are also important. For instance, the possible spatial variation of ε_G gives rise to pressure variation, which results in intense liquid phase motion. These secondary motions govern the rates of mixing plus heat and mass transfer.

The fractional gas holdup is defined as the volume fraction of gas in the gas-liquid dispersion and is measured in several ways (Joshi et al., 1990a). The measurements of average gas holdup $\bar{\varepsilon}_G$ and local gas holdup are both reasonably well developed. Despite the good agreement between different measuring methods, we have not yet reached a stage where holdup can be predicted for an unknown gas-liquid system, as next discussed.

The fractional gas holdup is principally governed by the following features of the bubbles: size, velocity, and number. The average bubble size depends on the sparger design, energy dissipation rate near the sparger, and the coalescing nature of the gas bubbles (which depends on liquid viscosity, surface tension, and other surface active properties). For a perforated plate and ring sparger, the energy dissipation rate is relatively small. The average bubble size decreases with a decrease in both the hole size and the surface tension. The coalescing nature has little influence on d_{bp} in the spargers. For sintered and ejector/injector type spargers, the coalescing nature of the liquid phase, however, has a substantial influence (Buchholtz et al., 1983; Heijnen and van't Riet, 1984; Zahradnik et al., 1997). The energy dissipation rate is also relatively high and, therefore, fine bubbles (a few micrometers to 1 mm) are generated in noncoalescing liquids. In the case of coalescing liquids, the bubbles grow a short distance from the sparger, and the bubble size is practically the same as that generated by perforated spargers.

Fractional gas holdup also depends strongly on superficial gas velocity and the nature of the gas-liquid system. Column diameter and height often have some influence on ε_G. The quantitative

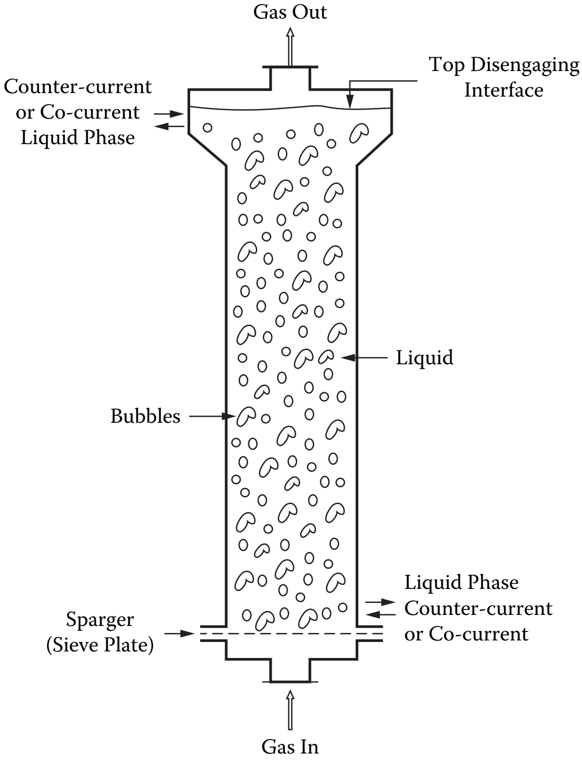

FIGURE 11.15 Schematic diagram of bubble column.

effect, however, depends on the regime of dispersion in bubble columns: homogeneous or heterogeneous. The homogeneous regime is characterized by almost uniform sized bubbles. Furthermore, the concentration of bubbles is also uniform, particularly in the transverse direction (Figure 11.17a). If the gas is sparged uniformly into the bottom of the column, it remains uniformly distributed across the column. All bubbles rise virtually vertically with only minor transverse and axial oscillations plus little coalescence or redispersion. Hence, the size of the bubbles in the homogeneous regime is governed mainly by the design of the sparger and the physical properties of the system.

In contrast, the heterogeneous regime is characterized by nonuniform bubble concentration (Figure 11.17b). The ε_G profile is usually parabolic and results in pressure profiles as shown in Figure 11.18a. These profiles cause upward liquid circulation in the central region and downward near the column wall (Figure 11.18b). In such a recirculatory flow, turbulence is much higher as compared to the homogeneous regime, where the recirculation is absent. In the heterogeneous regime, the bubbles retain their identity only over a small distance from the sparger, and this region is called the *sparger region*. In the bulk region, the bubble size is governed by the coalescence and redispersion phenomena. A wide bubble size distribution occurs in the bulk, and the average bubble size (which is called the *secondary bubble size*, d_{bs}) is decided by the balance between the breaking (viscous and turbulent shear stress), the retaining (surface tension) forces, and the coalescing nature of the liquid phase. The value of d_{bs} decreases with a decrease in surface tension and an increase in the power consumption per unit volume (**P**/*V*). Furthermore, for a given value of **P**/*V*, the average bubble size is smaller in noncoalescing liquids than in coalescing liquids. It is known that the coalescing nature increases with an increase in liquid viscosity and a decrease in gas density. Pure liquids usually show coalescing behavior. However, a mixture of two liquids gives some noncoalescing properties (Bach and Pilhofer, 1978). For example, water and aliphatic alcohol are individually of the coalescing type. The addition of small quantities of aliphatic alcohol to water makes

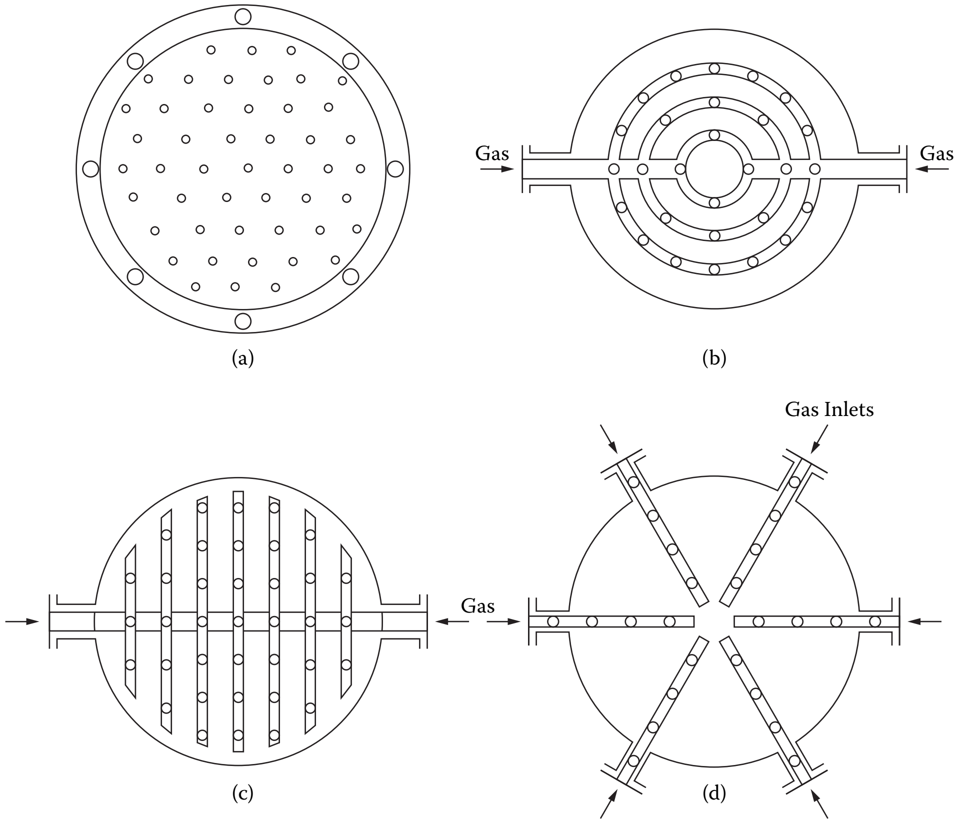

FIGURE 11.16 Schematic diagrams of spargers: (a) sieve-plate, (b) ring, (c) spider, and (d) radial.

the liquid mixture somewhat noncoalescing. The strength of the noncoalescing property increases with an increase in alcohol concentration (up to a limit) and an increase in the number of carbon atoms in the alcohol. An electrolyte in water imparts noncoalescing features, whose strength depends on its type and concentration. The presence of small amounts of surface active impurities may also impart noncoalescing features. For instance, tap water and distilled water often have quite different coalescing properties (Anderson and Quinn, 1970). The measurement and prediction of the strength of the noncoalescing nature is complex, which complicates the prediction of bubble size and fractional gas holdup.

The secondary bubble size, d_{bs}, generally is different from the primary bubble size, d_{bP}. In the near-sparger region, the primary size changes with distance from the sparger and finally attains the secondary size. The height of the sparger region depends on the difference between d_{bp} and d_{bs}. If special care is taken to bring d_{bp} close to d_{bs}, the height of the sparger region is small. When $d_{bp} < d_{bs}$, $\bar{\varepsilon}_G$ decreases with an increase in the column height. In contrast, when $d_{bp} > d_{bs}$ (for instance, in the case of single-point sparger), $\bar{\varepsilon}_G$ increases with an increase in the column height. For any difference between d_{bP} and d_{bS}, the height of the sparger region increases with an increase in the noncoalescing nature of the liquid phase. As a result, the height of the sparger region is in the range of $1 < H/D < 5$.

In the sparger region, the liquid flow pattern becomes developed. If the overall column height is much greater than the height of the sparger region, the holdup does not change with respect to the sparger design or the column height. However, care must be taken to account for the effect of the hydrostatic head on the superficial gas velocity. The value of u_G should be expressed at the average pressure between the bottom and the top.

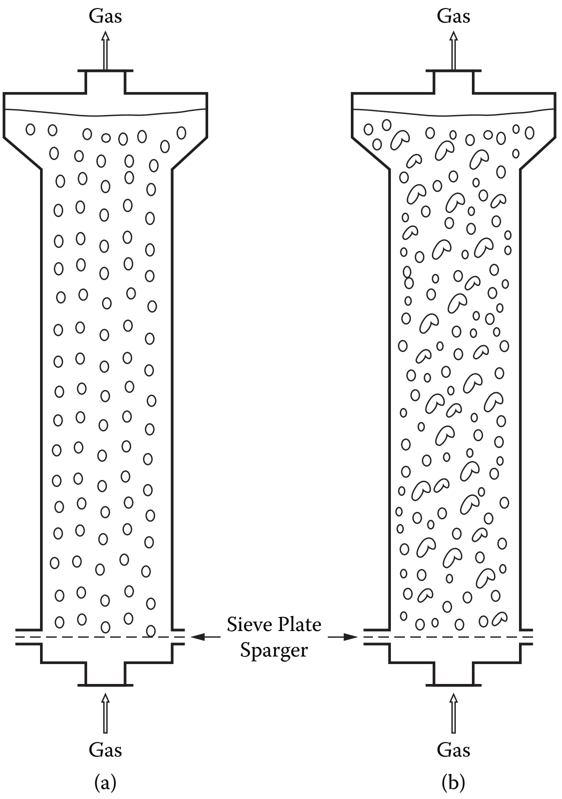

FIGURE 11.17 (a) Schematic representation of the homogeneous regime: uniform concentration and size distributions of bubbles in the transverse direction. (b) Schematic representation of the heterogeneous regime: nonuniform concentration and bubble size distributions in the transverse direction. (From Bhole, M. R. and Joshi, J. B. Stability analysis of bubble columns: Predictions for regime transition. *Chem. Engr. Sci.,* 4493–4507 (2005).)

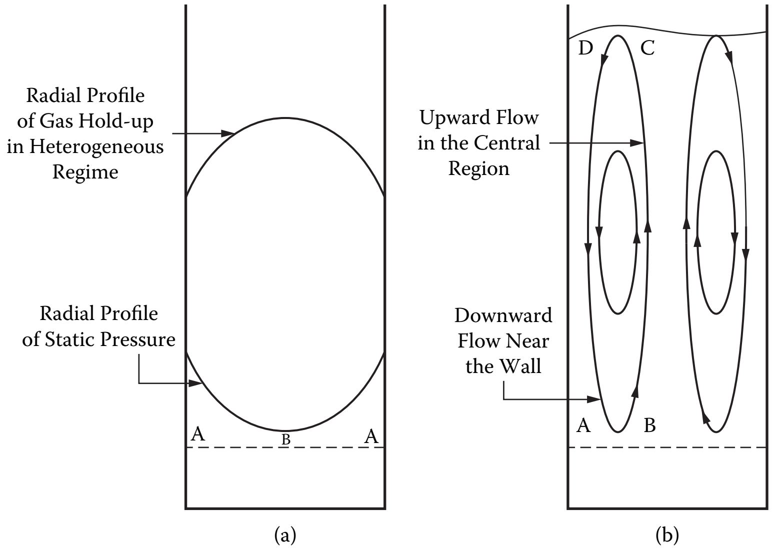

FIGURE 11.18 Some aspects of the heterogeneous regime: (a) radial profiles of gas holdup and static pressure, (b) scehematic of liquid circulation pattern.

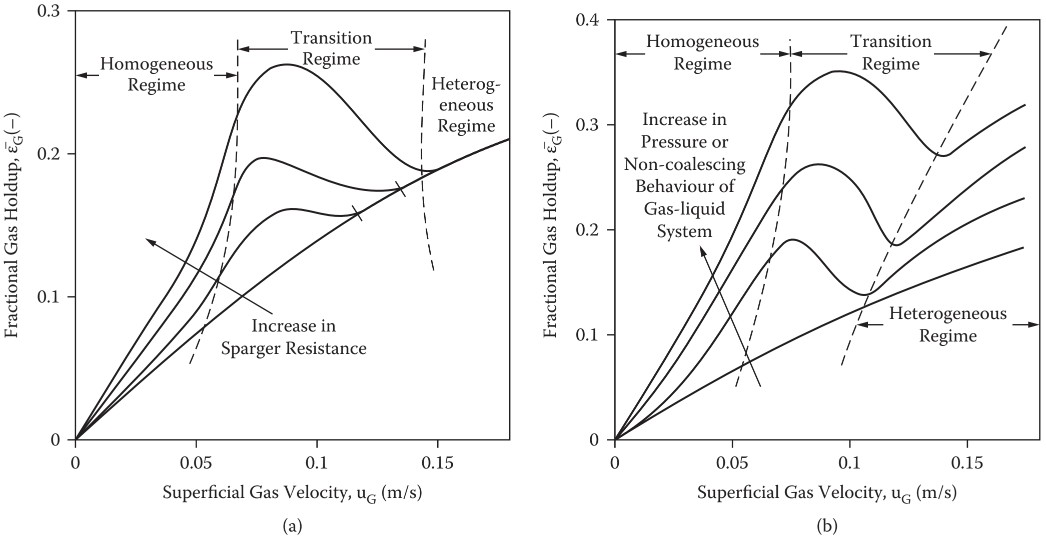

FIGURE 11.19 Relation between gas hold-up and superficial gas velocity for different regimes of operation: (a) effect of sparger resistance, (b) effect of total pressure and coalescing nature of the gas-liquid system.

The value of $\bar{\varepsilon}_G$ increases with an increase in the superficial gas velocity. However, the $\bar{\varepsilon}_G - u_G$ relationship depends on the regime of operation (Figures 11.19a and b). This in turn is governed by the design (sparger design, column diameter, column inclination) and operating (superficial gas and liquid velocities, μ_L, σ, ρ_G and the coalescing nature of the liquid phase) parameters. Figure 11.19a shows the effect of sparger design on regime transitions; the upper limit u_G (up to which the homogeneous or transition regime prevails) increases with an increase in sparger resistance. Once the heterogeneous regime is attained, the gas holdup is independent of sparger resistance. The effect of liquid-phase physical properties on regime transition is shown in Figure 11.19b. In this case, the upper limit of u_G increases with a decrease in bubble diameter, which happens with a decrease in liquid viscosity, increase in surface, increase in gas density, increase in the noncoalescing nature of the liquid phase, and so forth. Furthermore, in the heterogeneous regime and at the same u_G, the gas holdup increases with a decrease in bubble diameter. This observation is different from that shown for the sparger (Figure 11.19a). The $\bar{\varepsilon}_G - u_G$ relationship may be expressed in the form of a power law model

$$\bar{\varepsilon}_G \propto u_G^a \tag{11.105}$$

The value of a is greater than or equal to 1 in the homogeneous regime, whereas it is less than 1 (0.4 to 0.8) in the heterogeneous regime. In the transition regime, the value of x continuously decreases from a high homogeneous value to a low heterogeneous value. Other features of gas-liquid dispersions have been described by Joshi et al. (1998).

The fractional gas holdup is known to be independent of column diameter in both the homogeneous and heterogeneous regimes. However, for a given gas-liquid system, the value of $\bar{\varepsilon}_G$ is independent of the column diameter if the regime of operation is the same. The homogeneous regime prevails in small-diameter columns and the heterogeneous regime in large-diameter columns. Therefore, $\bar{\varepsilon}_G$ may depend on the column diameter. This problem is particularly noticeable at low values of u_G (< about 80 mm/s). At high values of u_G and for air-water type systems, the heterogeneous regime prevails, and the fractional gas holdup becomes independent of the column diameter when it exceeds about 150 mm. Such a critical value of column diameter increases with an increase

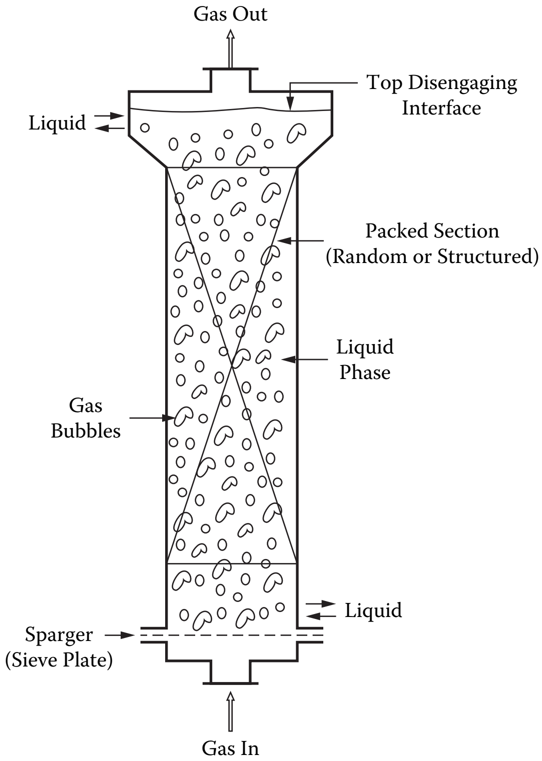

FIGURE 11.20 Packed bubble column.

in non-Newtonian behavior and an increase in viscosity beyond 100 mPa. Further details pertaining to bubble columns are reported by Deckwer (1992) and Joshi et al. (1998).

Bubble columns are simple in construction and operation, providing sufficient flexibility for the liquid-phase residence time. Also, they provide some flexibility even for the gas-phase residence time. However, the bubble columns have two limitations: back-mixing in the liquid phase and high pressure drop for the gas phase. To minimize these limitations, modified bubble columns are often used, as next reported.

11.4.2.1.2 Packed Bubble Columns

A bubble column filled with packings reduces liquid circulation (Figure 11.20). The extent of reduction depends on the resistance provided by the packings, which in turn depends on the voidage and packing factor. The packings may be random, wire mesh, or structured. Pandit and Joshi (1983) have reported that backmixing in packed bubble columns is three to five times lower than that in unpacked bubble columns. For a given duty, the volume of a packed bubble column is less than that of a bubble column, but the cost of the packed bubble column per unit volume is much higher. Therefore, the total equipment cost should be calculated before making any decision.

Packed bubble columns are also used as catalytic reactors where the packings are catalyst particles in the form of extrudates or tablets. These particles have a dual role: one as a catalyst and the second to reduce backmixing. In this case, there is the need to optimize column diameter, height, particle size, and shape.

11.4.2.1.3 Sectionalized Bubble Columns and Plate Columns

Liquid circulation is reduced by baffles. Figure 11.21 shows radial baffles with central openings. Figures 11.21a and b show flat and conical baffles, respectively (conical shape is preferable for a solid suspension). These baffles minimize liquid circulation. The resulting flow pattern is shown

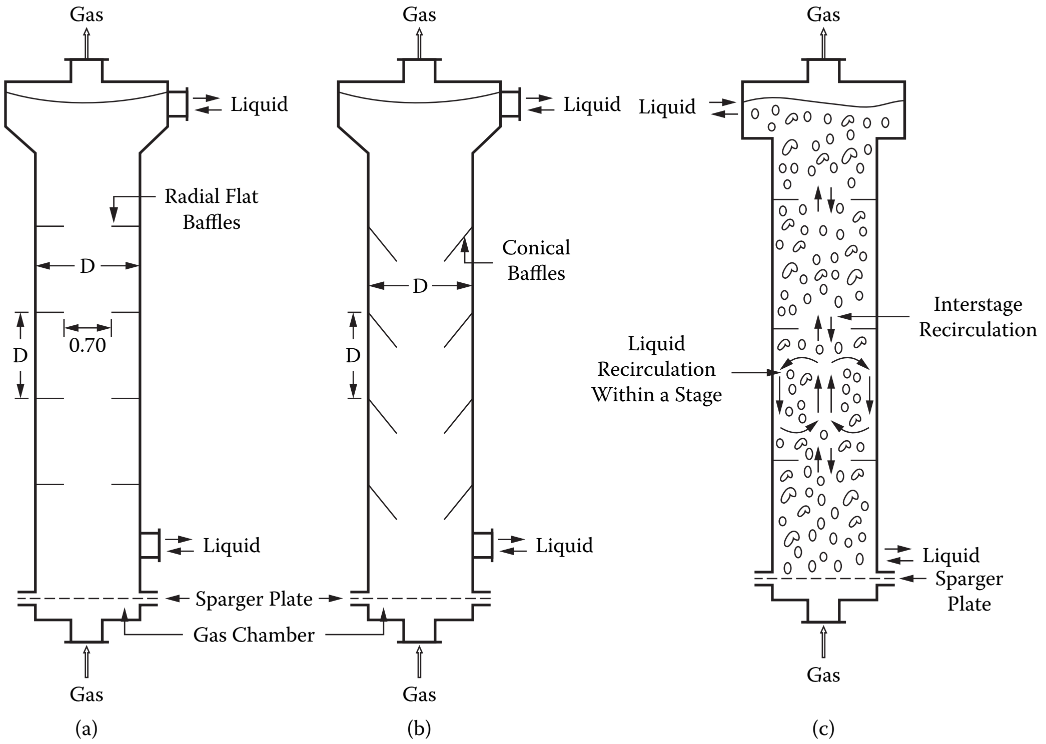

FIGURE 11.21 Sectionalized bubble columns: (a) flat baffles, (b) conical baffles, and (c) flow pattern.

schematically in Figure 11.21c. Joshi and Sharma (1979) analyzed the fluid mechanics of such a system and have recommended the optimum spacing to be 0.8 D and the central hole diameter 0.7 d_T, where d_T is the column diameter. As indicated in Figure 11.21c, multiple stages equal to the number of baffles are formed. There may be interstage recirculation through the central opening, which reduces the effectiveness of multiple stages. The recirculation can be reduced by decreasing the hole diameter; however, it affects the gas distribution. Alternatively, a sieve plate may be selected instead of a baffle. Holes are provided for the flow of gas. The hole diameter and free area are selected so that sufficient resistance is provided for the flow of gas and, as a result, gas spaces are formed below each plate as shown in Figure 11.22. The net liquid upflow/downflow occurs through riser/downcomer in cocurrent/countercurrent cases, respectively. Each section is considered as one backmixed stage. Five such backmixed stages (Levenspiel, 1991) give flow behavior very close to plug-flow if interstage recirculation is completely absent. In reality, finite weeping and entrainment take place, and it is desirable to have up to ten stages to obtain plug-flow.

The extent of weeping and entrainment decreases with an increase in plate resistance resulting from smaller hole diameter. However, there is a limit, and micrometer-size sintered plates are not used because of clogging and maintenance difficulties. Furthermore, for a given plate, the extent of weeping decreases with a decrease in liquid submergence on a plate. Also, entrainment decreases with an increase in the height of gas space. Therefore, in a conventional plate column, the liquid submergence, empty space height, and plate resistance are optimized for the combined objective of maximizing plate efficiency and minimizing the pressure drop. The former height is in the range of 50 to 200 mm and the latter 200 to 600 mm. Plate efficiency is typically 40% to 75%. In plate columns, the trays are generally bubble cap, valve, or sieve plate. On each plate, the liquid and gas flows occur in a crossflow manner, whereas the interstage liquid flow occurs through the downcomers. Further details on trays and plate columns are found in Treybal (1980) and in the "Distillation" (Chapter 12) and "Absorption" (Chapter 13) of this book.

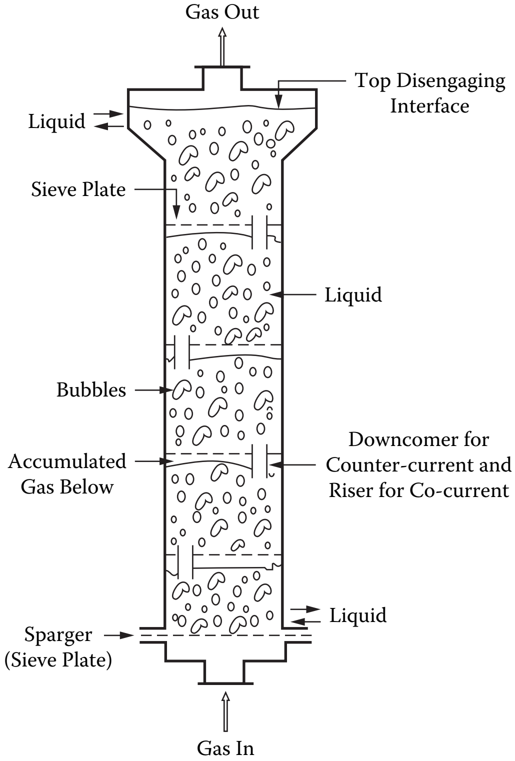

FIGURE 11.22 Sectionalized bubble column with sieve plate.

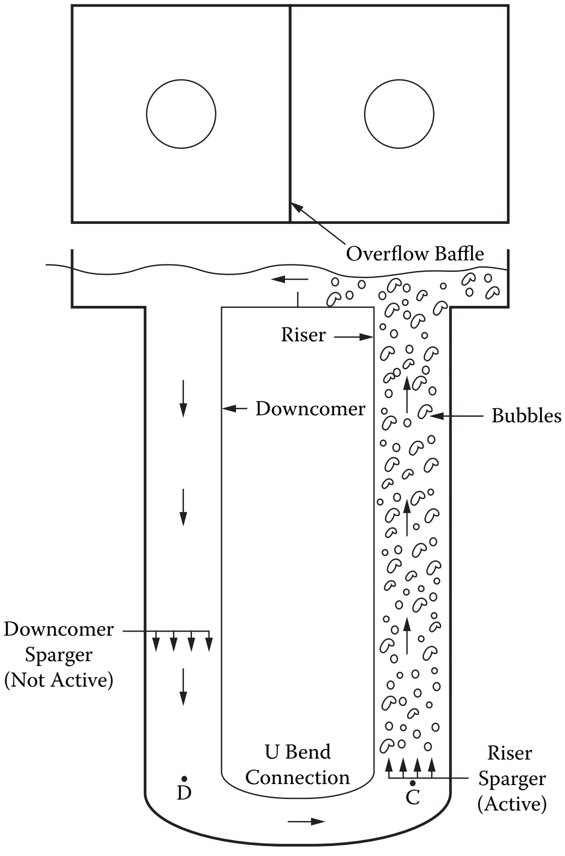
11.4.2.1.4 Air-Lift Reactors

The bubble column reactor suffers from two major limitations: (1) complete backmixing in the liquid phase and (2) high pressure drop. To overcome the first limitation, suitable modifications were described in previous sections. Now, let us consider the air-lift reactor, which offers the advantage of low pressure drop. Air-lift reactors are of two types: external-loop (Figures 11.23a and b) and internal-loop (Figure 11.24). An external-loop air-lift reactor (EL-ALR) consists of two columns that are connected at the bottom by a U-type connection as shown in Figure 11.23. At the top, a gas disengagement tank is provided. To start the operation of an air-lift reactor, gas is first introduced through the riser sparger. The gas phase ascends in the form of bubbles in the riser section and finally disengages at the top liquid surface in the disengagement tank. The gas bubbles are maintained on the riser side by a vertical baffle, which is located between the riser and downcomer sections. The downcomer section is kept bubble free during the startup. Since the gas-liquid dispersion is present only in the riser section, the average fluid density ($\varepsilon_L\rho_L + \varepsilon_G\rho_G$) is less in the riser section. Therefore, the static pressure at the bottom of the riser (point C in Figure 11.23a) is low as compared to that at the corresponding location (point D) in the riser. The resulting pressure generates flow from D to C, which further ascends in the riser, overflows the top baffle, and flows downward in the downcomer. As a consequence, well-directed circulation is established. The average liquid circulation can be calculated, as a first approximation, by equating the pressure driving head with the velocity head:

$$P_C = (\varepsilon_{LR}\rho_L + \varepsilon_{GR}\rho_g)gH_d \tag{11.106}$$

$$P_D = \rho_L g H_D \tag{11.107}$$



(a)

FIGURE 11.23 External-loop air-lift reactor: (a) riser sparging, (b) downcomer sparging. *Continued*

$$\rho_L \frac{u^2}{2} = P_D - P_C \tag{11.108}$$

Substituting Equations (11.106) and (11.107) in (11.108), assuming ρ_G to be negligible, and for simplicity assuming the same average liquid velocity in the downcomer and riser sections, we get

$$u = \sqrt{2\varepsilon_{GR} g H_D} \tag{11.109}$$

For instance, for a riser gas holdup, ε_{GR}, of 0.2 and a reactor height, H_D, of 10 m, the average liquid circulation velocity is 6.26 m/s. That is, liquid circulation velocity is very high. If a bubble is introduced in the downcomer, it is entrained downward if the liquid velocity is higher than the bubble rise velocity. It may be pointed out that the presence of gas on the downcomer side reduces the pressure driving force. However, the circulation continues even if part of the downcomer section is occupied by the gas phase. This is because (Figure 11.23b) part of the downcomer is bubble free. P_D is given by

$$P_D = [HSD(\varepsilon_{LD}\rho_L + \varepsilon_{GD}\rho_G) + (H - H_{SD})\rho_L]g \tag{11.110}$$

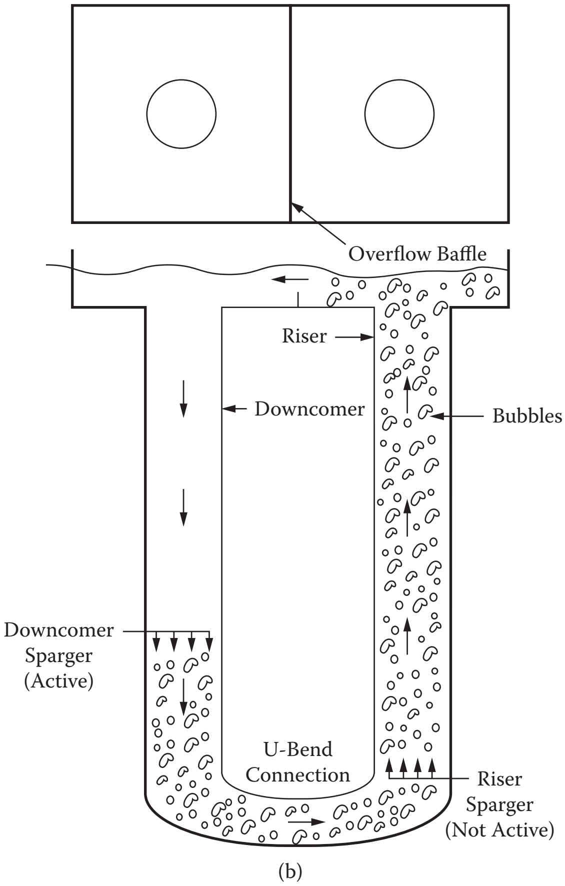


FIGURE 11.23 *Continued.*

where H_{SD} is the sparger location on the downcomer side and P_C is given by Equation (11.106). Now, the average liquid circulation velocity is given by

$$u = \sqrt{2\left(\varepsilon_{GR} g H_D - \varepsilon_{GD} g H_{SD}\right)} \tag{11.111}$$

The liquid circulation continues until the value of u is higher than the bubble rise velocity. This is true even if the riser sparger is stopped (of course, after the circulation pattern is well developed). Furthermore, from Equation (11.111), it can be seen that the circulation velocity decreases with an increase in H_{SD}. At a critical location of $H_{SD}(H_C)$, u equals the bubble rise velocity. In reality, H_{SD} has to be lower than H_C. As a factor of safety, typically, H_{SD} is up to 40% of H.

The gas phase (Figure 11.23b) is introduced downward through the downcomer sparger, takes a U turn at the bottom, ascends in the riser, and leaves the column through the disengagement tank. Thus the gas phase need not be introduced at the bottom as in the conventional bubble column, and hence the pressure drop can be reduced up to 40% since sparger location is permissible at a higher level where the static pressure is obviously lower. Since the gas phase passes through the bottom section, high pressure in the bottom section results in a high saturation concentration of the solute gas.

In addition to low pressure drop, external-loop air-lift reactors have several advantages over bubble-column reactors. The former offer much flexibility in design in terms of height-to-diameter ratio, area ratio of downcomer to riser, sparger locations, and so on. Conditions can be manipulated

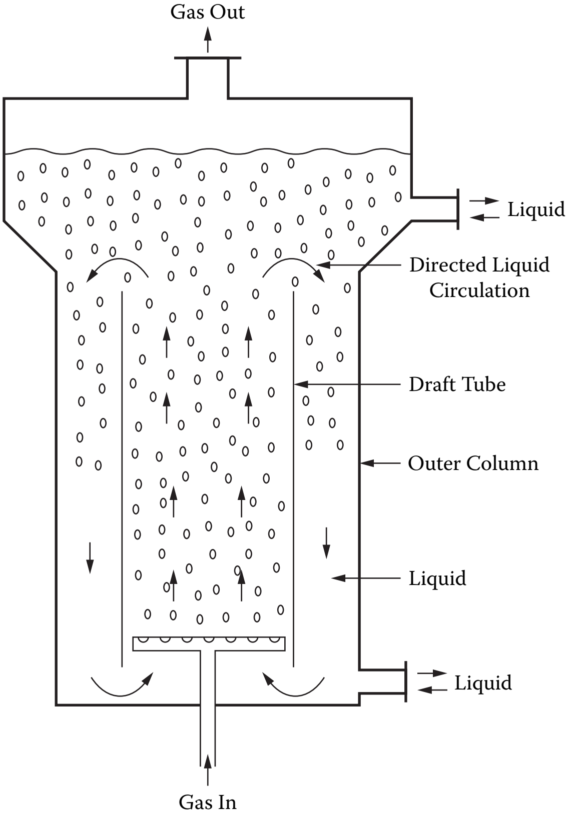

FIGURE 11.24 Internal-loop air-lift reactor.

for optimum performance to obtain the desired gas holdups, gas-liquid interfacial area, heat- and mass-transfer coefficients, and extent of mixing. If desired, the intensity of liquid circulation and turbulence can be kept low in an EL-ALR as compared to BCR. Therefore, the level of the shear stress (turbulent) is much smaller in EL-ALR as compared to BCR when compared at the same power consumption per unit volume. Low levels of shear in the loop reactor are generally desired for many biological reactions of shear-sensitive cells. Other design details of EL-ALR have been described by Joshi et al. (1990b) and Lele and Joshi (1993).

When the total reactor volume is small (< 5 to 10 m^3), an air-lift reactor can be used in the form of an internal loop as shown in Figure 11.24.

11.4.2.1.5 Two-Phase Pipe-Flow and Static Mixers

In previous sections, two-phase gas-liquid flow was considered in vertical bubble columns and modified bubble columns. In these reactors, the desired regime of gas-liquid flow is bubble flow, and therefore the column diameter is at least 150 mm. The superficial gas velocity usually varies from 10 to 500 mm/s and the superficial liquid velocity from 0.01 to 30 mm/s, with a liquid phase residence time from 10 min to a few days. In two-phase gas-liquid flows in horizontal pipes, the superficial gas and liquid velocities are in the range of 0.01 to 10 m/s and 0.1 to 5 m/s, respectively. For two-phase pipe-flow, the pipe diameter is usually up to 200 to 300 mm when used as a reactor.

In two-phase gas-liquid flows in horizontal pipes, various flow regimes occur, depending on the range of superficial gas and liquid velocities. These include (a) bubble or froth flow, (b) plug flow, (c) stratified flow, (d) wavy flow, (e) slug flow, and (f) spray or dispersed flow. In vertical pipes, the flow regimes are (a) bubbly flow (this regime was considered in the case of bubble column reactors); (b) piston, plug, or slug flow; (c) ripple or wavy flow; (d) annular or film flow;

and (e) mist flow. Regime maps for horizontal and vertical flows have been discussed in detail in various books (Green and Perry 2007). Such reference books also give the present status on the estimation procedures for two-phase pressure drop and factional phase holdup.

11.4.2.2 Liquid-Liquid Reactors

Liquid-liquid reactors are similar to gas-liquid reactors. In the former case, the dispersed phase is in the form of droplets as against bubbles in the latter. The motion of bubbles and drops can be described using a unified approach. A spray column (or a drop column) is the equivalent of a bubble column but with one difference. The dispersed gas phase is always lighter than the continuous liquid phase ($\rho_G < \rho_L$). However, the dispersed liquid phase in spray columns may be lighter or heavier than the continuous immiscible liquid phase. Nevertheless, spray columns can be easily described similar to bubble columns. Furthermore, packed bubble columns and sectionalized bubble columns can be considered equivalent to packed extraction columns and plate extraction columns. External-loop and internal-loop reactors are also possible (for equivalent gas-liquid reactors, refer to Section 11.4.2.1.4).

11.4.2.3 Solid-Liquid Reactors

The upward flow of a fluid through a fixed bed of particles results in rather low flow rates. However, when the superficial fluid velocity is sufficiently high, the particles become supported in the liquid, resulting in a fluidized bed. If the flow rate of fluid is increased beyond the minimum required to produce a fluidized bed, either of two possibilities occurs: (1) the bed continues to expand so that the average distance between the particles becomes greater with no holdup gradients in the radial direction, or (2) the excess fluid passes through the bed in the form of bubbles, resulting in holdup gradients. These types of fluidization are usually termed as *particulate* and *aggregative*, respectively. In general, particulate (or homogeneous) fluidization occurs with solid-liquid systems. For solid-gas systems, homogeneous fluidization occurs when the particle settling velocity is low (fine particles or/and high operating pressure) and is limited to a relatively small range of velocities. Heterogeneous fluidization occurs with all other solid-gas systems, and sometimes with solid-liquid systems as well when the particles are of high density or/and size. Particulate/aggregative fluidization has been discussed in detail by Joshi et al. (2001).

If a liquid is passed vertically upward through a bed of uniform particles, the pressure drop, ΔP, increases with an increase in the superficial liquid velocity, u_L. The relation between pressure drop and velocity is the same as for a fixed bed, as indicated by the following equation (Ergun, 1952):

$$\Delta P = \frac{150\mu_L u_L L}{d_p^2}\frac{\varepsilon_S^2}{\varepsilon_L^3} + 1.75\frac{\rho_L u_L^2 L}{d_p}\frac{\varepsilon_S}{\varepsilon_L} \quad (11.112)$$

For a given bed of particles, ρ_L and d_P, a log-log plot of ΔP vs. u_L (line LM in Figure 11.25) is linear. When the velocity reaches such a value that the frictional force on a particle equals the force due to the gravity minus the buoyancy, the particles become freely supported. At this stage (point M in Figure 11.25) the frictional pressure drop equals the buoyant weight of particles per unit bed cross-sectional area, and the bed is just fluidized and is said to be at the *point of incipient fluidization.* The superficial liquid velocity at this point is called the *minimum fluidization velocity,* u_{mf}. As the liquid velocity is further increased, the pressure drop across the bed remains constant (line MN in Figure 11.25) because the buoyant weight of solids remains constant. The wall pressure drop is usually negligible as compared with the frictional pressure drop at the particle-liquid interface.

The pressure drop in a fixed and fluidized bed can be given by the following single generalized equation (Pandit and Joshi, 1998):

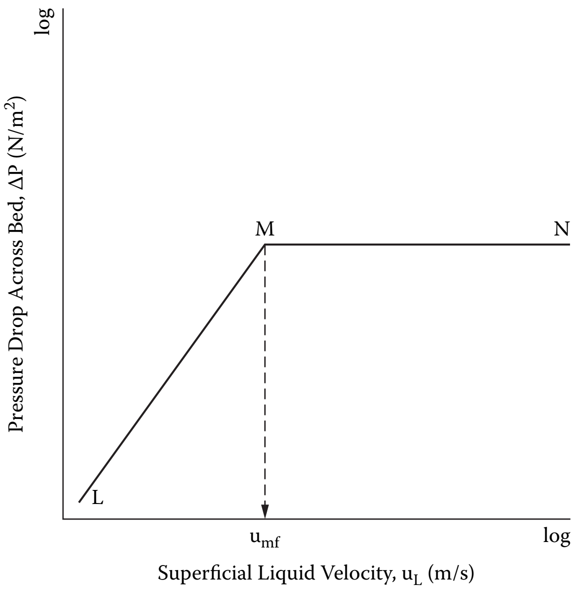

FIGURE 11.25 Log-log plot of pressure drop (ΔP) versus superficial liquid velocity for a liquid-liquid fluidized bed.

$$\frac{\Delta P}{L}\frac{d_p\varepsilon_L^{4.8}}{\varepsilon_S\rho_L u_L^2}=\frac{18}{\text{Re}_p}+0.33 \qquad (11.113)$$

In a solid-liquid fluidized bed, the bed expansion is determined by the Richardson-Zaki (1954) equation:

$$\frac{u_L}{u_{S\infty}}=\varepsilon_L^n \qquad (11.114)$$

Solid-liquid fluidization details are reported by Joshi (1983) and Di Felice (1995).

11.4.2.4 Gas-Solid Catalytic Fixed-Bed Reactors

The fixed-bed reactor is the most widely used reactor for reactions catalyzed by solid catalysts. The most important of a number of designs are the nonisothermal nonadiabatic fixed-bed reactor (NINA-FBR) (also called the tube-and-shell or heat exchanger type reactor), the single or multistage adiabatic fixed-bed reactor (A-FBR), and the radial flow fixed-bed reactor (RF-FBR). A newer design is the spherical reactor (Hartig and Keil, 1993). It is important at the outset to note the difference between the approaches to the design of the NINA-FBR and the A-FBR. A typical NINA-FBR unit is shown in Figure 11.26. It consists of a tube bundle, usually around 3 cm in diameter, placed in a shell. Often, the catalyst is placed in the tubes, and a heat exchange fluid is circulated through the shell. A less common design is one in which the shell contains the catalyst, and the heat exchange fluid is circulated through the tube bundle. The height of the reactor usually is in the range of 3 to 10 m, resulting in a temperature profile for reactions with even a low heat effect (exothermic or endothermic). Exothermic reactions result in hot spots that frequently lead to catalyst deactivation and adverse changes in conversion/selectivity. The design objective is to find the height for a required conversion using tubes of fixed diameter. Then, depending on selectivity, stability,

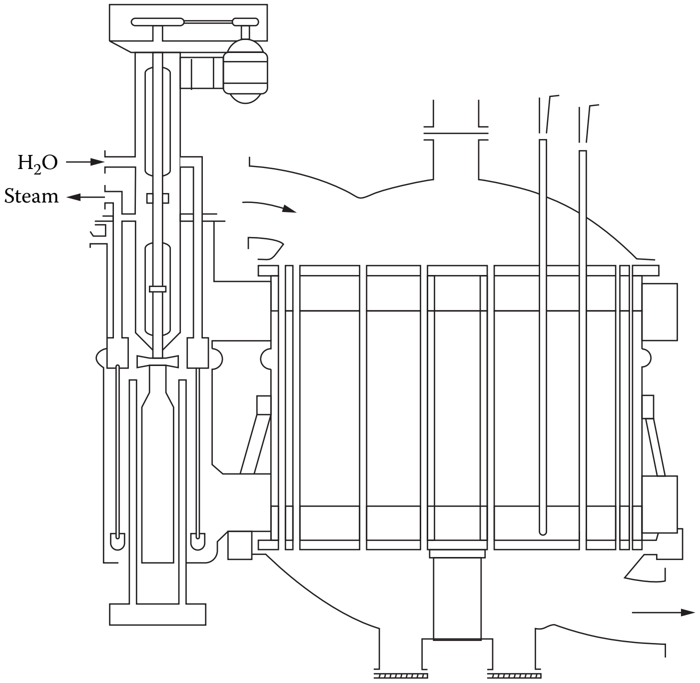

FIGURE 11.26 A typical NINA-FBR design: reactor for SO_2 oxidation (Suter, 1972).

radial and axial concentrations, and temperature profiles, the diameter and height are recalculated for optimum performance.

The approach to the design of an A-FBR is, however, quite different. There is no heat transfer in this reactor; radial transport of heat is absent, and that of mass can usually be neglected. Hence, the reactor diameter can be quite large, thus dispensing with the need for using small-diameter tubes as in the NINA-FBR. A single, large-diameter reactor should, in principle, be all that is needed. In practice, more than one stage may be needed to cool or heat the process fluid between stages. The design here calls for optimizing the inlet and outlet conditions (and therefore the stage height for a given diameter) for each stage to obtain the desired conversion/selectivity at the end of the final stage. The recommended method for optimizing is dynamic programming. A brief summary is presented below of the design procedures for both NINA-FBR and A-FBR units. An illustration of the use of the more important methods is provided in Case Study 11.4.

11.4.2.4.1 Fixed-Bed Reactors: Design of NINA-FBR

From the desired production rate and the allowable velocity in each tube, the number of tubes is obtained. Calculations are made to determine the height of the tube to obtain the required conversion. Since the tubes usually have ($L/D >> 50$), plug flow can usually be assumed. However, this assumption may not always be valid, because radial gradients often exist. Axial diffusion can also be present, thus modifying the conversion gradient that would normally exist due to flow as the reaction progresses from inlet to outlet. These gradients can cause severe deviations from the values corresponding to plug flow. To account for all these gradients and other possible nonidealities, several models have been proposed. Four are sketched in the Figure 11.27. Of these, the continuum model is the most common. Here, the solid-fluid system is considered as a single pseudohomogeneous phase with properties of its own. These properties (e.g., diffusivity, thermal conductivity, and heat transfer coefficient) depend on the properties of the gas and solid components of the pseudo phase. They are anisotropic; i.e., they have different values in the radial and axial directions.

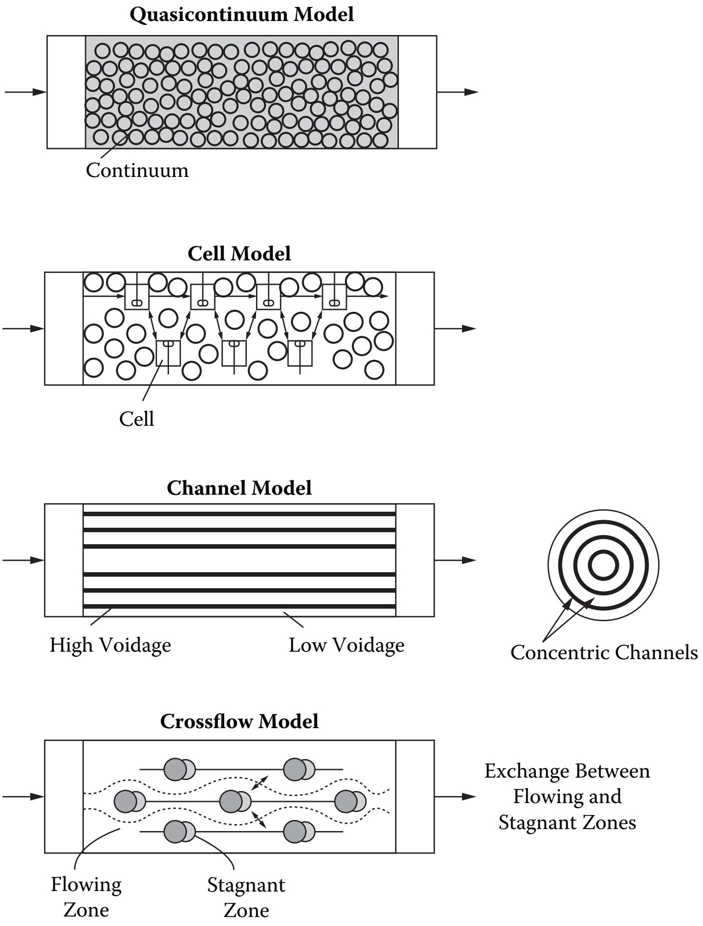

FIGURE 11.27 Models for NINA-FBR design.

Kulkarni and Doraiswamy (1980b) have compiled all the equations for predicting these effective properties. Both radial and axial gradients can be accounted for in this model; the system is really heterogeneous, involving transport effects both within the solid particles and between the particles and the flowing fluid. The simplest model is, of course, the homogeneous isothermal model with plug flow and no intra- or interphase effects. Varying degrees of complexity can be progressively added, as shown in Table 11.24.

Another important class of models are the cell models, which break up the reactor into many cells, with each cell (or microreactor) corresponding to a single pellet and its immediate neighborhood. By allowing for flow between cells in both the radial and axial directions, one- and two-dimensional models, as well as various degrees of mixing, can be simulated. The equations involved in these models are algebraic and not differential as in the continuum models. The continuum models are, however, most widely used, and hence we restrict our treatment to these models.

Taking model A1-a of Table 11.24, in which the assumption of isothermicity of the simplest model is relaxed, and applying it to the simple reaction

$$A \rightarrow R \qquad \text{R4.1}$$

the following mass and energy balance equations can be written:

TABLE 11.24
Classification of Models for Nonisothermal Nonadiabatic Fixed-Bed Reactors (NINA-FBR) (Doraiswamy, 2001)

Nonisothermal Nonadiabatic	
A	B
Pseudohomogeneous	Heterogeneous
A1	B1
One-dimensional	One-dimensional
A1-a	B1-a
PFR (basic model)	No axial mixing
A1-b	B1-b
Axial mixing	Axial mixing
A2	B2
Two-dimensional	Two-dimensional
A2-a	B2-a
PFR (basic model)	No axial mixing
A2-b	B2-b
Axial mixing	Axial mixing

Source: Doraiswamy, L. K., 1991; *Organic Synthesis Engineering,* New York: Oxford, 2001.)

$$u\frac{d[A]}{d\ell}+(-r_A)=0 \tag{11.115}$$

$$u\rho\frac{dT}{d\ell}=\frac{4U}{d_T}(T-T_w)-(-\Delta H_r)(-r_A)=0 \tag{11.116}$$

with the initial conditions

$$\left.\begin{matrix}[A]=[A]_0\\ T=T_0\end{matrix}\right\}\text{at } \ell=0 \tag{11.117}$$

These equations can be recast in dimensionless form as

$$\frac{dc}{dZ} + \Re_M\left(-r_A\right) = 0 \tag{11.118}$$

$$\frac{d\tau'}{dZ} = \frac{4Ud_p}{urC_pT_0}\left(\tau' - \tau'_w\right) - \Re_H\left(-r_A\right) = 0 \tag{11.119}$$

and the initial conditions

$$\left.\begin{array}{l} c = 1 \\ \tau' = 1 \end{array}\right\} \text{at } Z = 0 \tag{11.120}$$

The parameters $\Re_M$ and $\Re_H$ are the mass and heat transfer groups defined in terms of common physical properties (see Nomenclature).

If the reaction is assumed to be isothermal and first order, the following simple equation for the exit concentration of A results:

$$\ln\frac{[A]_0}{[A]} = \left(1 - \varepsilon_b\right)\frac{k_v L}{u} = \frac{kV_T}{F_T} \tag{11.121}$$

Equations for the more complex models are considered in Case Study 11.3.

An important aspect of NINA-FBRs is the role of hot spots in exothermic reactions. There is a certain region of parameter space (usually temperature and partial pressure) within which even a slight change in the value of one parameter (usually initial reactant partial pressure) results in a steep rise in the value of the other (usually temperature). In other words, in a well-defined initial pressure space, the temperature sensitivity of the reaction can be very high. Beyond a certain value, the reaction can "run away," sometimes leading to catastrophic consequences. This sensitivity varies for different controlling regimes. The reaction-controlled regime was considered by van Welsenaere and Froment (1970) and Rajadhyaksha et al. (1975) to avoid this runaway. Other criteria are also available (see, e.g., Hlavacek et al., 1969; Hlavacek, 1970; Oroskar and Stern, 1979), but the first two are perhaps the most useful of the safe limit ones.

Practical aspects of NINA-FBR design and operation include backmixing or axial dispersion, which depends to a large extent on the value of L/d_p. The effect of backmixing can be assumed to be absent if this ratio is greater than 50 (variously reported as 30 to 70) for gaseous reactions and 200 for liquid reactions (see Carberry and Wendel, 1963; Carberry, 1964, 1976). Since, in commercial reactors, this ratio is almost always much higher than the indicated values, backmixing is usually not a problem in their design. However, laboratory reactors are often shorter, so their data cannot be directly applied to large-scale reactors. A more rigorous analysis shows that the following criterion must be satisfied for the data to be free of backmixing effects (Mears, 1971b):

$$\frac{H}{d_p} > \frac{20}{Pe_{ma}}\ln\frac{[A]_0}{[A]_e} \tag{11.122}$$

where Pe_{ma} is the axial Peclet number, $d_p u/\mathbf{D}_{ea}$.

Another problem can arise if the catalyst is not uniformly distributed (leading to nonuniform pressure drops) among the thousands of tubes that are normally present in a NINA-FBR. If a particular tube has a lower pressure drop, more gas will flow through it, and some catalyst may be

blown out until the tube becomes almost empty. Such a situation can be avoided by making incremental additions (say, in 10% lots) of catalyst and measuring the pressure drop in each tube after each addition. The tubes must be tapped or vibrated between additions to ensure uniform pressure drop at each height. Another strategy is to provide for a much larger pressure drop at the tube entrance than that created by the catalyst bed itself, so that any fluctuations in the latter will not affect the flow distribution. This can be accomplished by using a tube sheet with a single nozzle at the bottom of each tube, with a high pressure drop across it. This practice is, however, not generally followed, since tackling the problem at the source, as described earlier, is a much better alternative. The problem of fluid distribution is not critical except in the headers whose diameter corresponds to the shell diameter, which is very much larger than that of the tubes.

11.4.2.4.2 Fixed-Bed Reactors: Design of A-FBR

As already mentioned, the design of an A-FBR is quite different from that for a NINA-FBR. If it becomes necessary to limit the height of each stage in this reactor to avoid excessive temperature rise or fall, then a large number of stages with interstage cooling or heating are required to achieve the desired conversion (Figure 11.28). Two decisions must be taken for each stage: the inlet temperature and the outlet conversion to be achieved in it. Thus, if there are *N* beds, 2*N* decision variables much be simultaneously varied to optimize reactor operation to maximize profit. This almost always involves prohibitive calculations. A practical method of reducing the amount of computation is

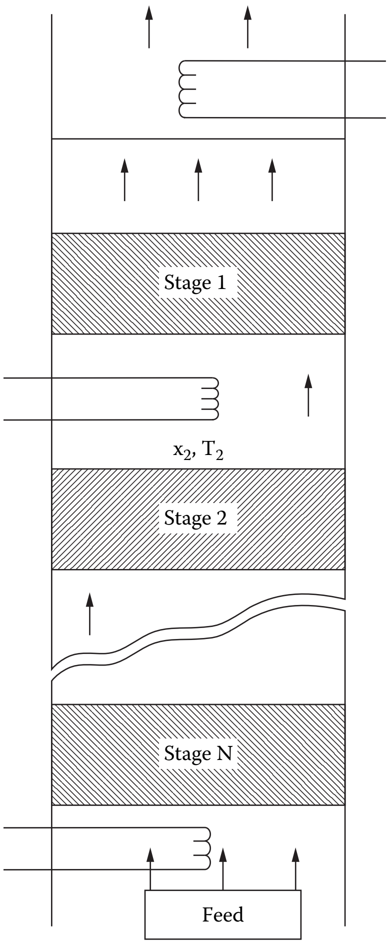

FIGURE 11.28 An interstage heat transfer scheme for A-FBR design.

dynamic programming (Bellman, 1957; Aris, 1961; Bellman and Dryfus, 1962; Roberts, 1964). Lee and Aris (1963) have applied a graphical procedure to optimize an SO_2 oxidation reactor.

Quite often, where the reaction is not highly exothermic or endothermic, a long, single bed is adequate. Because the reaction is adiabatic, there is a unique relationship between concentration and temperature for every reaction. In other words, two separate equations based on mass- and heat-balances are not required. For a reversible reaction of the type

$$A \leftrightarrow R \tag{R4.2}$$

the following single relationship results:

$$X_A = \left(\frac{F_{t0} C_{Pm}}{F_{A0}\left(-\Delta H_r\right)} \right)\left(T - T_0\right) \tag{11.123}$$

or, since $\Delta[A] = X_A[A]_0$,

$$\Delta[A] = J\Delta T \tag{11.124}$$

where

$$J = \frac{C_{Pm}\left[A\right]_0}{\left(-\Delta H_r\right)} \left(\frac{F_{t0}}{F_{A0}} \right) \tag{11.125}$$

This equation can compute conversion and temperature as functions of reactor length (for a given diameter) (Levenspiel, 1991; Doraiswamy, 2001). Procedures are also available (Levenspiel, 1999; see also Aris, 1965) for designing adiabatic reactors for various practically important situations, such as for the case of interstage cooling by cold feed (*cold shot cooling*) or by an inert external fluid.

Heat exchange in an overall adiabatic reactor is one of the most important aspects of its design. For example, heat is transferred from a hot to a cold stream within the insulated system; the exothermic heat is transferred (without removing it out of the system by external heat transfer media). The ammonia reactor is an excellent example of an adiabatic reactor for which many heat exchange schemes have been used. Four typical heat exchange schemes are sketched in Figure 11.29 (see Doraiswamy and Sharma, 1984; Aris, 1965, for a detailed analysis of adiabatic reactors).

11.4.2.4.3 Other Fixed-Bed Designs

In addition to the two most common reactors described above, the following have been used.

11.4.2.4.3.1 Radial-Flow Reactors

This configuration has been developed specifically to meet the high tonnage demands of basic chemicals such as ammonia (50 to 100 tons/h). In this reactor proposed by Haldor Topsøe, the catalyst is placed between coaxial cylinders, and the gas flows either from or to the center, as shown in Figure 11.30. The pressure drop is low, since only a short length of the catalyst bed is used. Based on several studies (Raskin et al., 1968a, b; Hlavacek and Kubicek, 1972; Hlavacek and Vortuba, 1977; Strauss and Buddle, 1978; Calo, 1978; Balakotaiah and Luss, 1981), some useful conclusions can be drawn:

1. The plug-flow assumption can be misleading; a simple and approximate criterion for plug flow is not generally satisfied:

$$Pe_{hr}(1 - \omega) > 50 \tag{11.126}$$

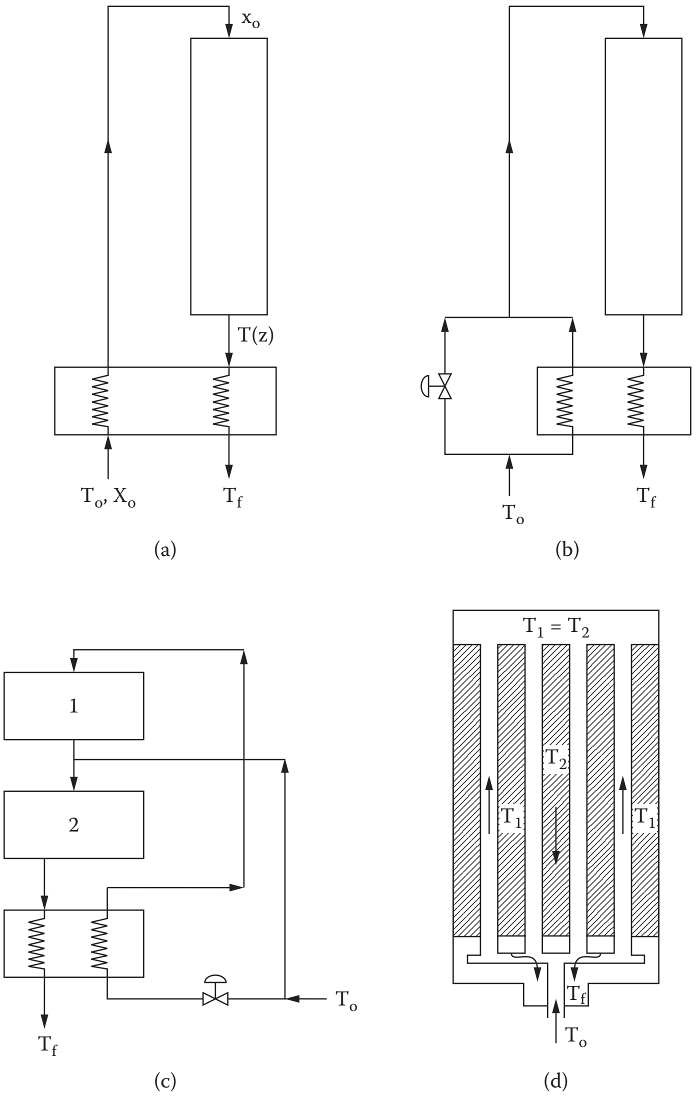

FIGURE 11.29 Typical heat exchange schemes for adiabatic operation.

2. For reactions with no volume change, outward flow of gas yields a higher conversion than inward flow for positive-order kinetics, whereas inward flow is superior for negative-order kinetics.
3. For a first-order reaction with increase in volume, outward flow gives higher conversions, whereas for a reaction with decrease in volume, inward flow is superior.
4. For ideal plug flow, the direction of flow is inconsequential. The difference in behavior between the two directions of flow is therefore due entirely to the dispersion effect. For example, for the ammonia reactor, which satisfies the plug-flow criterion given by Equation (11.126), the change of direction makes no difference.

11.4.2.4.3.2 Catalytic Wire-Gauze Reactors

In certain reactions involving precious metals like platinum, rhodium, or silver as catalyst, the catalyst is used in the form of wire gauze or filament. Examples of reactions that use wire-gauze

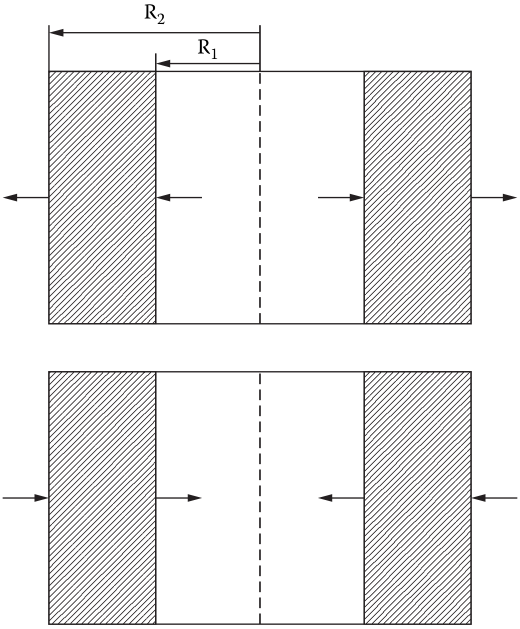

FIGURE 11.30 Radial-flow reactors.

catalysts are oxidation of ammonia to nitric oxide on Pt wire, oxidation of methanol to formaldehyde on Ag-Cu screen, oxidation of ethylene to ethylene oxide on Ag gauze, oxidation of some hydrocarbons on Pt screen, and the Andrussow process for manufacturing HCN on Pt gauze with NH_3, air, and CH_4. The most important consideration is prevention of the precious metal loss by vaporization. The *L/D* ratio for these reactors is usually very low, on the order of 1/200.

A condition known as *catalyst flicker* is mainly responsible for catalyst loss (e.g., Schmidt and Luss, 1971; Luss and Erwin, 1972; Edwards et al., 1973, 1974). Flicker is the result of nonuniform surface temperatures on the gauze caused by fluctuating transport coefficients. Changes in both wire temperature and surface concentration are important, but more work is needed before reliable predictions can be made. Studies on mass and heat transfer from/to wire gauzes have also been reported (e.g., Satterfield and Cortez, 1970; Shah and Roberts, 1974; Rader and Weller, 1974). The most important application of wire-gauze reactors is in the oxidation of ammonia. The catalyst employed consists of 20 to 60 layers of shining Pt wire screen along with other catalytic and support screens (Powell, 1969; Gillespie and Kenson, 1971). The principle, illustrated by Doraiswamy and Sharma (1984), is sketched in Figure 11.31.

11.4.2.5 Gas-Solid Catalytic Fluidized-Bed Reactors

Incipient fluidization, as outlined in Section 11.4.2.3 for liquid-fluidized beds, is equally valid for gas-fluidized beds. Following the onset of fluidization, however, bed behavior is different for the two cases. While fluidization by liquids results in an expansion of the bed with smooth internal movement of the individual particles of the suspension, fluidization by gas breaks up the flowing gas into bubbles (i.e., individual voids) after the onset of fluidization. As mentioned in Section 11.4.2.3, these two patterns of behavior are referred to as *particulate* or homogeneous and *aggregative* or heterogeneous fluidization, respectively. As the gas density increases, and/or the solid density decreases, the behavior approaches that of particulate fluidization (even if the fluid is not a liquid), and vice versa. The following criteria can be used to roughly distinguish between the two modes of fluidization (i.e., for defining the quality of fluidization):

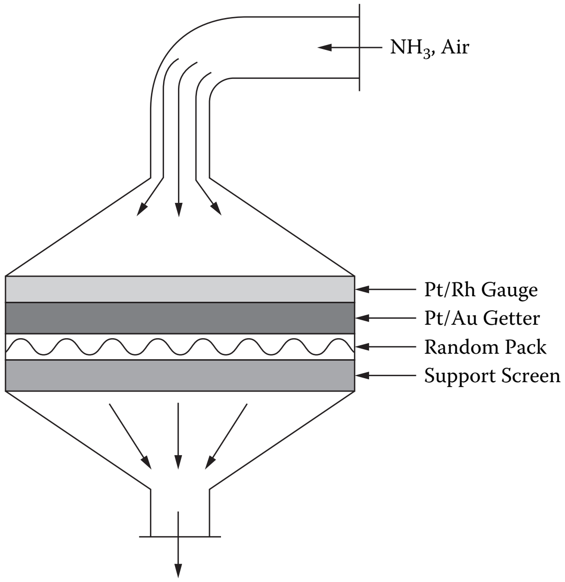

FIGURE 11.31 A typical catalytic wire-gauze reactor.

$$\left(Fr_{mf}\right)\left(Re'_{mf}\right)\left(\frac{\rho_s-\rho_G}{g}\right)\left(\frac{L_{mf}}{d_T}\right) \begin{cases} <100, \text{ particulate} \\ >100, \text{ aggregative} \end{cases} \tag{11.127}$$

where $Fr_{mf} = u^2_{mf}/gd_p$ (Froude group at minimum fluidization), and $Re_{mf}' = d_p u_{mf} \rho_G/\mu$ (Reynolds number at minimum fluidization).

Although several studies over many years have added to the understanding of fluidization, six developments stand out as significant—providing the basic structure of fluid-bed reactor analysis and design:

1. Davidson's fluid dynamic approach to fluid-bed reactor design (see Davidson and Harrison, 1963)
2. Geldart's classification (1973) of solids in terms of their fluidization behavior
3. Grace's explicit recognition (1986) of different regimes of fluidization (drawing from other similar previous studies, e.g., Yerushelmi and Cankurt, 1978; Werther, 1980; Li and Kwauk, 1980; Squires et al., 1985; Horio et al., 1986), through a comprehensive map that demarcates the different regimes
4. Kunii and Levenspiel's modification (see their book, 1991, for original references) of the Davidson model and formulation of reactor design procedures for the different categories of Geldart's particles
5. The finding by Lewis and Gilliland (see Kunii and Levenspiel, 1991) that solids circulation between two fluidized beds (usually a reactor and a regenerator) and in the transport lines connecting them can occur stably
6. The finding that a fluidized-bed reactor can operate at more than one steady state (Elnashaie and Cresswell, 1973; Bukur and Amundson, 1975a, b; Furusaki et al., 1978; de Lasa et al., 1980), in particular the Kulkarni–Ramachandran–Doraiswamy criterion in 1980 for multiple solutions for a first-order reaction

In view of the importance of the Davidson, Kunii-Levenspiel and other models, we consider them at some length in Case Study 11.5. The groundwork for these models as well as the other important features of fluidization mentioned earlier are briefly outlined below.

11.4.2.5.1 Two-Phase Theory of Fluidization

Fluidization theory supported by experiment indicates that the gas-solid fluid bed can be divided into two phases:

1. The bubble phase formed by gas in excess of that required for the onset of fluidization. The bubble is usually surrounded by a *cloud* of gas-solid mixture and is characterized by an indentation caused by suction due to the upward movement of the bubble. The solids that fill up this region are called the *wake*. The bubbles are usually large and move faster than the surrounding emulsion gas flowing at u_{mf}, thus giving rise to the cloud. This behavior is usually characteristic of Geldart **A** and **B** particles (see Section 11.4.2.2).
2. The gas at incipient fluidization percolates through the solid particles, creating a liquid-like phase referred to as the *emulsion phase*. Although this so-called two-phase theory (Toomey and Johnstons, 1952) is not entirely accurate, it is generally valid (within acceptable error limits) and has served as the basis for several fluidized-bed reactor models. These models indicate that conversions increase due to mass transfer between the emulsion and bubble phases.

The application of the two-phase theory to fluidized-bed reactor design is illustrated in Case Study 11.5.

11.4.2.5.2 Geldart's Classification

Based on extensive studies involving a variety of solid particles and fluids with a wide range of properties, Geldart (1973) classified the fluidization behavior into four categories of particles **A**, **B**, **C**, and **D** (Figure 11.32 based on the original). **B** particles conform strictly to the two-phase theory of fluidization described earlier: the gas in excess of that needed for the onset of fluidization immediately breaks into bubbles. In the case of **A** particles, bubbling commences only after a certain amount of gas has passed through the bed beyond incipient fluidization. The other significant features of the particles are explained in the figure. Our concern in this section is essentially restricted to **A** and **B** particles. The smaller **C** particles are too cohesive and fluidize poorly, while the larger **D** particles are more relevant to reactions in which the solid also reacts, such as coal combustion.

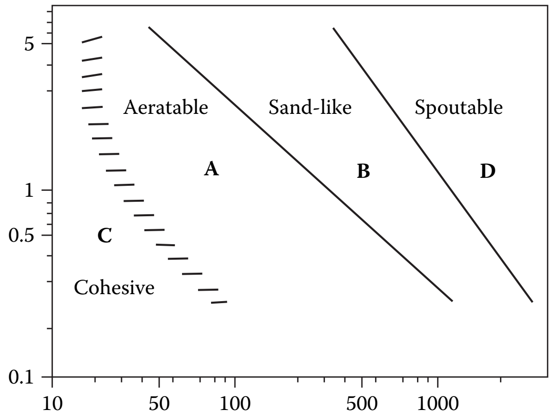

FIGURE 11.32 Geldart's classification of particles with respect to their fluidizability.

11.4.2.5.3 Classification of Fluidized-Bed Reactors

Several categories of fluidized-bed reactors are possible, depending on the mode of operation. The chief features of these reactors are summarized in Table 11.25 and sketched in Figure 11.33. As can be seen from this table, bed behavior (and category) is essentially determined by the fluidizing gas (reactant) velocity and particle size. This transition from fixed to pneumatic bed is usually depicted in terms of a *fluidization map* (e.g., Atipovi et al., 1978; van Deemter, 1980; Werther, 1980; Squires et al., 1985; Horio et al., 1986; Grace, 1986). The latest version, as consolidated by Kunii and Levenspiel (1991), is reproduced in Figure 11.34. Our main concern is with the bubbling bed, although the turbulent bed is only qualitatively different from it.

TABLE 11.25
Principal Features of Different Types (Regimes) of Fluidized-Bed Reactors

Type (Regime) of Fluidization	Main Features	Examples
1. Incipiently fluidized bed (stationary)	Upward flow of gas at about u_{mf} for **A** and **B** particles; no solids mixing; gas mostly in plug flow; solids mixing by a stirrer is sometimes useful; $u_o \leq 1.2\ u_{mf}$ with no bubbles; $\varepsilon_s \approx 0.5$–$0.6$ throughout bed	Methylchlorosilanes
2. Bubbling fluidized bed (stationary)	Upward flow of gas through a wide range of **A** and **B** particles; onset of bubbling depends on particle size, ranging roughly from $u_b = 40\ u_{mf}$ to $70\ u_t$ for small particles to a very narrow range ($u_{mf} < u_b \leq 2\ u_{mf}$) for large particles; $\in_s \approx 0.6$ (bottom)–0.4 (top)	Polymerization of ethylene to LD polyethylene, ethylene dichloride, vinyl acetate
3. Turbulent bed* (stationary)	Starts gradually at $u_o >> u_t$ for small particles and $u_p >> 0.5\ u_t$ for large particles, and merges smoothly into fast fluidized-bed region at higher velocities in each case; as u_o is not very high, internal cyclone is usually adequate; solids entrainment is usually high and, instead of bubbles, clusters of solids and voids of gas move through the bed; $\varepsilon_s \approx 0.3$–$0.4$ (bottom) to 0.2–0.3 (top); the void lifetime is short so that, overall, the bed looks more uniform than in regime 2.	Phthalic anhydride, *o*-cresol and 2–6 xylenol, acrylonitrile, chloromethanes
4. Fast fluidized bed* (circulating)	Continuous feed of both gas and solids; sufficiently high solids velocity—in excess of the upper limit for regime 5; the transition point (from the reverse direction) causes *choking* at the entry and collapse of the lean dispersion of that regime into the fluidized mass of regime 4; suitable gas distributor is used to ensure high density at bottom that merges smoothly with the low-density region at the top (corresponding roughly to the freeboard region of the bubbling bed); $\varepsilon_s \approx 0.5$–$0.2$ (bottom) to 0.05–0.01 (top); essentially a circulating bed with plug flow of gas accompanied by slugs of emulsion; bed even more uniform than in regime 3.	Fischer-Tropsch synthesis of hydrocarbons
5. Pneumatic or transport bed (circulating)	Upflow of gas with a low continuous feed of solids and no distributor plate; $u_o/u_s \approx 20$, $u_o \approx 20\ u_t$; gas in plug flow with $\sigma_s \approx 0.02$ throughout; is essentially a lean upflowing dispersed gas-solids mixture (with no bubbles)	FCC units for petroleum cracking

* The distinction between bubbling-bed and turbulent-bed reactors is not always clear. Hence, the classification of reactions under these categories is uncertain.

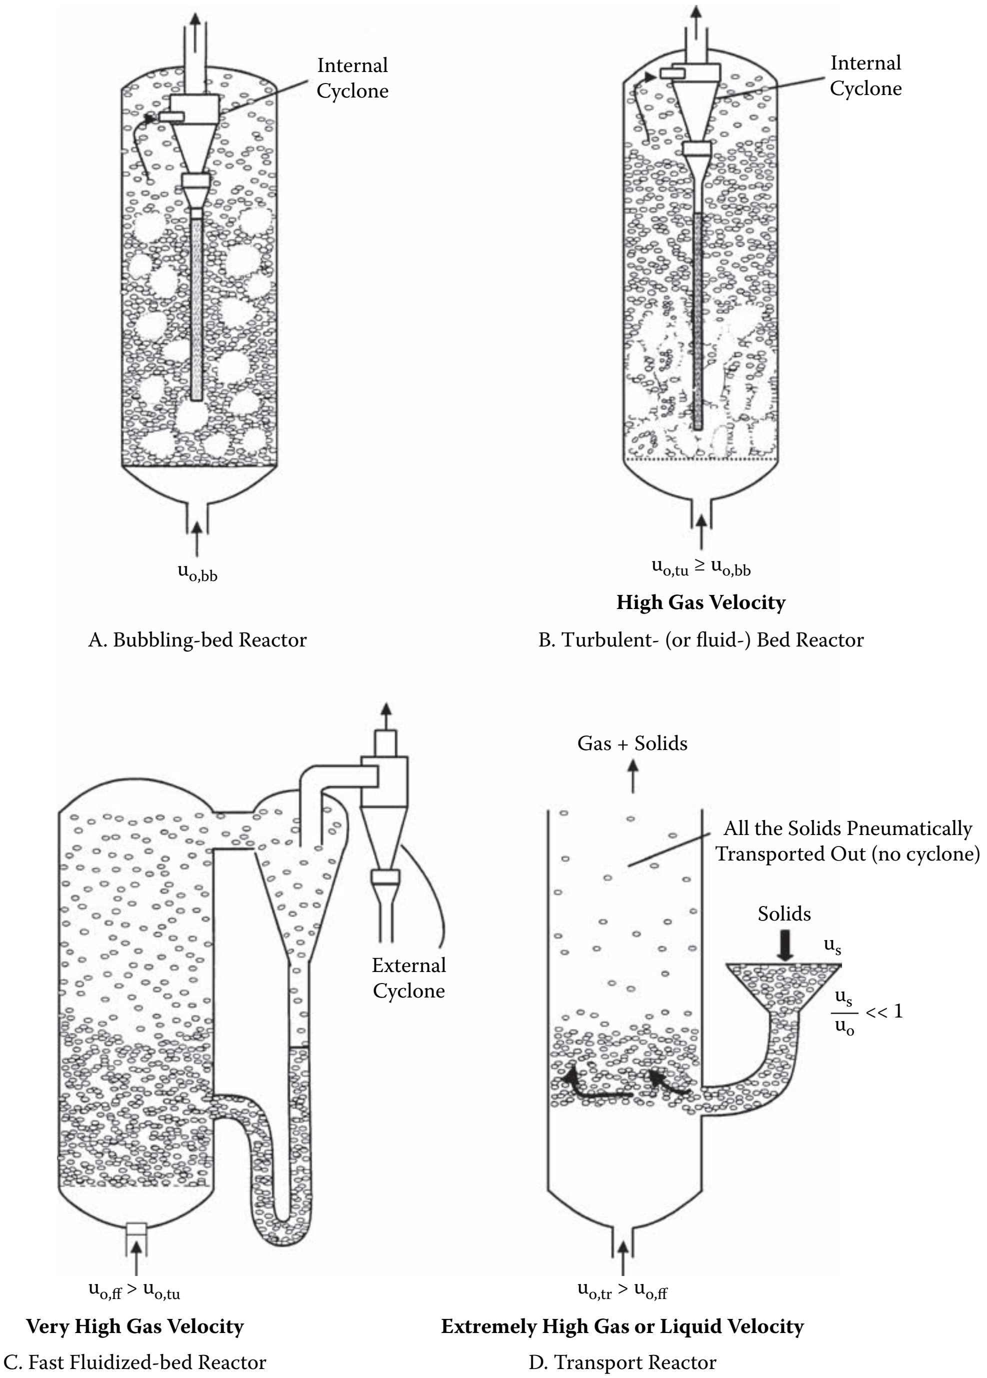

FIGURE 11.33 Classification of fluidized-bed reactors.

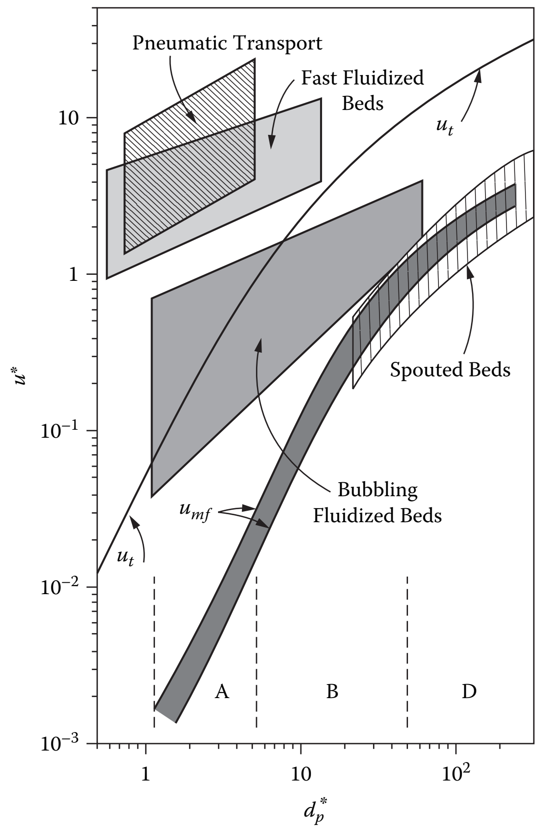

FIGURE 11.34 Fluidization map (from Grace, 1986, as modified by Kunii and Levenspiel, 1991). The parameters are $u^* = u\left[\frac{(\rho_s - \rho_G)_g}{\mu^2}\right]^{1/3}$, $d_p^* = \left[\frac{\rho_G^2}{\mu(\rho_s - \rho_G)}\right]^{1/3}$.

11.4.2.5.4 Design of Various Types of Reactors

From Table 11.25, four different (but somewhat overlapping) categories of fluidized-bed reactors can be recognized: bubbling-bed, turbulent- (or fluid-) bed, fast-bed, and pneumatic- (or transport-) bed. Occasionally, reactor operation at velocities close to u_{mf} has been attempted.

A fluidized-bed reactor can generally be divided into three zones of operation, as shown in Figure 11.35 (Doraiswamy, 2001). The lower jet zone is relevant only for cases with very high velocities (100 m/s) through the nozzles and is usually not important. Salient features of its design have been described by Behie et al. (1971, 1976) and Behie and Kehoe (1973).

11.4.2.5.4.1 Bubbling-Bed Reactor

Details of the bubbling-bed reactor are explained in Case Study 11.5 along with a comparison and discussion of alternative models with varying degrees of complexity. The Miyanchi–Marooka model for the freebroad region (or the dilute phase) is among the models considered. Kunii and Levenspiel (1991) have also proposed a freeboard model in continuation of their bubbling-bed model.

11.4.2.5.4.2 Turbulent-Bed Reactor

Due to the higher gas velocities (which make the bubble-bed reactor more suitable for high-throughput reactions), there is greater turbulence at the interface, leading to more violent bursting of bubbles and splashing of emulsion clusters. Otherwise, it is not much different from the bubbling-bed reactor, despite the fact that the bubble and emulsion phases are not as clearly demarcated.

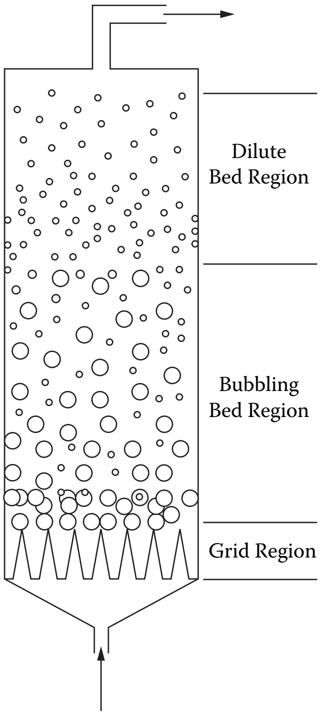

FIGURE 11.35 Operating zones of a fluidized-bed reactor.

Thus, the general procedure described for the bubbling bed including the dilute bed (Kunii and Levenspiel, 1991) or the Miyauchi–Marooka model described in Case Study 11.5 can be used. Then, the porosity distribution data will be different. In particular, the freeboard porosity will be higher. Strictly, new correlations for k_{bc} and k_{ce} are also required, but available correlations for the bubbling bed can be used as a first approximation.

11.4.2.5.4.3 Fast Fluidized-Bed Reactor

Here the gas velocity is even higher than in the turbulent bed. What we have is a bottom dense zone consisting of a mixture of bubbles with more solids in them than in the bubbling bed and clumps of emulsion rising through most of the bed's cross section, while some emulsion flows down at/near the wall. The overall coefficient K_f will be different from that defined by Equation (CS5.14) for Case Study 11.5. Kunii and Levenspiel suggest a relation for this; it requires data such as S_{core} and S_{wall}, which are not available. These observations are also true of the upper dilute region for which the parameter values would be quite different from those in Equation (CS5.19) for the freeboard region above the normal bubbling bed.

Obviously, more research is needed on the turbulent and fast fluidized-bed reactors. At present, tests on a series of pilot plant reactors ending with a semicommercial unit are unavoidable.

11.4.2.5.4.4 Transport (or Pneumatic) Reactor

Fluidized catalytic cracking (FCC) units are characterized by reaction in the transport lines between the reactor and the regenerator, in addition to that in the main reactor. Their design is complicated, involving more than one regime of fluidization. Innumerable studies have been reported on their modeling (e.g., de Croocq, 1984; Chuang et al., 1992). As already explained in Figure 11.33, the fluidization regime changes with increase in gas velocity (sometimes also expressed as the ratio of the superficial velocity to the minimum fluidization velocity). FCC units use very fine particles. In the more recent designs employing highly active zeolite catalysts, the main cracking occurs almost entirely in the riser, i.e., the section that transports the catalyst between the reactor and regenerator

or back into the same reactor. Hence, although the bubbling or turbulent regime may be involved within the reactor or regenerator, the transport line (or the riser) operates in the pneumatic regime. In the main reactor, bubbling does not commence immediately after u_{mf} is reached, and the turbulent regime sets in far beyond u_t. In this regime, bubble short-circuiting is much less prevalent, and hence the conversions are higher. On the other hand, the regenerator operates in the bubbling regime even though the velocities involved (0.6 m/s) correspond to the turbulent regime. This is because of the absence of fines. As indicated in Section 11.4.2.5.7, the presence of fines plays an important role (see Yadav et al., 1994).

11.4.2.5.4.5 Staged Reactors

Vertical staging of the catalyst can sometimes be advantageous because the gas flow often approximates plug flow. The region between two consecutive beds is obviously the freeboard region of the lower bed. The holes in the grid plates of these beds must be carefully designed to balance the upward and downward flows of solids from each bed. Thus, the holes in the plate of a given stage should be large enough to allow particles from the lower freeboard region to flow into this stage (thus preventing their accumulation at the bottom of the plate) but small enough to prevent particles from the bed to leak into this freeboard region and then into the lower stage. There is, however, always a through flow of solids, downward or upward. For countercurrent contacting of gas and solid, downflow of solids is necessary, as in fluidized-bed reduction of metal ores. For details of particle interchange at perforated plates and factors influencing particle leakage in staged reactors, see Briens et al. (1978).

11.4.2.5.5 Circulation Systems

In Table 11.25, we saw that certain types of fluidization (fast and pneumatic) involve solids recirculation. Figure 11.36 indicates that the solids are circulating between two fluidized beds A and B. They are connected through the two curves of a U-tube in such a way that the difference in static pressures drives the solids from one bed to the other. The use of a second U-tube completes the circulation between the beds. As there is a frictional resistance associated with solids flow (increasing with increasing flow rate), the rate of circulation is controlled by a balance between the frictional resistance and the static pressure difference mentioned earlier. The frictional resistance can be controlled by varying the average densities of the flowing gas-solid mixtures in the various sections of the circulation loop.

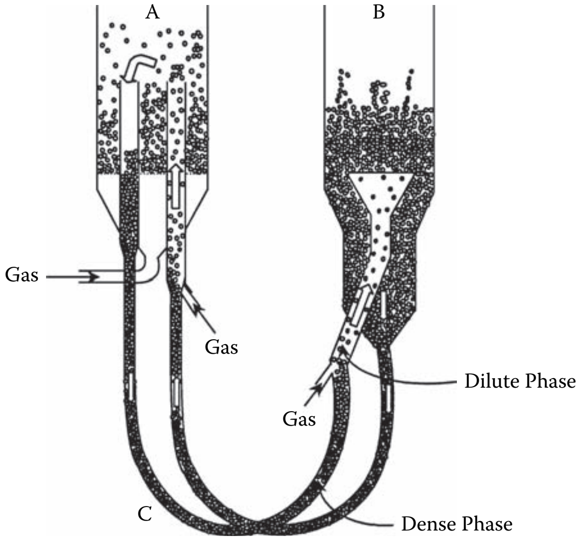

FIGURE 11.36 The main features of solids circulation in fluidized-bed reactors.

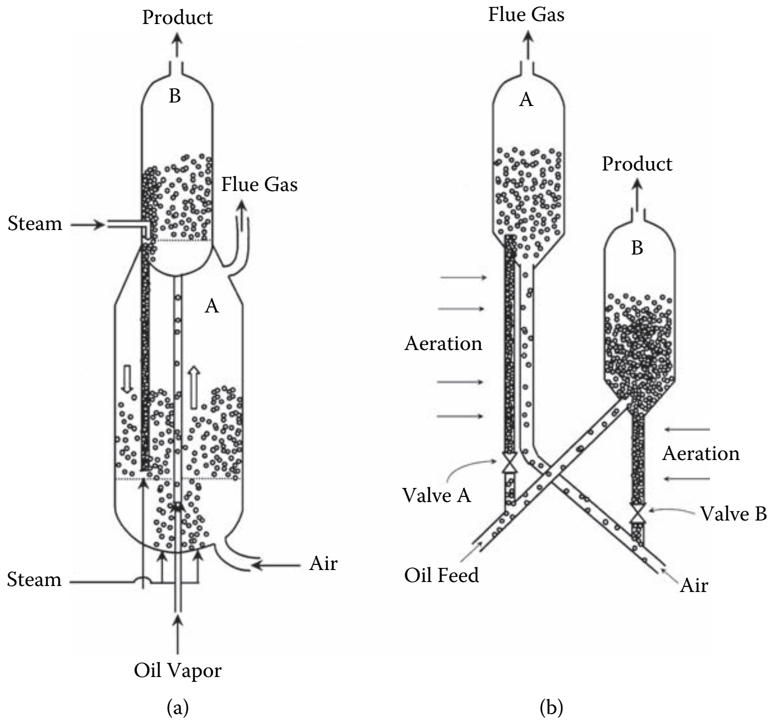

FIGURE 11.37 Two examples of circulation systems in fluidized-bed operation.

Two circulation systems are shown in Figure 11.37 (see Kunii and Levenspiel 1991). Solids circulation is most useful for a deactivating catalyst. Catalytic reaction including simultaneous deactivation by carbon deposition occurs in one location (the reactor), and catalyst regeneration by carbon burn-off with air occurs in a second location (regenerator). Although different fluidizing gases are used in the two reactors, the reactant (usually vaporized oil) in the case of the catalytic converter and air in the case of the regenerator, solids circulation can be restricted to a single loop for both the gases or can be accomplished in two loops, one for the oil and the other for the air.

The second important aspect of circulation is the heat balance between absorption in the endothermic reaction and release in the exothermic zone. The circulation system design depends on whether the overall scheme is deactivation controlled or heat transfer controlled. The final equations, with a brief reference to the principles, are provided for the two extreme cases.

11.4.2.5.5.1 Deactivation Control

To arrive at a balanced circulation rate of solids, let us first define the activity Ω of the catalyst as

$$\Omega = \frac{\text{rate of reaction on catalyst at a given condition}}{\text{rate of reaction on a fresh catalyst}} \tag{11.128}$$

We assume that the catalyst undergoes deactivation in the reactor but that the activity is not fully recovered in the regenerator. This general situation is depicted in Figure 11.38, which shows an average activity $\bar{\Omega}_1$ in the reactor and $\bar{\Omega}_2$ in the regenerator. Assuming first-order deactivation, we have

$$\text{Reaction:} \quad -\frac{d[A]}{dt} = k_v[A]\Omega \tag{11.129}$$

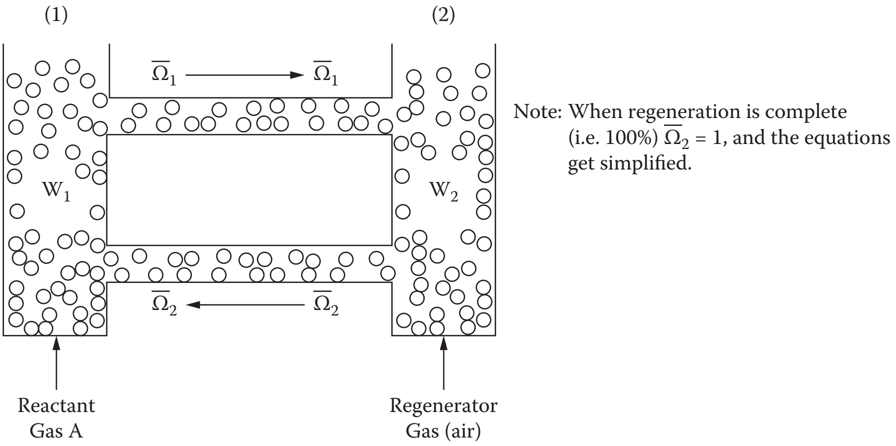

FIGURE 11.38 Fluidized-bed circulation system for catalyst deactivation control.

$$\text{Deactivation:} \quad -\frac{d\Omega}{dt} = k_d\Omega \tag{11.130}$$

$$\text{Regeneration:} \quad \frac{d\Omega}{dt} = k_a(1-\Omega) \tag{11.131}$$

It is reasonable to assume that the solids flow is fully backmixed with an exponential distribution of residence times. Based on this assumption and by writing an expression for the average activity of the leaving catalyst stream (which contains particles of all ages with their corresponding activities), the following equations are derived:

$$\text{Reactor:} \quad k_d\bar{t}_1 = \frac{\bar{\Omega}_2 - \bar{\Omega}_1}{\bar{\Omega}_1} \tag{11.132}$$

$$\text{Regenerator:} \quad k_a\bar{t}_2 = \frac{\bar{\Omega}_2 - \bar{\Omega}_1}{1-\bar{\Omega}_1} \tag{11.133}$$

where

$$\bar{t}_1 = \frac{W_1}{F_S}, \quad \bar{t}_2 = \frac{W_2}{F_S}$$

Eliminating $\bar{\Omega}_2$ from Equations (11.132) and (11.133),

$$\bar{\Omega}_1 = \frac{k_a\bar{t}_2}{k_d\bar{t}_1 + k_d k_a \bar{t}_2 + k_a\bar{t}_2} \tag{11.134}$$

This equation for average catalyst activity is then combined with the rate constant, k_v, to give $\bar{\Omega}k_v$ in the usual reactor equations that would normally use simply k_v. For the three gas flows, we obtain

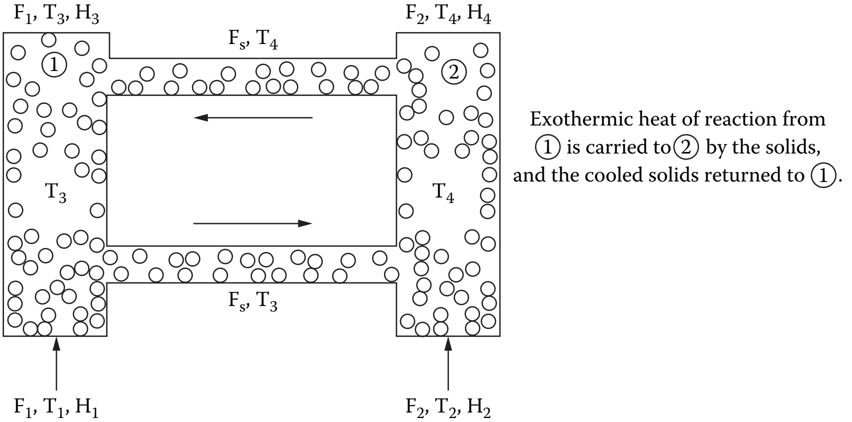

FIGURE 11.39 Fluidized-bed circulation system for heat transfer control.

$$\text{Fully mixed:}\quad \frac{[A]}{[A]_0}=\frac{1}{1+k_v\bar{\Omega}_1\bar{t}_1} \tag{11.135}$$

$$\text{Plug:}\quad \frac{[A]}{[A]_0}=\exp\left(k_v\bar{\Omega}_1\bar{t}_1\right) \tag{11.136}$$

$$\text{Fluidized:}\quad \frac{[A]}{[A]_0}=\exp\left(K_f\bar{\Omega}_1\bar{t}_1\right) \tag{11.137}$$

where K_f is the overall rate constant of the Kunii–Levenspiel model of the fluidized bed in the absence of deactivation [see Equation (CS5.14) of Case Study 11.5]. Solution of Equations (11.135) and (11.136) or (11.137) gives the circulation rate F_s and the bed weights for reactor (W_1) and regenerator (W_2).

11.4.2.5.5.2 Heat Transfer Controlled

An important aspect of solids circulation is that heat is transferred from its source (usually exothermic regeneration) to its destination (usually endothermic oil cracking). This can be the controlling feature of a reaction-regeneration system, and the necessary circulation rate for balancing the two depends on the enthalpies at various points in the scheme as shown in Figure 11.39 (see Kunii and Levenspiel 1991). The final equation derived by Kunii and Levenspiel (1991) assuming no heat loss is

$$F_s=\frac{F_1\left(-\Delta H_r+H_1-H_3\right)}{C_{ps}\left(T_3-T_4\right)}=\frac{F_2\left(H_4-H_2\right)}{C_{ps}\left(T_3-T_4\right)} \tag{11.138}$$

If the reaction is endothermic, the cooler is replaced by a heater, with no other change in the analysis.

11.4.2.5.6 Reactor Choice for a Deactivating Catalyst

Catalyst deactivation is always a problem in catalyst and catalytic reactor design. Empirical equations to represent deactivation rates in design calculations are reported by Weekman (1968), Sadana and Doraiswamy (1971), and Doraiswamy and Sharma (1984). Here, we briefly touch upon the

problem of reactor design and choice for a deactivating catalyst in general. An important parameter in considering the role of catalyst deactivation is the production or on-stream time (which is also the catalyst decay time). This is the time t_p for which the reactor is run before subjecting the catalyst to regeneration. The total decay time for a given level of decay is t_{p1}. Assuming that reactant A is passing through a decaying bed of catalyst under diffusion-free conditions and is undergoing a simple reaction, the first step in the analysis is to write the continuity equation for the reactor. Then, by introducing appropriate dimensionless groups, the following equations can be derived for the fixed-, fluidized-, and moving-bed reactors by assuming exponential decay of the catalyst, i.e.,

$$k_v(t_p) = k_{v0}\exp(-d_c t_p) \tag{4.36}$$

where d_c is the decay constant and k_{V0} is the rate constant for the fresh catalyst. The final equations obtained are the following.

Fixed-bed reactor:

$$\frac{dy_A}{dZ} = -B'\exp\left(-\lambda\hat{t}\right)y_A^m \tag{11.140}$$

where

$$\left.\begin{aligned} &\hat{t} = \frac{t_p}{t_{p1}}, \quad \lambda = d_c t_{p1} \\ &B' = \frac{M}{\rho_A S_{v,A}}(1-\varepsilon_B)k_{v0} \\ &Z = \text{reduced length} \end{aligned}\right\} \tag{11.141}$$

When a decaying catalyst is used, the average conversion over a given period of time is determined from

$$\bar{X}_A = 1 - \bar{y}_A = 1 - \int_0^1 y_A d\hat{t} \tag{11.142}$$

Fluidized-bed reactor:
If the solids are fully mixed, we have

$$\frac{dy_A}{dZ} = \left(\frac{B'}{\lambda+1}\right)y_A^m \tag{11.143}$$

Since this is a steady-state operation, the conversion is simply

$$X_A = 1 - y_A \tag{11.144}$$

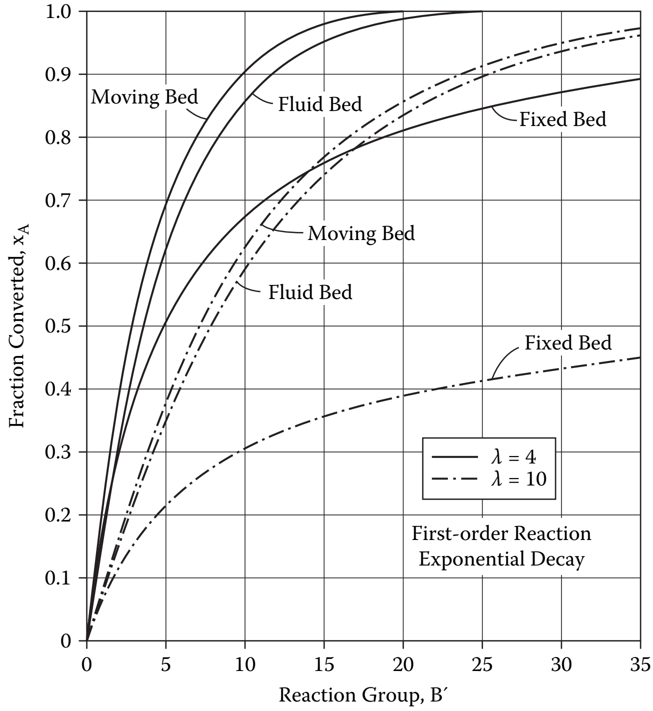

FIGURE 11.40 Comparison of performances of different reactor types for a reaction on a deactivating catalyst. (From Sadana, A. and Doraiswamy, L. K., 1971. *J. Catal.* 23: 147.)

Moving-bed reactor:

In this reactor, catalyst decay is a function of position; the decay time at any position z is given by zt_p. Hence, the reduced decay time is $zt_p/t_p = z$. The following equation is for the mole fraction of A:

$$\frac{dy_A}{dZ} = B' \exp(-\lambda Z) y_A^m \tag{11.145}$$

where X_A is given by Equation (11.144).

The performances of the three reactors are compared for different parameters in Figure 11.40 for a first-order reaction. The importance of the decay parameter λ is clearly evident and provides a strong point (among many other issues to be considered) in reactor choice. Sadana and Doraiswamy (1971) and Prasad and Doraiswamy (1974) have extended the comparisons to non-first-order and complex reactions.

11.4.2.5.7 Some Practical Considerations

The fluidized-bed reactor is far more difficult to scale up than the fixed-bed reactor. Practical considerations involved in its operations are briefly outlined here.

11.4.2.5.7.1 Slugging

The bed was once assumed to slug when the ratio of the bubble to tube diameter is greater than 0.8 to 0.9 (Stewart and Davidson, 1967). Baeyens and Geldart (1974) give a more elaborate criterion for such a situation. Generally, the conversion in a narrow slugging bed is higher than that in the scaled-up version. Since slugging is not an "unacceptable" mode of operation, multitubular reactors operating under fluidizing conditions are a useful alternative.

11.4.2.5.7.2 Defluidization of Bed

During the operation of a fluid-bed reactor, there should be no sudden increase in pressure due to malfunctioning of valves or choking in downcomers by solid particles. If it does occur, the mass velocity for minimum fluidization will increase at the same total flow rate, and a stage may be reached at which the minimum fluidization velocity might actually exceed the gas velocity, leading to defluidization. Defluidization can also occur due to an increase in temperature or coke deposition of catalyst particles (leading to increased u_{mf}). Another reason is the switch from an inert fluidizing gas used at startup to the actual gas.

11.4.2.5.7.3 Gulf Streaming

The phenomenon of gulf streaming arises from the formation of violent circulating currents induced by bubbles. These currents may become especially significant in large commercial beds (especially shallow beds). Davidson and Harrison (1971) have shown that circulation velocities of 200 mm/s can exist in large beds. As a result, the bubble residence time is smaller, leading to lower conversions. No simple way has yet been found to overcome this problem; thus, a pilot plot of appropriate size seems almost unavoidable.

11.4.2.5.7.4 Effects of Fines

A size distribution of particles is always desired rather than a single size in a fluidized bed. The two-phase theory of fluidized-bed operation is suspect when a bed contains appreciable fines, and models based on uniform particles should be used with caution. The dense phase in such cases should really be regarded as consisting of two phases: emulsion and clusters of fines ($d_p < 40$ μm). Indeed, the results of Yadav et al. (1994) on commercial propylene ammoxidation catalyst clearly show that the fines agglomerate. A critical level of fines (30%) was found in terms of bed expansion, aeratability, and cluster size at which fluid-bed behavior is optimum. They proposed a model that takes the two dense phase components (emulsion and cluster) into account. Adding fines widens the limits of operable gas velocities and minimizes the segregation of particles.

11.4.2.5.7.5 Start-Up

The start-up of a fluidized bed requires an initial burst of pressure to lift the solids and initiates fluidization. This can severely damage the bed internals, and indeed the entire structural framework. It is therefore essential to begin the operation with an empty reactor (by removing the solids after each shutdown) and progressively increase the gas velocity and introduce the solids incrementally at the same time.

Other practical considerations are attrition of particles; caking of catalyst from malfunctioning of the reactor due to formation of tarry products (resulting sometimes in "cakes" as large as the reactor diameter); and the need to avoid premixing of reactants (particularly when they can form explosive mixtures) and fix their relative locations within the bed (e.g., in the chlorination of methane and ammoxidation of propylene). Refer to Doraiswamy and Sharma (1984) for further details.

11.4.2.5.8 Fluidized-Bed vs. Fixed-Bed Reactors

Following their first major success in 1942 in the refining/petrochemical industries, fluidized-bed reactors were hailed as the panacea for most reactor evils. This optimism was clearly too hasty in view of many spectacular failures. But more recently there has been a better understanding of fluid-bed behavior in general. The main advantages are a prevalence of near-isothermal conditions in the entire bed due to solids movement (and therefore the absence of hot spots, a key drawback of fixed-bed reactors), less danger of explosions and temperature excursions, better operational flexibility, and higher heat and mass transfer rates compared to other modes of fluid-solids contacting (often leading to smaller sized heat exchangers). The fixed-bed reactors are less frequently chosen, in spite of their many advantages, namely relatively easy scale-up, minimum catalyst loss due to attrition, and the theoretical possibility of imposing an optimum temperature profile (taking advantage of the inherent nonisothermicity of the bed).

Pressurized fluidized-bed reactors are currently widely used in gas-solid noncatalytic systems such as coal gasification and coal combustion power plants (Dutta and Gualy, 1999). Higher pressures enhance productivity per unit reactor volume and often significantly increase equilibrium conversion and selectivity. An important example of reactor choice for gas-solid noncatalytic reactions, based on extensive studies on different alternatives, is the hot gas desulfurization process using zinc titanate as the regenerative adsorbent. ZnO, the active component of this adsorbent, reacts with H_2S to form ZnS, which is regenerated by air oxidation and recycled back to the adsorber. This process is part of the integrated gasification coal carbonization (IGCC) power plants. Experimental results on moving-bed, bubbling-bed, and circulating fluidized-bed reactors have clearly shown the circulating bed to be the preferred candidate (Dutta, 1994).

Note that gas-solid moving-bed catalytic reactors, once popular in petroleum cracking, are increasingly being replaced by circulating fluidized beds. They are still used in gas-solid noncatalytic reactors (see Section 11.4.2.6).

11.4.2.6 Gas-Solid Noncatalytic Reactors

For gas-solid catalytic reactors also, fixed-bed, fluidized-bed, and moving-bed reactors are commonly employed. However, since all gas-solid noncatalytic reactions are inherently time dependent, time becomes an unavoidable parameter in the analysis. We briefly outline the procedures for the three reactor types mentioned and also touch upon a few other types. In view of the special importance of fluidized-bed reactors for these systems, two case studies involving the use of this reactor are presented in Section 11.5 (Case Studies 11.6 and 11.12). Dutta and Gualy (1999) give a comparative evaluation of fixed- and fluidized-bed reactors.

11.4.2.6.1 Fixed-Bed Reactors

Fixed-bed reactors are employed for roasting and sintering of ores, incineration of solid wastes, reduction of metal oxides, and production of light-weight aggregates. They can be of the conventional types as shown in Figure 11.41a, in which a tube is packed with the reactant pellets and the gas passed through the bed. An alternative design, not used in catalytic reactors, is shown in Figure 11.41b. Here, the solids are continuously fed on a moving grate, and the gas is blown through the bed. The reaction front in the bed moves as the reaction progresses. The conventional design is usually restricted to batch reactions and hence is not applicable to large-scale production.

In an ideal fixed-bed reactor, plug flow of gas is assumed. This is, however, not a good assumption for reactive solids, because the bed properties vary with position, mainly due to changing pellet properties (and dimensions in most cases), and hence the use of nonideal models is often necessary. The dispersion model, with all its limitations, is still the most practical one. The equations involved are cumbersome, but their asymptotic solutions are simple, particularly for systems

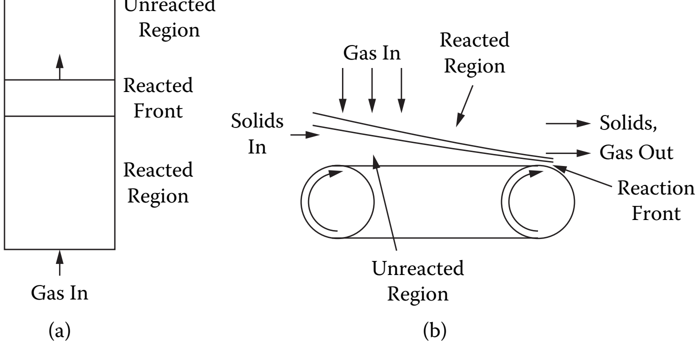

FIGURE 11.41 Reactors for gas-solid noncatalytic reactions.

conforming to pellet reaction control. Their use is especially appropriate for the following reasons. As brought out in Section 11.3.4, the controlling regime in a reactive pellet changes as the reaction progresses. For example, in the case of SIM, the reaction usually starts with reaction control but eventually becomes diffusion controlled, making it necessary to consider individual pellets in the reactor. Often, recourse to one- or two-dimensional heterogeneous models becomes necessary. In such cases, the choice of the gas-solid reaction model has an important bearing on reactor simulation (Sotirchos and Zarkanitis, 1989). Mutasher et al. (1989) have simulated a fixed-bed reactor using the zone model. The particle-pellet model used here has greater generality.

Consider a typical reaction,

$$A(g) + B(s) \rightarrow R(g) + S(s) \tag{R4.3}$$

As pointed out in Section 11.3.4, it can be assumed that the pellet itself is isothermal, even for reactions involving large heat effects. One can also reasonably assume that axial diffusion effects are absent (particularly for long beds), and hence the one-dimensional model can be used. We shall also assume that the heat generated by reaction is lost through the sensible heat carried by the gas leaving the system and by convection at the outside surface of the reactor wall. The nonisothermicity of the reaction greatly affects the linear velocity and density of gas along the reactor, and these effects should be considered. However, in our relatively simple approach, we ignore them.

Derivation of the model equation is reported by Evans and Song (1974). The following equations are written: material and energy balances for the gas phase and the rate equations for the pellet assuming any one of the models described in Section 11.3.4. As mentioned earlier, we use the particle-pellet model. Appropriate initial and boundary conditions are also written. Assuming isothermal behavior, the material balance equation is

$$-G_A \frac{\partial c}{\partial t} = \frac{(1-\varepsilon_p)(1-\varepsilon_b)\rho_{Bm}}{\upsilon} \frac{dX^x}{dt} + (\varepsilon_p + \varepsilon_b)[\bar{A}] \frac{\partial c}{\partial t} \tag{11.146}$$

where $[\bar{A}]$ is the external field concentration at some point in the bed, and c is the dimensionless external field concentration. The changing value of the concentration $[\bar{A}]$ with position allows for a more realistic simulation of the reactor.

Here the reactor equation is general and independent of the rate equation, which depends on the gas-solid reaction model used. It can also be adapted to other reactors with appropriate modifications. However, these involve unacceptable assumptions for the fluid-bed model.

The particle-pellet equation is written in terms of a generalized effectiveness factors defined as

$$\varepsilon = \frac{\int_0^1 \xi^{s-1} g \eta^{g-1} [\hat{A}]_p \, d\xi}{\int_0^1 \xi^{s-1} d\xi} \tag{11.147}$$

where s and g are, respectively, the shape factors for the pellet and grain [3 for the sphere, 2 for the cylinder, and 1 for the flat plate, based on Equation (11.49)], and ξ and η are the dimensionless positions in the pellet and grain, respectively. We use this in the material balance Equation (11.146) recast in dimensionless form to give

$$-\frac{\partial c}{\partial Z^*} = \frac{dX^*}{dt^*} = c\varepsilon \tag{11.148}$$

and then manipulate it into the form

$$\frac{dX^*}{dt^*} = \varepsilon \exp\left[-\int_0^{Z^*} \varepsilon d\lambda\right] \tag{11.149}$$

where λ is a dummy variable, and t^* and Z^* are dimensionless time and distance given by

$$t^* = \left(\frac{\upsilon k_s \left[\bar{A}\right]_0 S_g}{\rho_{Bm} g V_g}\right) t \tag{11.150}$$

$$Z^* = \frac{k_s S_g \left[\bar{A}\right]_0}{G_A g V_g} \left(1 - \varepsilon_p\right)\left(1 - \varepsilon b\right) L \tag{11.151}$$

and X^* is the extent of reaction of the pellet defined by

$$X^* = \frac{\int_0^1 \xi^{s-1}\left(1 - \eta^g\right) d\xi}{\int_0^1 \xi^{s-1} d\xi} \tag{11.152}$$

The calculation procedure is straightforward. We compute ε for different values of X_B and a reaction modulus σ that is defined as

$$\sigma = \frac{s V_p}{A_p}\left[\frac{\left(1 - \varepsilon_p\right) k_s}{\mathbf{D}_{e,As}} \frac{S_g}{V_g}\right]^{1/2} \frac{1}{\left(2 s g\right)^{1/2}} \tag{11.153}$$

and may be considered to be a dimensionless pellet size. The precise table given by Evans and Song (1974) can be used to estimate σ, but the following equation for a sphere (s = 3) is usually adequate (Sohn and Szekely, 1972):

$$\varepsilon \cong \frac{1}{s}\left(1 - X^*\right)^{1/g-1} + \sigma\left[2\left(1 - X^*\right)^{-1/3} - 2\right]^{-1} \tag{11.154}$$

Knowing ε from Equation (11.147), Equation (11.148) can be integrated and X^* plotted as a function of t^* for a given value of σ.

Several complicating features can be added, such as a different bed porosity at the wall by using the correlation of Chandrasekhar and Vortmeyer (1979), allowing for nonisothermicity of the bed (Sampath et al., 1975), accounting for propagation of the reaction front (Bagajewiicz, 1992), and the variation of gas properties throughout the bed.

11.4.2.6.2 Moving-Bed Reactors

The same approach as for the fixed-bed reactor is employed here but by making allowance for the special features of the moving-bed reactor (Figure 11.42). The main difference is that the solid is also moving, and a mass balance equation for the solid phase is therefore needed—both for

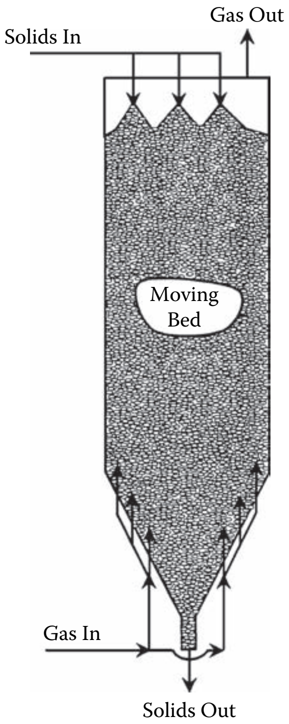

FIGURE 11.42 A typical moving-bed reactor.

plug flow and complete mixing of the solids. The following are based on the more likely plug-flow behavior.

The equations for the gas and solid phases are

$$\text{Gas:} \quad \frac{dc}{dZ^*} = -c\varepsilon \tag{11.155}$$

$$\text{Solid:} \quad \frac{dX^*}{dZ^*} = \upsilon\left(\frac{G_A}{G_B}\right)c\varepsilon = R'c\varepsilon \tag{11.156}$$

The boundary conditions are

$$c = 1,\ Z^* = 0 \tag{11.157}$$

and

for cocurrent flow, $X^* = 0$, $Z^* = 0$

for countercurrent flow, $X^* = 0$, $Z^* = L^*$ (11.158)

where L^* is a dimensionless reactor length defined for concurrent flow, defined as

$$L^* = \left[\frac{k_s\left[\bar{A}\right]_0 S_g\left(1-\varepsilon_p\right)\left(1-\varepsilon b\right)}{G_A g V_g}\right] L \tag{11.159}$$

From stoichiometry,

$$X^* - X_0^* = R'\left(c-1\right) \tag{11.160}$$

Substituting Equation (11.160) in (11.156) and integrating, we get

$$\text{for cocurrent flow:}\quad Z^* = \int_0^{X^*} \frac{d\chi}{\left(R'-1\right)\varepsilon\left(x\right)} \tag{11.161}$$

where χ is a dummy variable, and

$$\text{for counter-current flow:}\quad L^* = \int_0^{X_0^*} \frac{dX^*}{\left(R' - X^* + X_0^*\right)\varepsilon\left(X^*\right)} \tag{11.162}$$

Using Equation (11.147) for ε, these equations can be solved to give c and X^* as functions of Z^* or L^* for given values of σ. Countercurrent operation normally gives significantly higher conversions.

11.4.1.6.3 Fluidized-Bed Reactors

As with the other two reactors considered, the prerequisite for the design of a fluidized-bed reactor is a reaction model for the single pellet. These models have been discussed in Section 11.3.4. The main features of the fluidized bed were outlined in Section 11.3.3 and are further explained and illustrated in Case Study 11.5. What is unique to the fluidized-bed reactor for gas-solid noncatalytic reactions is the particle size distribution, which changes with reaction mainly because the particle density changes with reaction. Thus, an important design feature is the prediction of particle size distribution in the product solids from a knowledge of the distribution in the reactant solids. Allowance must be made for elutriation of fines and their partial return to the reactor. Particle growth or shrinkage during reaction will also affect the particle size distribution and fluidization characteristics of the bed and add further complexity to the design. This complexity can also arise in fixed- and moving-bed reactors but is not as crucial. In the foregoing treatment of fixed- and moving-bed reactors, it was assumed that the particle size remains constant. Nondecaying catalytic systems can be operated in the batch mode with respect to the solids, but the consequences of reaction and solids consumption often require that noncatalytic gas-solid reactions be operated in the continuous mode.

The main features of the design of a noncatalytic fluidized-bed reactor are described in Case Study 11.12 using the manufacture of chlorosilanes as an illustrative example. Hence, no further description of these reactors will be attempted here.

11.4.3 Kinetic Energy (Stirred Tank Reactors)

11.4.3.1 Introduction

In chemical process industries, stirred tank reactors are frequently used. For hydrogenation/oxidation applications, the heats of reaction are large, and the overall operation may be heat transfer controlled. In reactions where selectivity is of importance (for example, oxidation, hydrogenation,

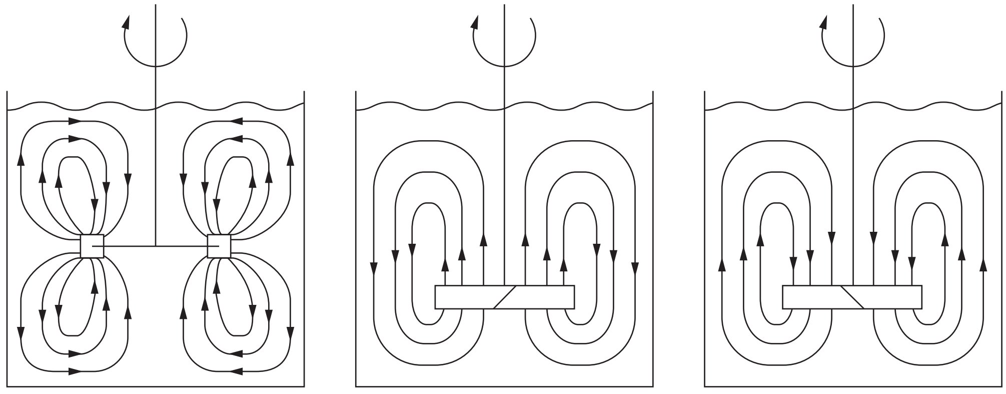

FIGURE 11.43 Flow patterns in a stirred tank reactor: (a), radial flow, (b) axial upflow, (c) axial downflow.

ethoxylation, alkylation), it may be necessary to maintain a uniform concentration in the reactor; in such cases, mixing is of importance. If the gas is sparingly soluble, its concentration in the liquid phase is fairly small, and the overall reaction may become mass transfer controlled. In many gas-liquid/gas-liquid-solid reacting systems, conversion of gas per pass is low. If it is undesirable (because of toxicity, explosion, or cost considerations) to vent this unreacted gas, then the unreacted gas has to be recycled back into the reactor. Hydrogenation, chlorination, alkylation, oxidation with pure oxygen, ozonolysis, hydrochlorination, and others are in this category. Recycling of the unreacted gas can be achieved with what is called a *dead-end reactor* in which the unreacted gas is not vented. These systems employ gas-inducing impellers, surface aerators, rotating disc contactors, jet-loop reactors, and plunging jet reactors to recontact the gas with the liquid phase.

All the above-mentioned processes require external energy input. In the stirred reactor, energy is supplied by the impeller. The fluid leaving the impeller receives mean and turbulent kinetic energy resulting from the impeller motion. The presence of a second or third phase may also introduce additional energy. The impeller designs are generally classified into two types: (1) radial flow impellers and (2) axial flow impellers. Rushton turbine, straight-blade turbines, curved-blade turbines, Brumagins, and so on belong to the radial flow category. The flow field generated by them is radially outward (Figure 11.43a), toward the wall. At the wall, this flow divides into two parts, one going above the impeller and the other going below. Both flows then return to the impeller near the vessel centerline. Axial flow impellers can be operated in either the "pumping-up" mode (Figure 11.43b) or "pumping-down" mode (Figure 11.43c). Marine propellers, pitched-blade turbines, hydrofoil impellers, and so forth fall under this category. In the pumping-down mode, the impeller generates a downward flow, which hits the vessel bottom, turns radially, and is ultimately converted to upflow before returning to the impeller. The mean flow generated causes bulk motion of the constituents, whereas the turbulence generated is responsible for eddy diffusion of momentum, heat, and mass. The size, shape, and number of impellers; vessel geometry such as number, location, and size of baffles; vessel diameter; liquid level; impeller clearance; and system properties all have a profound impact on the flow field, thus affecting the performance of the stirred vessel.

To design/select impellers on a rational basis, an understanding of two aspects is essential: (1) the relation between impeller design, vessel geometry, and the flow field produced; and (2) the relation between the flow field and design objectives such as mixing, heat transfer, solid suspension, gas dispersion, and others. From 1950 to 1970, impeller design was investigated mainly empirically. For this purpose, the investigators fabricated several different shapes and used them in laboratory-scale equipment. The performances of the various impellers in terms of a design objective (e.g.,

gas dispersion, solid suspension, blending, and so on) were studied, and the best design was chosen on the basis of such experiments (Kramers et al., 1953; Zwietering, 1958; van't Riet and Smith, 1973). Such experiments are costly and time consuming. Since the 1970s, the focus has shifted to modeling and understanding the phenomena at hand. Over the last 20 to 30 years, many models have been proposed for each of the above design objectives (Mann and Mavros, 1982; Warmoeskerken and Smith, 1985; Molerus and Latzel, 1987; Patwardhan and Joshi, 1999a). These models relate the flow generated by the impeller to the design objective. In the following paragraphs, an attempt is made to briefly discuss the important aspects of process design of stirred reactors for various objectives.

11.4.3.2 Blending

The blending process is characterized in terms of the blending time, commonly called the *mixing time*. This is considered to be the time between the introduction of a tracer at a certain point and the tracer concentration to reach a certain degree of homogeneity at some other point. The blending process occurs as a result of transport at three levels: molecular, eddy, and bulk (convection). Usually, bulk motion (or bulk diffusion) is superimposed on either molecular or eddy diffusion or both. In industrial practice, many blending operations are performed at turbulent conditions. In that case, molecular diffusion can be neglected in comparison to bulk diffusion and eddy diffusion. The blending time is commonly represented in terms of a dimensionless quantity (called the *homogenization number, Nt_{mix}*), which is the product of the impeller speed and mixing time. The value of Nt_{mix} depends on the impeller design, diameter, location, number, and size, and the location of baffles, presence of a draft tube, reactor dimensions, and so forth. Under laminar conditions, the value of Nt_{mix} is inversely proportional to impeller speed, but, at turbulent conditions, it is independent of impeller speed. Therefore, under turbulent conditions, the mixing time, t_{mix}, is proportional to N^{-1} or $P^{-1/3}$. Rewatkar and Joshi (1991a) investigated the effect of impeller design on mixing time. At a given power consumption, axial-flow impellers produce better mixing (lower t_{mix}) as compared to Rushton turbine impellers. Patwardhan and Joshi (1999a) investigated the blending characteristics of several axial flow impellers. Mixing is essentially controlled by the convective transport. They also correlated the mixing time data in terms of the secondary flow number of the impeller. Thus, the energy efficiency of the blending process depends on the impeller pumping capacity as well as the power consumed by the impeller. The authors give the values of the secondary flow number, N_{QS}, for a variety of impeller designs. The following correlation is recommended by Patwardhan and Joshi (1999a):

$$t_{mix} = \frac{12.66 N^{1/3} D^{2/3}}{N_{QS} \left(P / M \right)^{1/3}} \tag{11.163}$$

11.4.3.3 Gas Dispersion

In gas-liquid mechanically agitated contactors, the gas flow often alters energy input from the impeller. Typically, the quantity of gas fed to the reactor is characterized in terms of the superficial gas velocity, gas flow number, or volume of gas per unit volume of liquid per minute (VVM). For a given gas flow rate, an increase in impeller speed results in various modes of operation (called *regimes of operation*). The regimes of a pitched-blade downflow turbine with sparger below the impeller are shown schematically in Figure 11.44a. At very low speeds, the gas rises vertically with very little mixing, and the impeller does not disperse it. This is called *flooding* (LM in figure). As the impeller speed increases, the downward flow generated by the impeller becomes stronger and opposes the upward flow generated by the gas. As a result, the power consumption increases, and the P_G/P_O value can even be greater than 1 (point L in figure). At

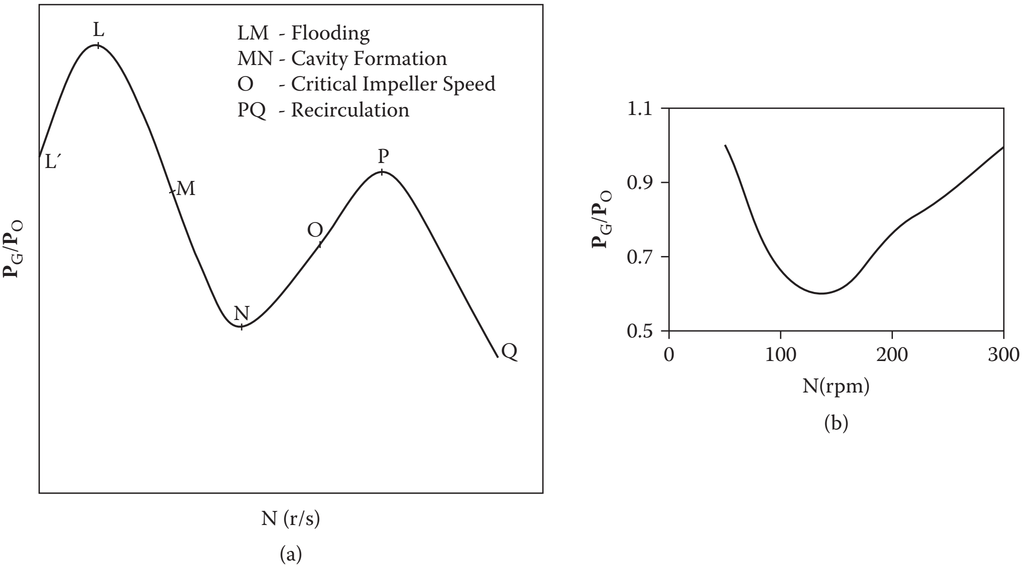

FIGURE 11.44 Regimes of operation in a strirred tank reactor: (a) with a pitched-blade downflow turbine with sparger below the impeller; (b) with upflow impeller.

this point, the gas becomes dispersed in the radial direction. As the impeller speed increases further, the gas is distributed radially from the impeller, i.e., loading occurs. Then the gas starts forming cavities behind the impeller blades (MN in figure). The size of the cavities increases with a higher impeller speed, and therefore $\mathbf{P}_G/\mathbf{P}_O$ falls. At still higher speeds, the impeller-generated flows are dominant and overcome the upward flow generated by the bubbles. Under these conditions, the impeller disperses gas even below the impeller. This is referred to as complete dispersion. Beyond this point (point N in figure), the shear forces become strong enough to break the cavities, and the cavity size reduces. This leads to an increase in the $\mathbf{P}_G/\mathbf{P}_O$ ratio (point O in the figure), and the so-called critical impeller speed is reached. At very high speeds, the impeller-dispersed gas phase is recirculated by the impeller-generated flow called recirculation (beyond point P in the figure). The gas holdup in the impeller region and therefore the average density in the impeller region start reducing; as a result, the $\mathbf{P}_G/\mathbf{P}_O$ ratio again starts reducing. To obtain efficient gas-liquid dispersion, the impeller should be operated at a speed above the critical speed required for complete dispersion.

For the upflow impeller, the $\mathbf{P}_G/\mathbf{P}_O$ vs. impeller speed curve is shown in Figure 11.44b. The flow generated by this impeller and the gas flow are complementary to each other, and thus formation of large cavities is prevented (Bujalski et al., 1988). Mhetras et al. (1994) have correlated the critical impeller speed for complete dispersion with the gas flow number as

$$Fr = aFl^b \tag{11.164}$$

Values of the constants a and b have been reported for many impeller designs.

Ideally, an impeller should have a $\mathbf{P}_G/\mathbf{P}_O$ ratio of unity. Efforts to reach this have resulted in the development of axial-flow impellers (up-pumping or down-pumping) with a high solidity ratio, as well as radial-flow impellers with convex-shaped blades. The power drawn by these impellers is practically constant, even at high gas flow rates. These are therefore called *gas-foil impellers*. When compared on the basis of equal power consumption per unit mass, gas-foil impellers show a larger gas holdup (that is, better gas dispersion) than conventional Rushton turbines (McFarlane and Nienow, 1996). Mhetras et al. (1994) found that axial-flow impellers give higher gas holdups

than radial-flow impellers. They also investigated the effect of blade twist so as to convert an ordinary pitched-blade turbine to hydrofoil shape. Hydrofoil shape gives larger gas holdups at low gas velocities (<15 mm/s), and a conventional pitched-blade turbine gives higher gas holdup at larger gas velocities (>15 mm/s). The following correlation is recommended for estimation of gas holdup (Rewatkar et al., 1993):

$$\varepsilon_G = 3.54\ (\mathbf{T}/D)^{2.08}\ Fr^{0.51}\ Fl^{0.43} \tag{11.165}$$

This was developed for pitched-blade turbines for air and water as the working fluids. In industrial practice, the physical properties of the fluids are likely to be dramatically different. Therefore, the constant in the equation may vary, but its values can be obtained with a few experiments in the laboratory. The new correlation thus obtained can be used for scale-up. Holdup correlations for other impellers are given elsewhere (Mhetras et al., 1994; McFarlane and Nienow, 1996).

11.4.3.4 Solid *S*uspension

As the impeller speed increases in a reactor containing solid particles and a fluid, the rolling and sliding of particles (on the base of the vessel) results in the formation of either a dune at the center (observed with radial-flow impellers) or a ring at the periphery (observed with axial-downflow impellers) of the vessel. With increasing impeller speed, the dune or the ring gradually reduces in size until a speed is reached at which it completely disappears; this is called the *critical impeller speed* for solid suspension and is denoted as N_{CS}. Evidently, several transitions in particle motion are possible, and the numerical value of the impeller speed depends on the state of suspension. The problem of selecting a representative speed for suspension is complicated, since the transition from one state of motion to another is gradual and occurs over a range of impeller speeds. The critical impeller speed can be defined in various ways, namely, (1) all the particles moving on the tank base (no particle is stationary on the tank base for more than 1 to 2 s), N_{CM}; (2) complete off-bottom suspension (particles do not remain on the tank base for more than 1 to 2 s), N_{CS}; and (3) suspension height (impeller speed required to get a particular suspension height, for instance 50% or 70% of the height), N_{C50}, N_{C70}, etc. When a particle is at the base of the tank, several forces act on it. These are the gravity force, buoyancy force, drag and lift forces due to motion of the fluid over the particle, and frictional forces between the particles or between the particles and the base of the reactor. The gravity and buoyancy forces are solely related to the particle size, shape, and density, and the density of the liquid. However, the drag and the lift forces depend on the velocity field around the particle, which in turn is influenced by the particle motion, the presence of other particles, and so on. Thus, the solid suspension process is fairly complex. Zwietering (1958), in pioneering work, correlated the effect of various parameters such as impeller design, diameter, clearance, particle size, solid loading, particle density, physicochemical properties of the liquid, and so forth, on the critical impeller speed for solid suspension. Since solid suspension occurs from the base of the reactor, its shape is an important aspect influencing the value of N_{CS}. Chudacek (1982) performed systematic investigations by altering the shape of the reactor bottom. For a small particle size (116 μm), the power required at critical suspension conditions was highest for a flat-bottom tank. The power required for a cone and fillet tank (CFT) was smaller by about 40%, and that for a profiled bottom tank (PBT) was about 60% smaller. For a larger particle size (290 μm), the CFT and PBT required only about 40 and 35% of the power required for a flat-bottom tank. Raghav Rao et al. (1988) investigated the effect of impeller design in detail. The power required at critical suspension conditions for a pitched-blade downflow impeller was about 20% of that for a disc turbine and about 33% of that for a pitched-blade upflow impeller. The following correlation is recommended for the estimation of the critical impeller speed for solid suspension for pitched-blade downflow turbine (PBTD) impellers:

$$N_{CS} = 1.15 \frac{u_{S\infty}^{0.28} X^{0.1}}{D^{0.85}} (\mathbf{D}/T)^{0.8} \tag{11.166}$$

For other impellers, see Zwietering (1958) and Chapman et al. (1983).

11.4.3.5 Heat Transfer

To operate isothermally, it is generally necessary to remove heat from, or supply heat to, the reactor. This can be achieved by using jacketed reactors or helical coils inside the reactor. The heat transfer area provided by jackets per unit volume of the reactor is equal to $4/d_T$, where d_T is the reactor diameter. Thus, upon scale-up, the heat transfer surface area per unit volume of reactor decreases. Helical coils provide larger heat transfer area per unit volume and are generally preferred. Under certain conditions, especially for low-viscosity applications, it may be necessary to consider the heat transfer coefficient on the reactor side as well as the jacket/coil side and then determine the overall heat transfer coefficient. When only one impeller is to be used, it is desirable to keep the impeller centrally located to obtain good heat transfer coefficients over the entire length of the jacket/coil. The reactor-side heat transfer coefficients for a jacketed vessel have been correlated as follows for a wide range of impeller designs (Uhl and Gray, 1966); they also report values of the exponents:

$$\frac{h\,D}{k_T} = a\left(\frac{N\mathbf{T}^2\rho}{\mu}\right)^b \left(\frac{c_P\mu}{k_T}\right)^c \left(\frac{\mu_w}{\mu}\right)^d \tag{11.167}$$

The values of b range from 0.66 to 0.75, those of c to from 0.25 to 0.50, and of d to from –0.14 to –0.25. The values of the constant a vary dramatically from 0.17 to 0.75. Since the heat transfer coefficient is typically proportional to $N^{0.67}$, it can be considered to be proportional to $(power)^{0.22}$ (Oldshue, 1983). Oldshue also provides a general correlation for the heat transfer coefficient for an immersed tube as

$$\frac{h\,\mathbf{T}}{k_T} = 0.17\left(\frac{ND^2\rho}{\mu}\right)^{0.67} \left(\frac{c_P\mu}{k_T}\right)^{0.37} \left(\frac{D}{\mathbf{T}}\right)^{0.1} \left(\frac{d}{D}\right)^{0.5} \left(\frac{\mu}{\mu_S}\right)^m \tag{11.168}$$

where m is a function as defined by Oldshue. Fasano et al. (1991) compared the heat transfer coefficients for a pitched-blade turbine and HE-3 impeller. At the same **T**/D and C/D ratios and at equal impeller Reynolds numbers, the heat transfer coefficient of the Rushton turbine was marginally smaller than that for the four-bladed pitched-blade turbine. Since the power number of the Rushton turbine is three times that of the four-bladed pitched-blade turbine (used in their work), this would mean that at equal power, the pitched blade turbine would give a roughly 35% higher heat transfer coefficient. The six-bladed pitched-turbine resulted in an even larger heat transfer coefficient. Oldshue (1983) had also previously recommended axial-flow impellers for efficient heat transfer.

11.4.3.6 Blending in Gas-Liquid Systems

Gas in a stirred reactor alters the flow pattern dramatically, depending on the regime of operation (flooding, loading, complete dispersion, and so on). Rewatkar and Joshi (1991b) systematically investigated the mixing characteristics in various regimes of operation. The mixing time in the presence of gas is larger than that in its absence. However, the relative increase depends on the

regime of operation. At very low speeds (flooding conditions), the mixing time decreases rapidly with increasing impeller speeds. As cavity formation starts and the cavity size increases (leading to a drop in $\mathbf{P}_G/\mathbf{P}_O$), the mixing time increases with an increase in impeller speed. At speeds higher than the critical impeller speed for complete dispersion of the gas, the cavity size reduces (leading to an increase in $\mathbf{P}_G/\mathbf{P}_O$ ratio), and the mixing time again begins to reduce with an increase in impeller speed. Rewatkar and Joshi (1991b) correlated the liquid phase mixing time in gas-liquid systems as

$$Nt_{mix} = 38.58D^2\mathbf{T}^{-1.94}u_G^{0.226} \tag{11.169}$$

leading to

$$\frac{\left(Nt_{mix}\right)_{G-L}}{\left(Nt_{mix}\right)_L} = 3D\,\mathbf{T}^{-0.94}u_G^{0.226} \tag{11.170}$$

Pandit and Joshi (1983) correlated the mixing time in the presence of gas for the disc turbine and propeller.

11.4.3.7 Blending in Solid-Liquid Systems

Raghav Rao et al. (1988) investigated the effect of solid phase on blending characteristics over a wide range of particle sizes and solid loadings. The mixing time in the presence of a solid phase is generally larger than that in the absence of one. However, the extent of increase depends on particle size, solid loading, impeller speed, and other factors. For a given solid loading, higher impeller speed increases the fraction of suspended solids. Part of the energy supplied by the impeller is dissipated at the solid-liquid interface. Thus, the increase in the liquid circulation velocity with an increase in impeller speed is less pronounced compared to that in the absence of solid particles. Therefore, the mixing time of liquid increases with an increase in particle size and solid loading. This increase is most pronounced when the speed is close to the critical impeller speed for solid suspension. At speeds much higher than the critical impeller speed for solid suspension, the solid particles circulate along with the liquid flow, and hence the mixing time increases only to a small extent. The correlation of Raghav Rao et al. (1988),

$$Nt_{mix} = CX^{0.19}d_P^{0.11}D^{0.32}\mathbf{T}^{-1.15} \tag{11.171}$$

is recommended for the estimation of the critical impeller speed for solid suspension. Comparing this correlation with that reported by Patwardhan and Joshi (1999a), we get

$$\frac{\left(Nt_{mix}\right)_{S-L}}{\left(Nt_{mix}\right)_L} = C'X^{0.19}d_P^{0.11}D^{-0.68}\mathbf{T}^{-0.15} \tag{11.172}$$

11.4.3.8 Suspension in Gas-Liquid-Solid Systems

The introduction of the gas phase leads to the formation of cavities behind the impeller blades. As a result, the power number and the impeller pumping capacity are reduced. Hence, the impeller speed has to be increased to compensate for the loss of pumping capacity. Consequently, the critical impeller speed for solid suspension was always higher in the presence of the gas phase (N_{SG})

(Rewatkar et al., 1991). N_{SG} increased with an increase in the superficial gas velocity, particle size, and solid loading. Their correlation is recommended for design:

$$N_{SG} - N_{CS} = 132.7 u_{S\infty}^{0.5} \mathbf{T}^{-1.67} D u_G \quad (11.173)$$

Chapman et al. (1983) provide a similar correlation.

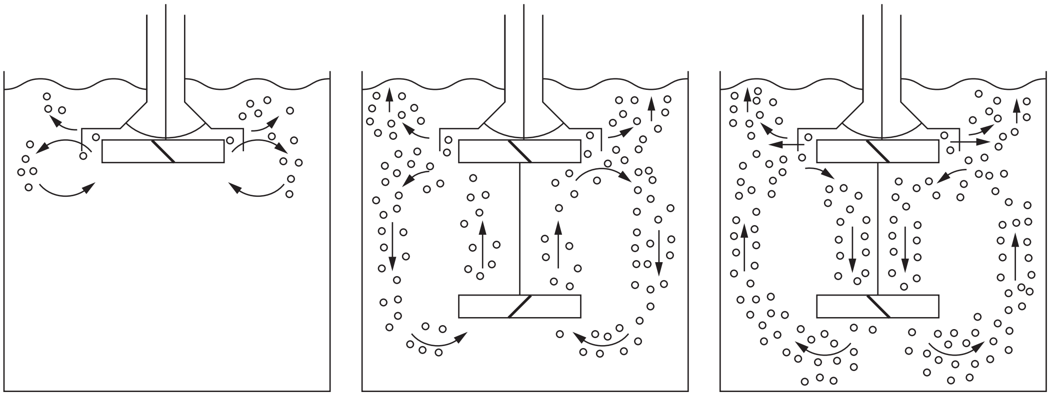
11.4.3.9 Heat Transfer in Gas-Liquid Systems

Heat transfer coefficients in gas-liquid systems are generally lower than those in the liquid alone (Karcz, 1999), a result of the reduction in power consumption in the presence of gas. The heat transfer coefficient is approximately proportional to $(power)^{0.22}$.

11.4.3.10 Dead End Systems

11.4.3.10.1 Gas-Inducing Impellers

A gas-inducing impeller generates a high velocity in the impeller region. The local pressure decreases sufficiently to overcome the hydrostatic head; gas is hence induced from the head space (Figure 11.45a). Many designs of these impellers have been reported in the published literature and are divided into three categories: hollow-pipe impellers, hollow pipes with dispersers, and stator-rotor systems. Saravanan and Joshi (1995, 1996) and Saravanan et al. (1996, 1997) investigated single- as well as multiple-impeller stator-rotor systems. When a single gas-inducing impeller is located close to the top liquid surface for maintaining a high rate of gas induction, the following drawbacks occur: poor dispersion of the induced gas, poor solid suspension ability, and so on. They arise from the fact that the liquid flow and turbulence characteristics are feeble in a major portion below the gas-inducing impeller. These drawbacks become more serious with a large-scale operation. These limitations have been overcome by using a second impeller below the gas-inducing impeller. The gas-inducing impeller can be positioned near the top liquid surface (about 100 to 200 mm below the liquid surface), irrespective of the scale of operation, to ensure a high gas induction rate. For performing gas dispersion (distribution of the induced gas throughout the equipment), solid suspension, heat transfer, mixing, and so forth, a second impeller is often used. The flow patterns for multiple-impeller combinations are depicted in Figures 11.45b and c. The design of the lower impeller was further optimized for different duties such as gas holdup, solid suspension



(a) (b) (c)

FIGURE 11.45 Gas-inducing reactors: (a) single inducing impeller, (b) inducing impeller together with upflow lower impeller, and (c) inducing impeller together with downflow lower impeller. (From Patwardhan, A. W. and Joshi, J. B., 1998.)

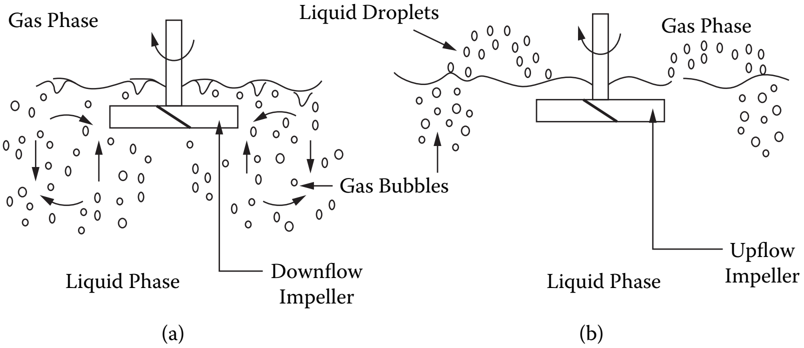


FIGURE 11.46 Surface aerators: (a) gas-in-liquid dispersion, (b) liquid-in-gas dispersion.

ability, and others. The optimum design of the lower impeller changes with the design objective. For example, to achieve a high fractional gas holdup, an upflow impeller should be at the bottom whereas, to achieve good solid suspension, a downflow impeller at the bottom is preferred. Recommended correlations are by Patwardhan and Joshi (1999b).

11.4.2.10.2 Surface Aerators
